5.1 Introduction 335
5.2 Vitamin A 337
5.3 Vitamin D 345
5.4 Vitamin E 349
5.5 Vitamin K 356
5.6 Thiamine 359
5.7 Riboflavin 364
5.8 Niacin 367
5.9 Pantothenic acid 370
5.10 Pyridoxal, pyridoxol and pyridoxamine 372
5.11 Biotin 375
5.12 Folacin 377
5.13 Corrinoids 380
5.14 Vitamin C 384
5.15 Other active substances 396

CHAPTER 6 *MINERALS* **402**

6.1 Introduction 402
6.2 Chemistry of minerals 404
6.3 Essential elements 416
6.4 Non-essential elements 442
6.5 Toxic elements 444
6.6 Toxic inorganic anions 451
6.7 Radionuclides 454

CHAPTER 7 *WATER* **459**

7.1 Introduction 459
7.2 Drinking water 459
7.3 Water in foods 463
7.4 Structure 464
7.5 Properties 466
7.6 Interactions 466
7.7 Phase interfaces 473
7.8 Food dispersed systems 477
7.9 Water activity 494

CHAPTER 8 *FLAVOUR-ACTIVE COMPOUNDS* **499**

8.1 Introduction 499
8.2 Odour-active substances 500
8.3 Taste-active substances 621

CHAPTER 9 *PIGMENTS AND OTHER COLORANTS* **656**

9.1 Introduction 656
9.2 Tetrapyrroles 657
9.3 Other nitrogen pigments 669
9.4 Flavonoids 677
9.5 Xanthones 699
9.6 Curcuminoids 701
9.7 Isochromenes 701
9.8 Quinoid pigments 703

9.9 Carotenoids 713
9.10 Iridoids 730
9.11 Other terpenoid pigments 730
9.12 Enzymatic browning reactions 732

CHAPTER 10 *ANTINUTRITIONAL, TOXIC AND OTHER BIOACTIVE COMPOUNDS* **741**

10.1 Introduction 741
10.2 Antinutritional compounds 743
10.3 Toxic compounds 747

CHAPTER 11 *FOOD ADDITIVES* **847**

11.1 Introduction 847
11.2 Substances prolonging the shelf life of foods 848
11.3 Substances regulating odour and taste 863
11.4 Substances modifying colour 875
11.5 Substances modifying texture 882
11.6 Substances increasing biological value 888
11.7 Other food additives 888

CHAPTER 12 *FOOD CONTAMINANTS* **892**

12.1 Introduction 892
12.2 Technological contaminants 894
12.3 Microbial toxins 942
12.4 Persistent organohalogen contaminants 963
12.5 Chlorinated aliphatic hydrocarbons 999
12.6 Pesticides 999
12.7 Veterinary drugs 1022
12.8 Contaminants from packaging materials 1031

BIBLIOGRAPHY **1041**

Preface

During the 15 years that have elapsed since the first Czech edition of the textbook *The Chemistry of Food* was published, many important monographs and scientific articles from various areas of food science have appeared in the literature, thanks to developments in analytical instrumentation and advances in the knowledge in the field of food technology. All these, plus the interest expressed by the readers, were the impetus that led to the third Czech edition of the book in 2009. This first English edition of *The Chemistry of Food* has remained essentially unchanged in terms of the basic structure of the 12 chapters and the majority of the text, tables, figures and formulae. Certain specific parts, however, have, necessarily, been revised, supplemented and updated.

The Chemistry of Food is the result of many years of experience by workers at the Department of Food Chemistry and Analysis (now Department of Food Analysis and Nutrition), Institute of Chemical Technology in Prague, through the teaching of this subject, plus other related topics taught in the Faculty of Food and Biochemical Technology. The reader will first be introduced to the chemical composition of foods, the important properties of food components and their functions. After these set descriptions, subsequent sections deal with the changes and reactions that occur, or may occur, in foods under certain conditions. It is necessary for the reader to be able to understand the context and complexity of all the processes taking place in foods. As in the previous Czech editions, the authors have tried to reduce to a minimum the amount of text, as is typical for textbooks on biochemistry, microbiology, organic, inorganic and physical chemistry, so that it should not be necessary to consult other specialised textbooks too often, but, at the same time, ensuring the text is clear to both students and professionals.

The textbook contains an introductory chapter and then 11 chapters dealing with the main and accessory nutrients that determine the nutritional and energy value of food raw materials and foods. There is a chapter describing amino acids, peptides and proteins, a chapter dealing with fats, oils and other lipids, as well as chapters on carbohydrates, vitamins, mineral substances and water. Another chapter considers compounds responsible for the aroma, taste and colour attributes that determine the sensory quality of food raw materials and foods. The remaining chapters discuss substances that affect, or may affect, the hygienic–toxicological quality of food raw materials and foods, including antinutritional, toxic and other biologically active food components, food additives and food contaminants.

The third Czech edition featured the work of many workers from the Department of Food Chemistry and Analysis, along with colleagues from other departments of the Faculty of Food and Biochemical Technology and also external authors. Jan Pánek acted as a co-author of the chapters dealing with the main nutrients, and Helena Čížková and Michal Voldřich participated in these and other chapters. Co-authors of the chapter on amino acids, peptides and proteins were Karel Cejpek and Roman Kubec, of the chapter on fats, oils and other lipids Jana Dostálová and Vladimír Filip, of the chapter on carbohydrates Karel Cejpek and Kamila Míková, of the chapter on minerals Richard Koplík, of the chapter on flavour-active substances Jan Šavel, of the chapter on pigments and other colourants Jana Dostálová, of the chapter of antinutritional and toxic substances Pavel Kalač and Přemysl Slanina, and of the chapter on contaminants Jaroslav Dobiáš, Marek Doležal and Jana Hajšlová. The co-authors of the sections dealing with food legislation were Vladimír Kocourek and Kamila Míková. Most of these co-authors were also involved in the first and second Czech editions of this publication. In addition, co-authors of the first and second Czech editions included Jan Pokorný (the chapter on fats, oils and other lipids), Jiří Davídek (the chapter on vitamins and contaminants), Tomáš Davídek (the chapter on carbohydrates), Karel Hrnčiřík (chapters on vitamins and antinutritional and toxic compounds) and Helena Valentová (the chapter on pigments and other colourants). I would like to take this opportunity to thank all of my co-authors and other colleagues for their thorough work. Considerable thanks are also due to the reviewers of the first Czech edition, Prof. Ing. Alexander Príbela, DSc. (Slovak University of Technology in Bratislava, Slovak Republic) and Ass. Prof. RNDr Jan Staněk, PhD, who also did a great deal of hard work on the project.

The co-authors of the Czech editions were Ass. Prof. Ing. Karel Cejpek, Ing. Helena Čížková, PhD, Prof. Ing. Jiří Davídek, DSc., Ass. Prof. Ing. Jaroslav Dobiáš, PhD, Ass. Prof. Ing. Marek Doležal, Prof. Ing. Jana Dostálová, PhD, Prof. Ing. Vladimír Filip, PhD, Prof. Ing. Jana Hajšlová, PhD, Prof. Ing. Vladimír Kocourek, PhD, Prof. Dr Ing. Richard Koplík, Ass. Prof. Ing. Kamila Míková, PhD, Ass. Prof. Ing. Jan Panek, PhD, Prof. Ing. Jan Pokorný, DSc., Ass. Prof. Dr Ing. Kateřina Riddellová and Prof. Ing. Michal

Voldřich, PhD, staff of the Faculty of Food and Biochemical Technology, Institute of Chemical Technology in Prague. External co-authors were Ing. Tomáš Davídek, PhD (Nestlé, Orbe, Switzerland), Ing. Karel Hrnčiřík, PhD (Unilever, Vlaardingen, The Netherlands), Prof. Ing. Pavel Kalač, PhD (University of South Bohemia, České Budějovice), Ing. Roman Kubec, PhD (University of South Bohemia, České Budějovice), Prof. Přemysl Slanina, DVM, PhD (National Food Administration, Uppsala, Sweden), Ass. Prof. Ing. Jan Šavel, PhD (Budweiser Budvar n.p., České Budějovice) and Ing. Helena Valentová, PhD (Hügli Food Ltd, Zásmuky).

The website includes:

- Powerpoints of all figures from the book for downloading
- PDFs of tables from the book
- Powerpoints of all formulae from the book

1
Introduction

The term **food** means material (eaten or drunk) that contains or consists of nutrients (proteins, fats, carbohydrates, vitamins and minerals) and many other chemical substances. Food is usually of plant or animal origin but, to a lesser extent, it may come from other sources, such as algae or microorganisms. Organisms use food to perform one or more of the four essential functions: to supply energy, to build, repair and maintain body tissues, to supply chemical substances that regulate body processes and to supply chemical substances that protect the organism. Traditionally food was provided through agriculture, but today most of the food consumed by the world's population is either supplied by the food industry or home-grown.

Human food, including such items as meat, poultry, fish, milk, vegetables, fruit and beer for example, is chemically very complex. According to rough estimates, fresh foods contain about half a million different chemical compounds. A much larger number of compounds are the result of biochemical (enzymatic) and chemical (non-enzymatic) reactions that occur during the storage of raw materials and foods and during their industrial and culinary processing.

Food science – the scientific study of food – is one of the major branches of the life sciences. Every aspect of food is covered, integrating and incorporating concepts and information from many different fields, including natural, technical and social sciences. It draws primarily on the knowledge of chemical science (biochemistry, organic, inorganic, physical and analytical chemistry), some areas of physics (such as the mechanics of solids and liquids), biology (especially microbiology), biotechnology, some of the branches of medical science (human nutrition, human physiology, pharmacology, toxicology) and agricultural science (e.g., crop and livestock production, post-harvest plant physiology and *post-mortem* muscle physiology). It also uses a range of experiences from technical engineering disciplines, such as agricultural and food engineering, particularly in the form of genetic food engineering. Food science may also call upon some experience of economics, sociology, psychology and other branches of social science.

The most important building blocks of food science are **food chemistry** and **food technology**. Food chemistry deals not only with the composition of food raw materials and end food products, but also with the behaviour, interactions and reactions of food components and the changes occurring in these food raw materials and end food products under various conditions during production, storage, processing, preparing and cooking. Food technology covers the entire gamut from procuring food raw materials to processing them into food products to preserving, packaging and delivering the food products to the consumer market. The common interest of both disciplines is examination of the possibilities of enhancing the positive changes and preventing the unwanted ones, elimination of antinutritive and toxic food components, and prevention of possible contamination with substances that can pose health risks and guarantee food safety. Producing safe and nutritious food for human and animal consumption is one of the principal aims of both food chemistry and food technology.

The most important natural constituents of foods are the **nutrients** that all organisms need in order to live and grow. The **main** (primary or basic) **nutrients** are **proteins**, **fats** (mainly triacylglycerols and phospholipids, but also numerous other lipids) and **carbohydrates** (such as some poly-, oligo- and monosaccharides) that determine the **nutritional** (nutritive) **value** of food, as they provide structural material (e.g., proteinogenic amino acids used for protein synthesis and lipids from which cell membranes are built) and energy. They may also have other functions. Nutrients are said to be essential if they must be obtained from an external source, either because the organism cannot synthesise them or it cannot produce them in sufficient quantities. Essential main nutrients include not only essential amino acids, but also lipids that are precursors of biologically active substances (such as essential fatty acids and some signalling molecules) and thus have protective functions. Also, some oligosaccharides are biologically active substances (e.g., breast milk oligosaccharides that act as receptor analogues to inhibit the adhesion of pathogens on the epithelial surface).

The Chemistry of Food, First Edition. Jan Velíšek.

The energy value of consumed food depends on the content of nutrients and on such factors as their digestibility, utility, content of some other substances, dietary regime, mental health status and other factors. Energy value is mainly related to proteins, fats and carbohydrates.

Organic nutrients also include **vitamins**. Inorganic chemical compounds, such as dietary **minerals**, **water** (and oxygen), may also be considered nutrients. Vitamins and dietary minerals are collectively known as **accessory (additive) nutrients** and are often referred to as **essential nutritional factors**. With the exception of some vitamins that humans cannot synthesise, these accessory nutrients must be obtained from foods. They are therefore known as **exogenous factors**. Another essential nutrient is water, which is obtained in small amounts by oxidation of primary nutrients, but in much larger quantities from foods, and especially from beverages. Most foods contain a mixture of some or all of the nutrient classes, together with many other substances. Some nutrients can be stored internally (such as the fat soluble vitamins), while others are required more or less continuously. Poor health may be caused by a lack of required nutrients or, in extreme cases, too much of a required nutrient.

Some nutrients, such as proteins, peptides and amino acids, lipids, carbohydrates, vitamins and minerals, are also sensorially active substances (e.g., sweet or bitter). The main nutrients along with other substances (certain organic acids, such as acetic and citric acids, and sugar alcohols, such as glucitol, known as sorbitol) can simultaneously also be a source of energy, for example, ethanol has a relatively high energy value.

In human nutrition, nutrients are often inaccurately classified in a way that reflects the amount that the body requires. These nutrient classes can be categorised as either **macronutrients** (required in relatively large amounts) or **micronutrients** (required in smaller amounts). The macronutrients include proteins, fats, carbohydrates and water; the micronutrients are minerals and vitamins. A third class of dietary material, known as fibre (such as non-digestible polysaccharide cellulose), is also necessary, for both mechanical and biochemical reasons. Other micronutrients include antioxidants and various phytochemicals, which are said to influence or protect some body systems. Their necessity is not well established.

Besides nutrients, foods contain many substances that influence the food sensory impression and its **organoleptic properties**. These food constituents are known as **sensorially active compounds**. They determine the **sensory value** (quality) of foods, inducing an **olfactory** sensation (perception), which is described as the aroma, odour and smell, **gustative** perception, which is the taste, **visual** perception, which is the colour, **haptic (tactile)** perception, which is the touch and feel, and **auditorial** perception, which is the sound. The olfactory sensation is derived from odour-active compounds and the gustative perception from taste-active compounds. Flavour is the sensory impression determined by the chemical senses of both taste and smell and is caused by flavour-active food components. Haptic sensation is the **texture**, which is affected mainly by high molecular weight compounds, such as proteins and polysaccharides, often referred to collectively as hydrocolloids. Geometric aspects of texture that evoke both haptic and visual sensations symbolise the terms **appearance** and **shape**. Aspects of texture related to mechanical properties of food are called **consistency**. Auditorial sensations are associated with a range of textural characteristics (such as crispiness).

Food also contains a range of substances with beneficial or, vice versa, with a negative impact on human health. There is now increasing evidence to support the hypothesis that some foods and food components have beneficial physiological and psychological effects over and above the provision of the basic nutrients. Food that does not have a significant history of consumption or is produced by a method that has not previously been used for food is called **novel food**. This was first termed by the European Union (EU) in Regulation (EC) No. 258/97 of the European Parliament and of the Council of 27 January 1997 concerning novel foods and novel food ingredients. An example of a novel food is margarine containing phytosterols that help to reduce the blood cholesterol level. Other examples include canola oil produced from rapeseed with low levels of both erucic acid and glucosinolates and exotic fruits and vegetables, which have a long history of safe use. **Functional foods** are defined as foods (beverages) having disease preventing and/or health promoting benefits in addition to their nutritive or processing value. A food can be regarded as functional if it is satisfactorily demonstrated to affect beneficially one or more target functions in a body, beyond adequate nutritional effects. Functional food can be a natural food, a food to which an existing ingredient has been added, or a food from which a harmful component has been removed by technological or biotechnological processes. The term functional food (officially not used by the EU) was first used in Japan in the 1980s. (FOSHU, Ministry of Health, Labor and Welfare, Japan. Available at: http://www.mhlw.go.jp/english/topics/foodsafety/fhc/02.html.) Examples of functional foods with a long history are table salt fortified with iodine or margarine fortified with vitamin D. Another example is yoghurts with live microorganisms beneficial to the host organism (bacteria of the genus *Bifidobacterium*), which have advantageous effects on health and are called **probiotics**. **Prebiotics** are non-digestible food ingredients (usually oligosaccharides and other substances classified as soluble dietary fibre) that stimulate the growth and/or activity of beneficial bacteria in the small intestine. **Symbiotics** contain both prebiotics and probiotics. **Nutraceuticals** are foods and food products, in some countries physiologically active compounds isolated from foods, which reportedly have a physiological benefit or provide protection against chronic diseases. Such products may range from nutrients (essential amino acids, essential fatty acids, vitamins and minerals), to **dietary supplements** (also known as food supplements or nutritional supplements) and specific diets, to genetically modified foods and other products. Dietary supplements provide nutrients, fibre and various biologically active substances from foods, usually classified according to their effects as antioxidants and anticarcinogens, which may be missing or may not be consumed in sufficient amounts in food. Some countries define dietary supplements as foods, while in others they are defined as drugs or natural health products. Supplements containing vitamins or dietary minerals are included as a category of food in the 'Codex Alimentarius', a collection of internationally recognised standards, codes of practice, guidelines and other recommendations relating to foods, food production and

food safety. **Organic food** is food that is produced using methods that do not involve modern synthetic inputs, such as synthetic pesticides and chemical fertilisers, and does not contain genetically modified organisms or food additives and is not processed using irradiation.

The food components that impair utilisation of nutrients (proteins, lipids, carbohydrates, vitamins and minerals) by biochemical mechanisms are called **antinutritional substances**. An example of such an antinutritional substance is oxalic acid, found in spinach and rhubarb, and which binds up calcium to insoluble calcium oxalate and prevents its absorption. Many foods (especially foods of plant origin) contain various natural toxic substances. These may be toxic only to certain individuals causing an **allergy**, which is related to the immune system response of the organism, or a **food intolerance**, which occurs when food irritates a person's digestive system or when a person is unable to properly digest or breakdown the food. The most common food allergies are peanuts, tree nuts (such as walnuts, pecans and almonds), fish and shellfish, milk, eggs, soy products and wheat. Intolerance to lactose in milk and other dairy products is the most common food intolerance.

Substances toxic to all individuals are called **toxic substances** or **toxins**. Once a toxic substance has contacted the body it may have either acute (immediate) or chronic (long term) effects. Most of food-born toxins are substances with low acute toxicity (such as the pungent alkaloid piperine in black pepper), although some may present chronic effects, such as hepatotoxic pyrrolizidine alkaloids in plants (such as comfrey and coltsfoot species) or cause pathological changes to the respiratory system (e.g., tobacco smoke).

Many chemical compounds in foods (as well as in feeds for livestock) are added intentionally as food **additives**. The purpose is to protect foods against spoilage, oxidation and increase some aspects of the food quality (e.g., nutritional value, aroma, taste, colour or texture). Preservatives, colours and flavours are the best-known additives, but there are in fact many categories of additives, each tailored to a specific purpose.

Contaminants are harmful chemical substances (chemical contamination) and toxic microorganisms (microbiological contamination) that have not been intentionally added to food but may be present there as a result of human activities in agriculture or industry. They may enter food at various stages of its production, packaging, transport or storage. A separate issue is genetically modified food or the presence in food of ingredients from genetically modified organisms, which is sometimes referred to as a form of food contamination. In relation to food, contaminants are sometimes differentiated into primary or exogenous contaminants that come from the external environment (e.g., residues of agrochemicals such as pesticides) and secondary or endogenous contaminants, which are, under certain circumstances, generated during food processing (e.g., by heating and fermentation) from natural food components (nutrients and other constituents). These contaminants are often called technological, processing or process-induced contaminants. They are absent in the raw materials, and are formed by chemical reactions between natural and/or added food constituents during processing. Typical examples are acrylamide formed in potato chips from asparagine, methanol produced in fruit alcoholic beverages by hydrolysis of pectin and chloropropanols formed from fats and hydrochloric acid in hydrolysed vegetable proteins.

Food contaminants and some additives used inappropriately, and sometimes even natural toxic substances, are collectively termed **xenobiotics**. The term is primarily understood to describe artificial substances that do not exist in nature and also covers substances that are present in much higher concentrations than are usual. Their presence in foods is related to the **hygienic–toxicological quality**.

As food chemistry is a dynamic discipline, it also deals with the biochemical and chemical reactions, interactions and physical processes that occur during food processing and storage. Knowledge of these processes is a prerequisite for their eventual regulation and also allows the optimisation of production processes, so that it is possible to produce high value foods in all aspects of quality, foods with high nutritional, sensory and hygienic–toxicological value (healthy foods), while satisfying all the requirements and demands of the consumers. In addition, knowledge of these processes can be applied in ordinary culinary experiences. Finally, food chemistry examines the ways in which to enhance positive changes and to prevent the unwanted ones, eliminate the antinutritive and toxic substances, and prevent possible contamination with substances that can pose health risks to guarantee food safety. Producing safe and nutritious food for human and animal consumption is one of the principal aims of both food chemistry and food technology.

This book takes you on a tour of food chemistry, an incredibly fascinating field of study that will provide you with a constant sense of discovery. For better or for worse, food chemistry is all around us every day and everything in food is chemistry, as chemistry is essential to meet our basic needs of food, energy, health, water and air. Food plays a role in everyone's lives and touches almost every aspect of our existence in some way. Therefore, the magic of food composition and its changes has attracted inquisitive minds for centuries. The understanding of the nature of chemicals and pivotal chemical processes occurring in foods, which the reader will gain, has been divided into 11 chapters, each of which provides insights into different classes of food constituents and related reactions, including proteins, peptides and amino acids, fats and other lipids, saccharides and their derivatives, vitamins, mineral compounds, water, odour- and taste-active substances, colours, beneficial, antinutritive and toxic components, food additives and contaminants and covering all aspects of the subject that are necessary for a comprehensive understanding about how things work. Let us wade into this information soup.

2

Amino Acids, Peptides and Proteins

2.1 Introduction

Aminocarboxylic acids (see p. 5) occurring in nature have vital functions in living organisms. Many of these amino acids are found as free substances or higher molecular weight compounds, where the amino acid building units are connected to each other by amide bonds, –CO–NH–, termed **peptide bonds**. Depending on the size of the molecule (the number of bound amino acids), these compounds are divided into two large main groups, which are:

- **peptides**, usually composed of 2–100 monomers
- **proteins**, which contain more than 100 monomers, but also hundreds or even thousands of amino acids.

Proteins and peptides may even contain some further compounds in addition to amino acids. Proteins are undoubtedly the most important amino acid derivatives: they are the basic chemical components of all living cells and therefore are also part of almost all food raw materials and foods of plant, animal and microbial origin. In organisms, proteins perform a number of unique and extraordinary functions. Along with ribonucleic acids (RNA) and deoxyribonucleic acids (DNA), polysaccharides, some lipids and other macromolecules (such as polyisoprene, the major component of rubber tree latex), peptides and proteins are often known as biological polymers or biopolymers. Nucleic acids (RNA and DNA) have almost no significance as food components in human and animal nutrition, although they play fundamental roles in living systems. Plants and some microorganisms are capable of synthesising proteins from basic substrates such as carbon dioxide, water and inorganic nitrogen compounds, but animals rely on getting their necessary vegetable or animal protein from their food. In the process of digestion, the food proteins are enzymatically broken down (hydrolysed) to their building blocks, from which animals may synthesise their own proteins or use them (along with carbohydrates and lipids) as a source of energy. Therefore, proteins, together with carbohydrates and lipids, belong to the category of **main (primary) nutrients**. In human and animal nutrition, proteins are irreplaceable because they cannot be substituted by other nutrients over a long period of time.

The following sections deal with important amino acids, peptides and proteins, their structure, occurrence, properties, fate in the human organism, nutritional aspects and important interactions and reactions that fundamentally affect the nutritional value, organoleptic properties (odour, taste, colour and texture) and the hygienic–toxicological quality of food commodities.

2.2 Amino acids

Amino acids are found in foods – they are the building units of proteins, peptides and many other compounds – but they also occur as free compounds. Plants, animals and other organisms have been shown to contain more than 700 different amino acids. Some of these are spread quite generally throughout nature, while others occur only in certain species of plants, animals or in other organisms. According to their origins, therefore, the following two groups of amino acids are recognised:

- amino acids found in all living organisms (bound in proteins, peptides or occurring as free amino acids)
- amino acids found only in some organisms (bound in peptides or present as free compounds) that are not protein constituents.

The amino acids bound in proteins (22 compounds) are called proteinogenic, encoded, basic, standard or primary amino acids; 21 of them are constituents of proteins, food raw materials and foods. Of the 22 proteinogenic amino acids, 20 are encoded by the

The Chemistry of Food, First Edition. Jan Velíšek.

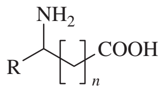
universal genetic code. The remaining two amino acids (selenocysteine and pyrrolysine) are incorporated into proteins by unique synthetic mechanisms. For each of the encoded amino acids, specific transfer RNA molecules exist, and proteins of each organism arise as products of protein synthesis controlled by the genetic code. Amino acids bound in peptides or free amino acids have the same nutritional value as proteins, but their importance in nutrition is usually negligible due to the small amounts in which free amino acids and peptides commonly occur in foods. An example of an amino acid occurring only in some organisms is pyrrolysine, which occurs as a component of enzymes involved in the production of methane in some methanogens, members of a group of single-celled microorganisms of a relatively new domain, Archaea, in the classification of life.

The process of protein biosynthesis is called translation. Post-translational oxidation, alkylation and esterification of some amino acids that are bound in proteins yield modified proteinogenic amino acids (see Section 2.2.1.1.2). Non-proteinogenic (non-encoded, non-standard or secondary) amino acids do not function as building blocks of proteins, as they have other roles in organisms. Amino acids also have an influence on the organoleptic properties of food, especially on their taste. Products of reactions of amino acids are often important compounds influencing odour, taste and colour of foods.

2.2.1 Structure, terminology, classification and occurrence

Amino acids are organic compounds, containing at least one primary amino group, $-NH_2$, together with at least one carboxyl group, –COOH, and various side groups in the molecule. They can be also defined as amino group substituted carboxylic acids. According to the distance of the amino group from the carboxylic group, amino acids (**2-1**) are generally divided into:

- **2-aminocarboxylic acids** (α-aminocarboxylic acids) that have the amino and carboxyl groups attached to the same carbon atom (such as α-alanine);
- **3-aminocarboxylic acids** (β-aminocarboxylic acids) that have the amino and carboxylic groups attached to adjacent carbon atoms (such as β-alanine);
- **4-aminocarboxylic acids** (γ-aminocarboxylic acids) that have one carbon atom (group) between the amino and carboxylic groups (such as γ-aminobutyric acid);
- **5-aminocarboxylic acids** (δ-aminocarboxylic acids) that have two carbon atoms (groups) between the amino and carboxylic groups (such as 5-aminolaevulinic acid, the precursor of the biosynthetic pathway that leads to haem in mammals and chlorophyll in plants);
- **6-aminocarboxylic acids** (ε-aminocarboxylic acids) that have three carbon atoms (groups) between the amino and carboxylic groups (such as lysine).



2-1, 2-amino acid ($n = 0$)
3-amino acid ($n = 1$)
4-amino acid ($n = 2$)
5-amino acid ($n = 3$)
6-amino acid ($n = 4$)

The amino acids also include carboxylic acids that contain a secondary amino group –NH– in the molecule that is a part of three-, four-, five- or six-membered rings. These amino acids are actually derivatives of the saturated nitrogen heterocycles aziridine, azetidine, azolidine (pyrrolidine) and azinane (piperidine) or of other more complex heterocyclic compounds. For example, the only proteinogenic amino acid with a pyrrolidine ring is proline, which in biochemical literature is sometimes incorrectly classified as an imino acid, but imino acids contain imino –C(=NH)– functional groups instead of secondary amino groups.

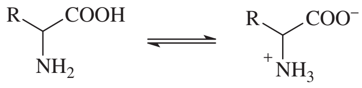
In most foods, about 99% of amino acids are bound in proteins and peptides. The rest (about 1%) are free amino acids. There is a larger amount of free amino acids in foods in which proteolytic enzymes or chemical agents have hydrolysed proteins during manufacture or storage. Larger amounts of free amino acids can be found in some cheeses, beer and wine. The enzymatic hydrolysates of proteins (such as soy sauce) or acidic protein hydrolysates (used as soup condiments) contain only free amino acids with small amounts of peptides, but no protein.

2.2.1.1 Amino acids of proteins

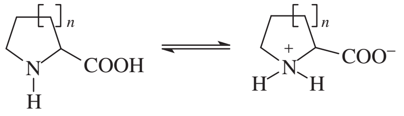
2.2.1.1.1 Proteinogenic amino acids

Proteinogenic amino acids bound in all proteins are exclusively 2-amino (α-amino) acids that have the primary or secondary amino and carboxyl groups attached to the same carbon atom in position 2 (α) to the carboxyl group. In other words, the amino groups are attached to the carbon adjacent to the carboxyl groups. The carbon atom in position 2 (α) is commonly referred to as C_α carbon in biochemical literature.

The proteins in most organisms contain only 21 basic amino acids, of which 20 amino acids have the primary amino group (**2-2**), while one amino acid is an alicyclic amino acid with a secondary amino group (**2-3**). All amino acids except glycine (which is achiral) are optically active (chiral) compounds that contain an asymmetric centre (chiral atom) and thus can occur in two non-superimposable mirror-image forms, D- and L-forms (optical isomers or enantiomers) that are the mirror images of each other. Proteinogenous amino acids almost exclusively belong to the L-series, thus have the L-configuration (see Section 2.2.3.2).



2-2, aliphatic α-amino acid



2-3, alicyclic α-amino acid

One or more hydrogen atoms of the substituent R of L-α-amino acids, known as a side chain, specific to each amino acid (**2-2**), may be substituted by a carboxyl group (called a distal carboxyl group), an amino group (or distal amino group) or other functional groups, such as a hydroxyl group –OH, a sulfhydryl (mercapto) group –SH, a sulfide group –S–CH_3, a guanidino group –NH–C(=NH)–NH_2 or a phenyl group –C_6H_5. The methylene group or nitrogen atom of the secondary amino group of α-amino acids can also be substituted (**2-3**).

The proteinogenic amino acids are often known by their trivial names, which are derived from their properties or the source from which they were first isolated. Systematic names of the proteinogenic amino acids are rarely used, but are more frequent in the non-protein amino acids. Each amino acid has both a three-letter code (mostly the first three letters of the trivial name) and a single-letter code that is used for the registration of long sequences of amino acids in proteins (Table 2.1).

Each classification of amino acids is somewhat imprecise and conforms to certain purposes. The most common way of sorting the proteinogenic amino acids in food chemistry is classification according to the structure of their side chain and functional groups present therein. This will distinguish the following groups of amino acids:

- aliphatic amino acids (monoaminomonocarboxylic acids) with an unsubstituted side chain, which include the simplest amino acid **glycine** (sometimes also classified as the only amino acid without a side chain), its higher homologue **alanine** (known as α-alanine) and branched chain amino acids **valine**, **leucine** and **isoleucine**;

Table 2.1 Trivial and systematic names of proteinogenic amino acids and their codes.

Trivial name	Systematic name	Three-letter code	One-letter code
Glycine	Aminoacetic acid	Gly	G
L-Alanine	L-2-Aminopropionic acid	Ala	A
L-Valine	L-2-Amino-3-methylbutanoic acid	Val	V
L-Leucine[a]	L-2-Amino-4-methylpentanoic acid	Leu	L
L-Isoleucine[a]	L-2-Amino-3-methylpentanoic acid	Ile	I
L-Serine	L-2-Amino-3-hydroxypropanoic acid	Ser	S
L-Threonine	L-2-Amino-3-hydroxybutanoic acid	Thr	T
L-Cysteine	L-2-Amino-3-mercaptopropanoic acid	Cys	C
L-Selenocysteine	L-2-Amino-3-selanylpropanoic acid	Sec	U
L-Methionine	L-2-Amino-4-methylthiobutanoic acid	Met	M
L-Aspartic acid[a]	L-Aminosuccinic acid	Asp	D
L-Glutamic acid[a]	L-2-Aminoglutaric acid	Glu	E
L-Asparagine[a]	L-2-Amino-4-carbamoylbutanoic acid	Asn	N
L-Glutamine[a]	L-2-Amino-5-carbamoylpentanoic acid	Gln	Q
L-Lysine	L-2,6-Aiaminohexanoic acid	Lys	K
L-Pyrrolysine	(2*R*,3*R*)-*N*6-[3-Methyl-3,4-dihydro-2*H*-pyrrole-2-ylcarbonyl]-L-lysine	Pyl	O
L-Arginine	L-2-Amino-5-guanidylpentanoic acid	Arg	R
L-Histidine	L-2-Amino-3-(4-imidazolyl)propionic acid	His	H
L-Phenylalanine	L-2-Amino-3-phenylpropionic acid	Phe	F
L-Tyrosine	L-2-Amino-3-(4-hydroxyphenyl)propionic acid	Tyr	Y
L-Tryptophan	L-2-Amino-3-(3-indolyl)propionic acid	Trp	W
L-Proline	L-Pyrrolidine-2-carboxylic acid	Pro	P

[a]In addition to the specific amino acid codes, three-letter code and one letter-code placeholders are used for ambiguous amino acids, i.e. Asx and B for aspartic acid or asparagine, Glx and Z for glutamic acid and glutamine, Xle and J for leucine or isoleucine and Xaa (Unk) and X for unspecified (unknown) amino acid.

- aliphatic hydroxyamino acids, which include **serine** and **threonine**;
- aliphatic sulfur-containing amino acids **cysteine** and **methionine**;
- selenoanalogue of cysteine called **selenocysteine**;
- amino acids with carboxyl groups in the side chain (monoaminodicarboxylic acids), such as **aspartic acid** and **glutamic acid**;
- their monoamides (amino acids with carboxamide groups in the side chains): **asparagine** and **glutamine**;
- amino acids with basic functional groups in the side chain, that is, diaminomonocarboxylic acid **lysine**, lysine derivative with a 1-pyrroline ring known as **pyrrolysine**, **arginine** with a guanidino group in the side chain and the derivative of 1*H*-isomer of imidazole called **histidine**;
- amino acids with aromatic and heterocyclic side chains, which include **phenylalanine**, its hydroxyl derivative **tyrosine** and **tryptophan** with an indole ring;
- **proline** is the amino acid, in which the functional group is involved in the ring structure.

For clarity, formulae of amino acids are shown in the non-ionised form. Non-ionised molecules are, however, virtually absent in aqueous solutions and in animal and plant tissues. Amino acids are ionised and form inner salts (**2-2** and **2-3**), and carboxyl groups exist as $-COO^-$ anions and amino groups as $-NH_3^+$ cations. The amino acid molecule simultaneously carries positive and negative charges. Because the resulting amino acid contains one positive and one negative charge, it is a neutral molecule called a **zwitterion**. These forms are the predominant ionic forms of amino acids under neutral conditions (about pH 7 in solution). Under these conditions, the distal carboxyl groups of aspartic and glutamic acids, distal amino group of lysine, guanidine group of arginine and imidazole cycle of histidine are also more or less ionised. The nitrogen atoms of the imidazole ring of histidine are denoted by pros ('near', abbreviated π) and tele ('far', abbreviated τ) to show their position relative to the side chain.

In biochemistry, the most common and perhaps most practical classification of proteinogenic amino acids is according to the side chain polarity and its ionic forms occurring in neutral solutions, which is related to non-bonding interactions in proteins (see Section 7.6.2.2). The following groups of amino acids are recognised:

- **hydrophobic amino acids** with non-polar side chains, which include valine, leucine, isoleucine, methionine, phenylalanine, tyrosine and proline; sometimes the hydrophobic amino acids also include glycine, alanine and tryptophan, even though these amino acids are rather amphiphilic amino acids, which forms a transition between the hydrophobic amino acids and the following group;
- **hydrophilic amino acids** with polar side chains, which include serine, threonine, cysteine, selenocysteine, aspartic and glutamic acids and their amides asparagine and glutamine, as well as lysine, pyrrolysine, arginine and histidine.

Hydrophilic amino acids are classified according to the ionic form in which they occur in living organisms into:

- **neutral** (polar side chain has no electric charge in neutral solutions), which includes most amino acids;
- **acidic** (polar side chain has a negative charge in neutral solutions), which includes aspartic acid and glutamic acid;
- **basic** (polar side chain has a positive charge in neutral solutions), such as lysine, pyrrolysine, arginine and histidine.

According to the significance in human nutrition, proteinogenic amino acids are divided into:

- **essential** (or indispensible: valine, leucine, isoleucine, threonine, methionine, lysine, phenylalanine and tryptophan) that cannot be synthesised by the human body;
- **semi-essential** (arginine and histidine);
- **non-essential** (other amino acids; tyrosine forms by hydroxylation of the essential amino acid phenylalanine) that are synthesised by the human body *de novo*.

Amino acids that the body cannot synthesise must be obtained entirely from food. These amino acids are called **essential amino acids**. Essential amino acids are routine constituents of most protein-based foods or dietary proteins and are fairly readily available in a reasonably well-balanced diet. However, there are some amino acids that are present in lower concentrations than the same amino acid in a high quality protein (e.g. lysine in wheat and eggs). These amino acids are called **limiting amino acids**, because if a person's diet is deficient in one of them, this amino acid will limit the usefulness of the others (and will limit the extent of protein synthesis in the body), even if the others are present in what would otherwise be large enough quantities. Limiting amino acids are distinct from non-essential amino acids that the body can synthesise and are therefore sometimes used for food and animal feed enrichment.

In rapidly growing organisms (such as infants, for instance), some non-essential amino acids (arginine and histidine), which the young organism cannot synthesise in sufficient quantities, become essential amino acids. These amino acids are sometimes called **semi-essential amino acids**. Arginine is synthesised at a rate that is insufficient to meet the growth needs of the body, and the majority of it that is synthesised is cleaved to form urea. Histidine was initially thought to only be essential for infants, but longer-term studies established that it is also essential for adult humans. The amino acids methionine and phenylalanine are also sometimes considered semi-essential for reasons not directly related to lack

of synthesis. Methionine is required in large amounts to produce cysteine if the latter amino acid is not adequately supplied in the diet. Similarly, phenylalanine is needed in large amounts to form tyrosine if the latter is not adequately supplied in the diet.

The amino acids that the body can synthesise are called **non-essential amino acids**. They are biosynthesised from intermediates of the citric acid cycle used by all aerobic organisms to generate energy and through other metabolic pathways (glycolysis and the pentose cycle). All living organisms, including humans, synthesise glutamic acid from 2-oxoglutaric acid (derived from the citric acid cycle) and ammonium ions. This reaction is known as reductive amination. Glutamic acid then becomes the precursor of glutamine, proline, ornithine and arginine. Transamination of oxaloacetic acid (from the citric acid cycle) yields aspartic acid that is a precursor of asparagine. Transamination of pyruvic acid (a product of glycolysis) yields alanine. Another intermediate of glycolysis, 3-phospho-D-glyceric acid (and D-ribulose 1,5-bisphosphate in plants), yields serine, which is a precursor of glycine, cysteine and selenocysteine. D-Ribose 5-phosphate from the pentose cycle (the product of photosynthesis in plants) is a precursor of histidine.

Essential and semi-essential amino acids

- **Valine** Valine occurs in animal and plant proteins (meat, cereals) in amounts of 5–7% (average content is 6.9%). Egg and milk proteins contain 7–8% valine. The structural protein elastin has the highest amount of valine (16%).

- **Leucine** Leucine occurs in all common proteins, usually in amounts of 7–10% (average content is 7.5%). Cereals contain a variable amount of leucine, wheat proteins contain about 7% and maize proteins about 13%. Free leucine forms in larger amounts during cheese ripening due to bacterial activity.

- **Isoleucine** The largest amounts of isoleucine are found in milk and egg proteins (6–7%), while meat and grains contain 4–5% of leucine (average content is 4.6%).

- **Threonine** A rich source of threonine is meat and brewer's yeast. Its content in animal proteins (meat, eggs and milk) is around 5%. There is a relatively high amount of threonine in wheat, but its content in other cereals is lower (often around 3%), meaning that threonine sometimes becomes the limiting amino acid.

- **Methionine** Animal proteins contain 2–4% of methionine, whereas plant proteins contain only 1–2% (average content is 1.7%). Methionine is the limiting amino acid in legumes. Methionine (and cysteine) is present only in small amounts in histones and is completely lacking in protamines.

- **Lysine** The average content of lysine in proteins is 7%. High amounts of lysine are found in most animal proteins; meat, eggs and milk proteins commonly contain 7–9% of lysine, fish and shellfish proteins contain 10–11% of lysine. In contrast, vegetable proteins, such as proteins of cereals (especially gliadins, but not glutelins) and cereal products contain only 2–4% of lysine, which is the limiting amino acid.

- **Phenylalanine** Good sources of phenylalanine are meat, fish and most protein containing foods, where this amino acid occurs in sufficient amounts (4–5%, average content is 3.5%). In some individuals, its presence in the diet causes phenylketonuria, an inherited defect in which phenylalanine is incompletely and abnormally metabolised (see Section 10.3.1.2).

- **Tryptophan** The average tryptophan content in proteins is 1.1%. Animal proteins contain 1–2% of tryptophan, except for histones and collagen, which do not contain tryptophan at all. Tryptophan is also not present in gelatine or in acid protein hydrolysates used as soup seasonings. Therefore, the tryptophan content in meat products can serve as an indicator of the quality of the meat used. (The contents of 3-methylhistidine or creatinine have been measured for the same purpose.) Cereals contain $<1\%$ of tryptophan; the glutenine fraction of gluten has a somewhat higher content of tryptophan. In fruits and fruit juices N^1-(β-D-glucopyranosyl)-L-tryptophan is also found. Its amount in juices ranges from 0.1 to >10 mg/l. The highest amount of this glycoconjugate was found in pear juices (13.5 mg/l). Humans can partly use tryptophan for biosynthesis of nicotinic acid (see Section 5.8.3). In ruminants, if present in excessive amounts in the diet, tryptophan causes pulmonary oedema (fluid accumulation in the lungs) that may cause respiratory failure. The cause is the heterocyclic compound 3-methylindole (skatole), which is a fermentation product of tryptophan in the rumen.

- **Arginine** Arginine occurs in all proteins in amounts of 3–6% (average content is 4.7%). Basic proteins protamines from fish roes have particularly high levels of arginine. Peanuts and other oilseeds are also rich sources (arginine content of up to 11%).

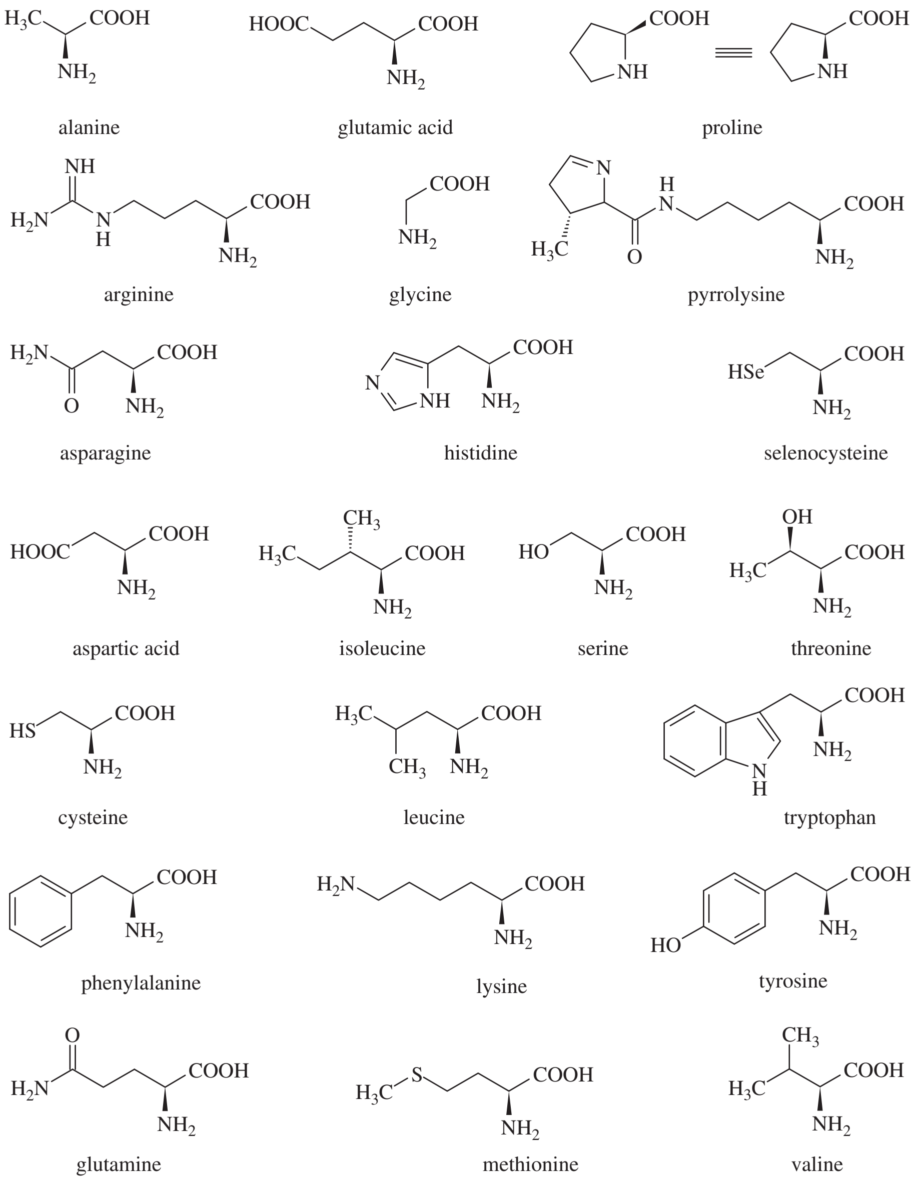
- **Histidine** Common proteins contain 2–3% histidine (average content is 2.1%), and blood plasma proteins contain up to 6% histidine. The flesh of some fish (especially mackerel and tuna) contains from 0.6 to 1.3% (and sometimes more than 2%) of free histidine. The free histidine content in the flesh of other fish is only 0.005–0.05%.

Non-essential amino acids

- **Glycine** Glycine is contained in a significant amount (25–30%) mainly in the structural protein collagen and in gelatine; in the majority of albumins it is not present at all (average content is 7.5%).

- **Alanine** Alanine occurs in almost all proteins in amounts of 2–12% (average content is 9.0%). Maize prolamine protein zein and animal protein gelatine contain about 9% of alanine.

- **Serine** Serine is found in many proteins; generally in an amount of 4–8% (average content is 7.1%).



2-4, basic amino acids

- **Cysteine** The highest amount of this amino acid and its oxidation product cystine (**2-5**) is present in keratin (up to 17%); it occurs in many other proteins in smaller amounts (1–2%). The average content is 2.8%. In the organism, cysteine can partially replace the essential amino acid methionine.

- **Aspartic acid and asparagine** The average content of aspartic acid in proteins is 5.5%; the average content of asparagine is 4.4%. Aspartic acid is the major amino acid of animal proteins known as globulins and albumins (6–10%). Vegetable proteins contain 3–13% aspartic acid, mainly in the form of asparagine (e.g. wheat proteins contain about 4% and maize proteins about 12%).

- **Glutamic acid and glutamine** The average content of glutamic acid and glutamine in proteins is 6.2 and 3.9%, respectively. Glutamic acid is the most abundant amino acid in the nervous tissue. In conventional proteins, both amino acids are usually found in larger quantities (especially in globulins) in cereal and legume proteins (18–40%). Wheat gluten (in its component gliadin) contains about 40%, soy protein contains about 18% and milk proteins contain about 22% of glutamic acid.

- **Selenocysteine** In most foods of both vegetable and animal origin, selenocysteine is the main form of selenium bound in proteins. The content of this amino acid, as well as the contents of other amino acids and peptides containing selenium (L-selenocystine, *Se*-methyl-L-selenocysteine, L,L-selenocystathionine, L-selenomethionine and γ-glutamyl-*Se*-methyl-L-selenocysteine), is unknown. Selenocysteine is typically located in a small number of active centres of proteins of Archaea, bacteria and eukaryotes (in glutathione

peroxidase, thioredoxin reductase, formiate dehydrogenase, glycine reductase and in some hydrogenases). Usually only one molecule of selenocysteine is bound in the peptide chain; however proteins containing multiple molecules of this amino acid are also known. For example, the isoenzyme of mammalian glutathione peroxidase, known under the abbreviation GPx6, is a selenoprotein in humans with cysteine-containing homologues in rodents.

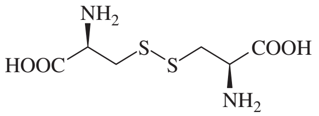
- **Tyrosine** Tyrosine accompanies phenylalanine in most proteins in an amount of 2–6% (average content is 3.5%). Gelatine contains only traces of tyrosine.

- **Proline** Proline is present in most proteins in amounts of 4–7%; the average content is 4.6%. Its content in the component of wheat gluten, gliadin, is about 10%, and about 12% of proline contains casein. Proline content in gelatine can be up to 13%. In bacteria, plants and animals it also plays a role as an osmoprotectant that helps stabilise proteins and cell membranes from the damaging effect of high osmotic pressure.

2.2.1.1.2 Modified proteinogenic amino acids

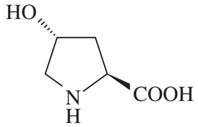
Post-translational modification, which extends the range of functions of the protein, is one of the later steps in the biosynthesis of many proteins. Post-translational modification of proteins occurs by methylation, hydroxylation, acetylation and phosphorylation of the protein functional groups, by attaching various lipids and carbohydrates to the protein molecule and by making structural changes such as the formation of disulfide bonds from cysteine residues by oxidation.

Post-translational oxidation of the thiol groups of cysteine residues in proteins yields L-**cystine** (Cys-Cys, **2-5**). The disulfide bond (or bridge) plays an important role in the structure of many proteins, as it combines two different polypeptide chains or two molecules of cysteine in the same peptide chain. For example, the major globular protein of milk β-lactoglobulin contains two disulfide bridges, and the glycoprotein of egg white ovomucoid has three domains connected by disulfide bridges. The protein keratin has a high cystine content: for example, human hairs contain about 5% cystine.



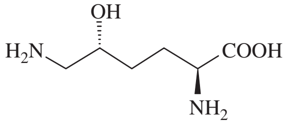
2-5, cystine

Another common post-translationally modified amino acid is the proline derivative L-4-**hydroxyproline**, (2*S*,4*R*)-4-hydroxyproline, also known as L-4-hydroxypyrrolidine-2-carboxylic acid (abbreviated Hyp, **2-6**), which is an important structural component of collagen, gelatine (about 12% of content) and the polypeptide (glycopeptide) of plant cell walls known by the trivial name extensin (see Section 4.5.1.3.1). Its content is low in most other proteins. The amount of 4-hydroxyproline in meat products therefore correlates with the lower quality of raw material used, for instance where the products contain skin, wherein collagen is the major protein. 4-Hydroxyproline also occurs in smaller amounts in plants. For example, concentrations ranging from 1.0 to 4.2 mg/kg have been found in the edible part of bergamot fruits (*Citrus bergamia*, Rutaceae).



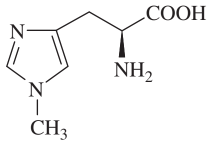
2-6, 4-hydroxyproline

4-Hydroxyproline in collagen is accompanied by a small amount of its isomer, L-3-hydroxyproline (L-3-hydroxypyrrolidin-2-carboxylic acid) and by a hydroxy derivative of lysine, also known as L-5-**hydroxylysine**, (2*S*,5*R*)-5-hydroxylysine, L-5-hydroxy-2,6-diaminohexanoic acid (abbreviated Hyl, **2-7**). In glycoproteins, hydroxylysine is bound as *O*-glycoside. Small amounts of hydroxylysine occur in plant materials (as a free amino acid in alfalfa forage, *Medicago sativa*, Fabaceae).



2-7, 5-hydroxylysine

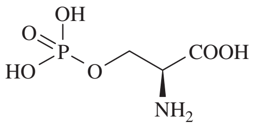
The minor amino acid typically present in the meat myofibrillar protein actin (also in some myosin isoforms and in dipeptide anserine, see Section 2.3.3.1.3) is L-3-**methylhistidine** (**2-8**), which is formed by methylation of histidine bound at the 73rd position of the protein chain. The functional significance of this modification of actin is not known; it is probably related to the metabolism of phosphates, with which the side chain of methylhistidine interacts. Methylhistidine does not occur in other protein-rich foods such as milk, eggs and soybeans. Its contents might therefore serve as a criterion for determining the quality ingredients in meat products.



2-8, 3-methylhistidine

The other amino acid that is usually modified is L-serine. It can be esterified with phosphoric acid. This ester, *O*-**phosphoserine** (**2-9**), occurs in many proteins, such as glycophosphoprotein phosvitin (also known as phosphovitin) from egg yolk (see Section 2.4.5.3.2). Phosvitins are one of the most phosphorylated (10%) proteins in nature, and are important for sequestering cations of calcium, iron and other metals for the developing embryo. Serine in phosvitin represents nearly 50% of the amino acids and there

are about 90% of the molecules of serine phosphorylated. Phosphoserine also occurs in the glycoprotein α_{S1}-casein (eight phosphoserine residues) and β-casein (five phosphoserine residues). Phosphoserine (as phospatidyl-L-serine) is also a component of phospholipids distributed widely among animals, plants and microorganisms. Phosphoserine usually constitutes less than 10% of the total phospholipids, the greatest concentration being in myelin from brain tissue and in wheat germ. Threonine residues in proteins are also esterified fairly frequently with phosphoric acid yielding *O*-**phosphothreonine**. Phosphatidyl-L-threonine was first detected in animal brains and tuna muscle, before it was characterised definitively as a minor component of neurons, macrophages, viruses and some bacterial species.



2-9, *O*-phosphoserine

2.2.1.2 Other amino acids

Plants and microorganisms are able to generate all 21 amino acids necessary for protein synthesis, and they can additionally synthesise many more. Foods contain numerous other less common amino acids in addition to those that are constituents of proteins (proteinogenic) and modified proteinogenic amino acids. It is estimated that there are around 700 amino acids known in nature, of which at least 300 are found in plants. They are often bound in peptides (see Section 2.3) or are present as free amino acids. In biochemistry, these **non-protein amino acids** are often classified as the so-called secondary metabolites, as they are the products of three major routes: modification of an existing (often proteinogenic) amino acid, modification of an existing pathway and by novel pathways. These amino acids become the biosynthetic precursors of many biologically active nitrogenous compounds, such as signalling molecules, vitamins, alkaloids (such as valine, leucine, isoleucine, threonine, arginine, lysine, phenylalanine and tryptophan), bile acids and pigments. Some of these amino acids also have specific functions in organisms; they act as neurotransmitters, stimulants and hormones. For example, phenylalanine (or 3,4-dihydroxyphenylalanine) is a precursor of adrenal hormones catecholamines (such as epinephrine, which is also known as adrenaline; see Section 10.3.2.10.1) and of the thyroid hormone thyroxine (see Section 2.2.1.2.5). Other amino acids increase plant tolerance to abiotic stress factors, act as toxic substances which protect plants against invading viruses, microorganisms, other plants and predators (e.g. the arginine analogue canavanine found in some legumes) and also serve as a storage and transport form of nitrogen and sulfur. Some of the unusual amino acids form secondarily during storage of raw materials and food processing via the activities of microorganisms and by chemical transformation of proteins (e.g. lysinoalanine, see **2-121**), peptides or free amino acids.

The following sections of this chapter present some of the most important non-protein amino acids in foods and feeds. For clarity, they are sorted according to the structure in which they are present in living organisms and not by function (these functions often are not well known).

2.2.1.2.1 Neutral aliphatic and alicyclic amino acids

3-Amino acids and 4-amino acids

In addition to α-amino acids, β- and γ-amino acids can also be found in food. Naturally occurring β-alanine (3-aminopropionic acid, **2-10**) acts in the biosynthesis of pantothenic acid, acetyl coenzyme A, other acyl coenzymes A (see Section 5.9.1) and some histidine dipeptides. β-Alanine is synthesised in several different ways, by aspartic acid decarboxylation (in bacteria), but also by the transformation of propionic acid (in bacteria and some plants), by degradation of the polyamines spermine and spermidine (in yeasts and many plants, such as tomato, soybean and maize), or arising from the pyrimidine derivative uracil that occurs in all animals and in some plants, such as wheat.

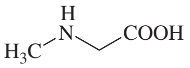
2-10, β-alanine

The higher homologue of β-alanine is γ-aminobutyric acid (4-aminobutanoic acid), known under the acronym of GABA (**2-11**), which is formed almost exclusively by enzymatic decarboxylation of glutamic acid. It is mainly present in the brain tissue of animals, where it acts as an inhibitor of nerve impulse transmissions. It is also found in plants and microbial cells, where it has a role as a signal molecule, and is also a constituent of some peptides such as nisine (see Section 11.2.1.2.1).

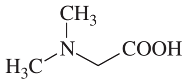
2-11, γ-aminobutyric acid

N-Substituted amino acids

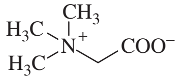
N-Alkylsubstituted amino acids are commonly found in foods. The simplest of these amino acids is *N*-methylglycine (sarcosine, **2-12**), which is a product of the catabolism of choline (see Section 3.5.1.1.1), creatine (see Section 2.2.1.2.4) or forms by *N*-methylation of glycine. Sarcosine probably has a regulatory function in methylation reactions. The subsequent *N*-methylation of sarcosine gives *N*,*N*-dimethylglycine (**2-13**), which is a component of pangamic acid ranked first among the vitamins (see Section 5.15). *N*,*N*,*N*-Trimethylglycine (*N*,*N*,*N*-trimethylammonioacetate, **2-14**) was named glycinebetaine or just betaine after its discovery in sugar beet (*Beta vulgaris*, Amaranthaceae), where it occurs in the amount of about 2.5 g/kg in the root. Glycinebetaine is a very effective osmolyte of microorganisms and higher plants, which results from choline or by *N*-methylation of glycine and sarcosine, respectively, and acts in various transmethylation reactions. It is present in higher amounts in sugar beets and molasses. Glycinebetaine was found to accumulate at high levels in some higher fungi. For example, its content in horse mushroom (*Agaricus arvensis*) is 7.8% dry matter.



2-12, *N*-methylglycine (sarcosine)

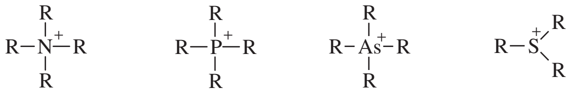


2-13, *N*,*N*-dimethylglycine



2-14, *N*,*N*,*N*-trimethylglycine

The terms **betaines** include glycinebetaine and similar zwitterionic ammonium compounds derived from other amino acids. By extension, betaines are also neutral molecules having charge-separated forms with an onium atom which bears no hydrogen atoms (such as phosphonium, sulfonium and arsonium ions) that is not adjacent to the anionic atom. Examples of the most common onium ions (ammonium, phosphonium, sulfonium and arsonium ions) are given by the general formulae **2-15**. The attached atoms are typically organic substituents, for example methyl groups. The most common betaines are quaternary ammonium compounds that occur in foods of animal and plant origin. In animals, betaines participate (along with *S*-adenosyl-L-methionine, pyridoxine, folic acid and vitamin B_{12}) in the protection of the cardiovascular system by lowering the potentially toxic concentrations of L-homocysteine. L-Carnitine plays an important role in the metabolism of fatty acids in biological systems plays (see Section 5.15). An arsenic analogue of betaine, arsenobetaine, accumulates in the body of some fish (see Section 6.2.3.1). Betaines are particularly ubiquitous in plants. They are generally referred to as osmolytes as they, like their amino acid precursors, tend to accumulate in the cytoplasm and intercellular fluids, where they exert protective functions for proteins, nucleic acids and cell membranes in response to abiotic stresses, such as cold, freezing, high temperature, the presence of toxic metals, reduced availability of water and high salinity. Some of the major betaines are listed in Table 2.2. Their structures are given by formulae **2-16**.



ammonium ion phosphonium ion arsonium ion sulfonium ion

2-15, general structures of some onium ions

An important group of *N*-substituted amino acids are *N*-acylamino acids (**2-17**). An important metabolite is hippuric acid, also known as *N*-benzoylglycine (**2-17**). Hippuric acid arises from glycine as a result of detoxification of benzoic acid and other aromatic acids in humans and animals. In higher concentrations it occurs in the urine of herbivores and reportedly inhibits some pathogenic bacteria in the urinary tract. Benzoic acid is found (usually in small amounts) in many plant materials, including fruit, vegetables and forage crops (see Section 8.2.6.1.6), and is also used as a food preservative (see Section 11.2.1.1.1). Cows partially excrete hippuric acid into their milk, up to a concentration of 60 mg/kg. Microorganisms used in the production of fermented dairy products hydrolyse hippuric acid to glycine and benzoic acid. For example, the content of benzoic acid in yoghurts can reach, on average, 15 mg/kg.

N-phenylpropenoyl amino acids (**2-17**) have been identified as the key contributors to the astringent taste of non-fermented cocoa beans and cocoa products. Besides the already known (*E*)-*N*-[3′,4′-dihydroxycinnamoyl-3-hydroxy-L-tyrosine (known as clovamide), (*E*)-*N*-(4′-hydroxycinnamoyl)-L-tyrosine (deoxyclovamide) and (*E*)-*N*-(3′,4′-dihydroxycinnamoyl)-L-tyrosine, seven additional amides derived from cinnamic, 4-coumaric, caffeic and ferulic acids, namely, (+)-(*E*)-*N*-(cinnamoyl)-L-aspartic acid, (+)-(*E*)-*N*-(4′-hydroxycinnamoyl)-L-aspartic acid, (+)-(*E*)-*N*-(3′,4′-dihydroxycinnamoyl)-L-aspartic acid, (+)-(*E*)-*N*-(4′-hydroxy-3′methoxycinnamoyl)-L-aspartic acid, (−)-(*E*)-*N*-(4′-hydroxycinnamoyl)-L-glutamic acid, (−)-(*E*)-*N*-(3′,4′-dihydroxycinnamoyl)-L-glutamic acid and (−)-(*E*)-N-(4′-hydroxycinnamoyl)-3-hydroxy-L-tyrosine, were recently identified.

Table 2.2 Some important betaines.

Betaine	Initial amino acid	Occurrence
β-Alaninebetaine (homobetaine)	β-Alanine	Plants of the Plumbaginaceae family, citrus species, meat
Gababetaine	γ-Aminobutyric acid	Molluscs, citrus species
L-Carnitine	Lysine and methionine	Meat, dairy products, legumes, vegetables, higher fungi
Laminine (lysinebetaine)	Lysine	Some higher plants
Stachydrine (cadabine, prolinebetaine)	Proline	Higher plants (e.g. citrus species), fungi
Betonicine (4-hydroxystachydrine, 4-hydroxyprolinebetaine)	4-Hydroxyproline	Plants of the Lamiaceae family
Hercynine (histidinebetaine)	Histidine	Higher fungi, citrus species
L-Ergothioneine (2-thioimidazolebetaine)	2-Mercaptohistidine	Higher fungi, plants
Homarine	Pyridine-2-carboxylic acid	Some higher plants
(Dimethylsulfonium)propanoate	Methionine	Marine phytoplankton, seaweeds

2-17, structures of important *N*-acylamino acids

Exposure to light rapidly converted (*E*)-isomers of *N*-phenylpropenoyl amino acids into the corresponding (*Z*)-isomers.

Alicyclic amino acids

A common neutral amino acid derived from cyclopropane is 1-aminocyclopropane-1-carboxylic acid. The precursor of this carboxylic acid is methionine, or strictly *S*-adenosyl-L-methionine which is derived from methionine (Figure 2.1). 1-Aminocyclopropane-1-carboxylic acid is also present in apples, pears and other fruits. 1-Aminocyclopropane-1-carboxylic acid serves as a precursor of ethylene (ethene) in essentially all tissues of vascular plants and also in fungi and algae. Ethylene is a signalling molecule in plants (a hormone) that regulates seed germination, plant growth, flowering, ripening of fruits, leaf abscission and aging. Plants also synthesise ethylene in various stressful situations (mechanical damage, frost damage, flooding, pathogen attack and in the presence of heavy metals). Production of ethylene is connected with the formation of hydrogen cyanide, a process known as cyanogenesis (see Section 10.3.2.3).

The seeds of lychee fruit (*Litchi chinensis*) from the soapberry family (Sapindaceae), native to southern China and South-east Asia, contains an unusual amino acid L-α-(methylenecyclopropyl)glycine, that is, (2*S*,3*S*)-2-(methylenecyclopropyl)

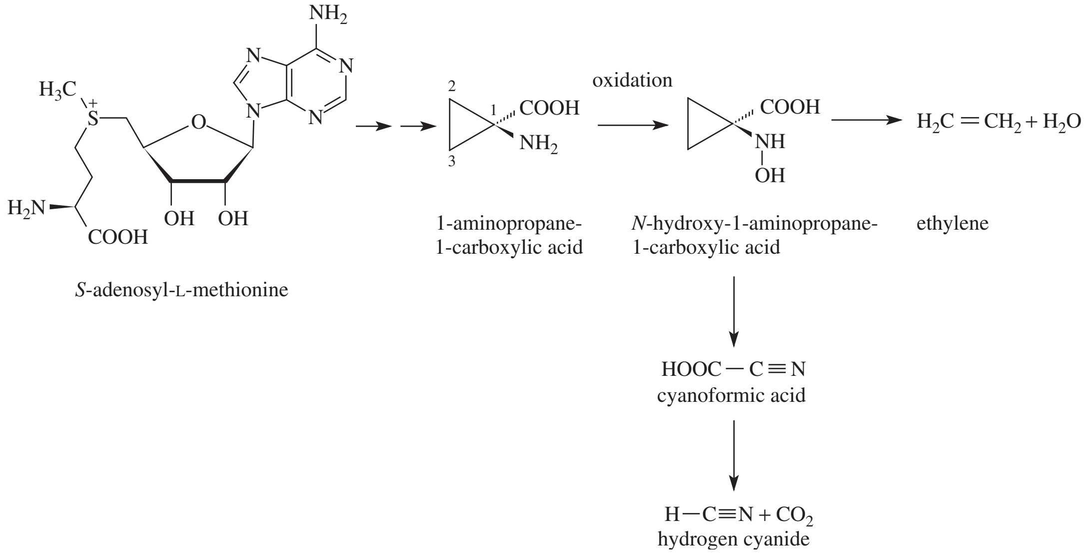

Figure 2.1 Formation of ethylene and hydrogen cyanide in plants.

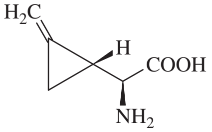
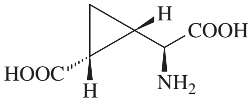
glycine (**2-18**), which lowers blood glucose levels. Symptoms of poisoning, known as toxic hypoglycaemic syndrome, occur 6–48 hours after ingestion of seminal immature follicles. The poisoning is manifested by vomiting, drowsiness, fatigue and hypoglycaemia. The toxin (the active metabolite is methylencyclopropylacetyl-CoA) interferes with the metabolism of branched-chain amino acids, irreversibly binds to FAD and inhibits acyldehydrogenases acting in β-oxidation of fatty acids.

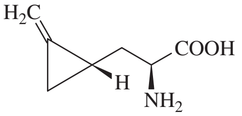


2-18, 2-(methylenecyclopropyl) glycine

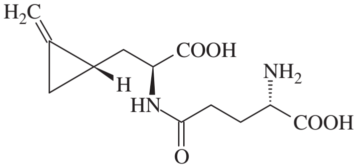
The same amino acid, together with derived γ-glutamyl dipeptide and (2*S*,1′*S*,2′*S*)-2-(2′-carboxycyclopropyl)glycine (**2-19**) occurs in the seeds of ackee fruit (*Blighia sapida*, Sapindaceae), native to tropical West Africa. A higher homologue of 2-(methylenecyclopropyl)glycine, that is, L-3-(methylenecyclopropyl)alanine, also known as hypoglycin A (**2-19**), is present in this fruit in much higher concentrations. Hypoglycin A (now known as hypoglycin) occurs as a mixture of (2*S*,4*R*)- and (2*S*,4*S*)-diastereoisomers in fruits (in the edible arilli portion) and seeds. The former is the dominant isomer in the arilli. Formula (**2-20**) shows the (2*S*,4*S*)-isomer, which also has a hypoglycaemic effect, but the other primary toxic effect is known as Jamaican Vomiting Sickness (see Section 10.3.2.7). Ackee fruit also contains the γ-glutamyl dipeptide of hypoglycin A, known as hypoglycin B (**2-21**). The amount of hypoglycin A in totally green and yellow–green or orange–green arilli and seeds is 6.7–7.9 and 8.2–8.4 g/kg, respectively. Dull and shrivelled arilli (mainly from red fruits) and seeds contain 0.27–0.55 and 1.5–2.6 g/kg of hypoglycin A, respectively. The content of hypoglycin B in the seeds of unripe fruit is 1.6–3.1 g/kg, while in seeds of ripe fruit the content ranges from 11.7 to 12.6 mg/kg. Higher concentrations of hypoglycins A and B also occur in seeds of the common sycamore (*Acer pseudoplatanus*, Aceraceae). For example, The Food and Drug Administration and Health Canada sets the maximum permissible level of hypoglycin A to 100 mg/kg.



2-19, 2-(2′-carboxycyclopropyl)glycine

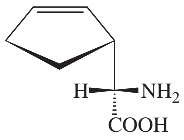


2-20, hypoglycin A

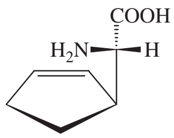


2-21, hypoglycin B

An important alicyclic amino acid in some genera of tropical plants of the Flacourtiaceae, Passifloraceae and Turneraceae families is cyclopentenylglycine occurring as a mixture of two stereoisomers, (2*S*,1′*R*)-2-(cyclopent-2′-en-1′-yl)glycine (**2-22**) and (2*S*,1′*S*)-2-(cyclopent-2′-en-1′-yl)glycine (**2-23**), in which the (2*S*,1′*R*)-isomer predominates. Cyclopentenylglycine is a precursor of unusual fatty acids (see Section 3.3.1.4.3) and also cyanogenic glycosides (see Section 10.3.2.3.1).



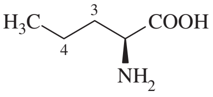
2-22, (2*S*,1′*R*)-2-(cyclopent-2′-en-1′-yl)glycine



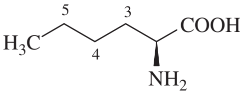
2-23, (2*S*,1′*S*)-2-(cyclopent-2′-en-1′-yl)glycine

Hydroxyamino acids

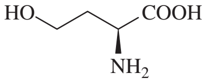
Various legumes (seeds of plants of the Fabaceae family) are rich sources of free aliphatic hydroxyamino acids. Common amino acids such as 4-hydroxyleucine, 4-hydroxynorvaline and 5-hydroxynorleucine are hydroxyderivatives of branched chain amino acids, L-leucine (2-4), L-isoleucine (**2-4**), L-norvaline (**2-24**) and L-norleucine (**2-25**). Another common amino acid in legumes is L-homoserine (**2-26**), which is derived from 2-aminobutyric acid, the intermediate in the biosynthesis of threonine from aspartic acid. Frequently *O*-acyl- and *O*-amino derivatives of homoserine are seen. An example of an *O*-aminoderivative of homoserine is a toxic amino acid known as canaline (see Section 2.2.1.2.4). The most common source of this amino acid is the jack bean (*Canavalia ensiformis*).



2-24, norvaline



2-25, norleucine



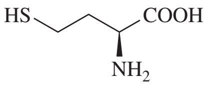
2-26, homoserine

These hydroxyamino acids are frequent components of peptides occurring in toxic mushrooms. For example, peptides of some *Amanita* species (see Section 10.3.2.9.2) contain (2*S*,4*R*)- and (2*S*,4*S*)-isomers of 4-hydroxyleucine and some other hydroxysubstituted amino acids, including amino acids with unsaturated side chains.

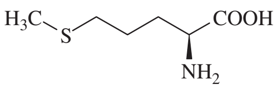
2.2.1.2.2 Sulfur and selenium amino acids

Foods of plant origin contain numerous sulfur amino acids, mostly derived from cysteine, methionine and their higher homologues,

such as L-homocysteine (**2-27**) and L-homomethionine, also known as L-5-methylthionorvaline (**2-28**).



2-27, homocysteine

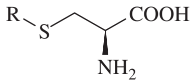


2-28, homomethionine

Cysteine derivatives

Plants synthesise a number of *S*-cysteine (and *S*-glutathione) conjugates that are released by the action of L-cysteine-*S*-conjugate thiol-lyases (deaminating) to produce various volatile flavour-active thiols in fruits and vegetables (see Section 8.2.9.1.2).

Other important derivatives of cysteine are *S*-alk(en)yl-L-cysteines (**2-29**), which accompany, in small amounts, the predominant *S*-alk(en)yl-L-cysteine *S*-oxides, also called *S*-alk(en)yl-L-cysteine sulfoxides (**2-30**). *S*-Alk(en)yl-L-cysteine sulfoxides may occur in two optical isomers (thanks to the free electron pair on the sulfur atom). Only (+)-*S*-isomers, also known as (S_S)-isomers, occur in vegetables. However, isoalliin is an exception. It occurs as an (R_S)-isomer because of the priority of the other substituent. The bond between the sulfur and oxygen atoms in *S*-alk(en)yl-L-cysteine sulfoxides differs from a conventional double bond between carbon and oxygen. As a result, the molecule has a dipolar character, with the negative charge centred on the oxygen and the sulfur atom being a chiral centre. These amino acids originate from γ-glutamyl *S*-alk(en)yl-L-cysteine storage compounds via *S*-alk(en)yl-L-cysteines (see Section 2.3.2.1.2) and are the precursors of many biologically and flavour active compounds (see Section 8.2.9.1.4). Particularly rich sources of these amino acids are some genera of the plant families Brassicaceae (the genus *Brassica*), Amaryllidaceae (subfamily Allioideae, genera *Allium* and *Tulbaghia*) and Fabaceae (*Phaseolus*, *Vigna* and *Acacia*). *S*-Alk(en)ylcysteine derivatives also occur in plants belonging to the families Olacaceae (*Scorodocarpus*) and Phytolaccaceae (*Petiveria*), in some higher fungi, such as mushrooms in the genera *Marasmius*, *Collybia* and *Lentinula* (known as shiitake), and in brown (*Undaria*) and red (*Chondria*) seaweeds.



2-29, *S*-alk(en)ylcysteines

The basic member of the homologous series, *S*-methylcysteine (**2-29**, R = CH_3), and its sulfoxide, (R_C,S_S)-*S*-methylcysteine sulfoxide, also known as (+)-*S*-methyl-L-cysteine sulfoxide or methiin (**2-30**, R = CH_3), occurs in cabbage, garlic, onion and other *Brassica* and *Allium* vegetables and also in beans. There is roughly 0.2–0.7 g/kg in fresh Brassica vegetables. The methiin levels in *Allium* vegetables are given in Table 2.3. Note that methiin is a toxic amino acid to ruminants (see Section 10.3.2.7.1). (R_C,S_S)-*S*-Carboxymethylcysteine sulfoxide (**2-30**, R = CH_2–COOH), occurs, for example, in radish (genus *Raphanus*, Brassicaceae). Some species of *Brassica* plants and some members of the genus *Allium* (e.g. elephant garlic, onion, shallot, leek and chive) contain traces of ethiin, that is, (R_C,S_S)-*S*-ethylcysteine sulfoxide (**2-30**, R = CH_2–CH_3) (Table 2.3).

	Concentration in g/kg fresh weight			
Substituent	**Garlic (*Allium sativum*)**	**Onion (*Allium cepa*)**	**Leek (*Allium porum*)**	**Chive (*Allium schoenoprasum*)**
Methyl	0.05–4.24	0.22	0.04	0.32
Ethyl	0–traces	0.05	traces	0.01
Propyl	0–traces	0.06	traces	0.07
Prop-2-en-1-yl (allyl)	1.10-10.5	traces–0.05	traces	0.02
Prop-1-en-1-yl	traces–1.11	0.50–1.31	0.18	0.31

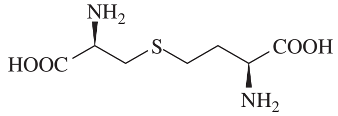
Another related amino acids are (R_C,S_S)-*S*-allylcysteine (deoxyalliin), and (R_C,S_S)-*S*-(prop-2-en-1-yl)cysteine sulfoxide, which is known as alliin (**2-30**, R=CH_2–CH=CH_2). Alliin is the major sulfur containing amino acid of garlic (Table 2.3). Its isomer (R_C,R_S,1*E*)-*S*-(prop-1-en-1-yl)cysteine sulfoxide, or isoalliin (**2-30**, R=CH=CH–CH_3), is the major free amino acid of onions. It is also found in smaller amounts in garlic (Table 2.3). (R_C,S_S)-*S*-Propylcysteine sulfoxide, or propiin, R = $[CH_2]_2$–CH_3 (**2-30**) occurs in onions, shallots and chives and in trace amounts in some garlic species, for example in bulbs of *A. vineale* (0.01 mg/kg fresh weight), *A. ursinum* (0.02 mg/kg fresh weight) and *A. triquetrum* (0.09 mg/kg fresh weight). Its higher homologue butiin, that is, (R_C,S_S)-*S*-butylcysteine sulfoxide, R=$[CH_2]_3$–CH_3 (**2-30**), occurs in some species of the genus *Allium*, in bulbs of *A. siculum* (0.3 g/kg fresh weight) and *A. tripedale* (5.7 g/kg fresh weight) together with (R_C,S_S,1*E*)-*S*-(but-1-en-1-yl)cysteine sulfoxide, R=CH=CH–CH_2–CH_3 (**2-30**), known as homoisoalliin. The concentrations found in fresh bulbs of the ornamental plants *A. siculum* and *A. tripedale* were 3.5 and 1.2 g/kg, respectively. The important cysteine sulfoxide (R_S,R_C)-*S*-(methylthiomethyl)cysteine-4-oxide, known as marasmin (**2-30**), carrying a methylthiomethyl moiety as the aliphatic residue, was found in South African society garlic (*Tulbaghia violacea*) and in wild (woodland) garlic (*T. alliacea*), in *A. stipitatum* and *A. suworowii* (*Allium* subgenus *Melanocrommyum*) and as a γ-glutamyl derivative, γ-glutamyl-(S_S,R_C)-marasmin, in various mushroom species belonging to the genus *Marasmius* (such as *M. alliaceus*). Marasmin is the precursor of the thiosulfinate marasmicin, which shows antifungal and tuberculostatic activities. (R_C,S_S)-*S*-(Pyridin-2-yl)cysteine sulfoxide (**2-30**) and several pyridyl compounds, which were formed from this amino acid by the action of alliinase, were identified in bulbs of the drumstick onion *Allium stipitatum* (*Allium* subgenus *Melanocrommyum*), which is used as a crop plant and in folk medicine in Central Asia. (R_C,S_S)-*S*-(Pyrrol-3-yl)cysteine sulfoxide is found in another member of the subgenus *Melanocrommyum*, *A. giganteum*.

To date, six *S*-alk(en)ylcysteine sulfoxides, namely *S*-allyl-, (*E*)-*S*-(prop-1-en-1-yl)-, *S*-methyl-, *S*-propyl, *S*-ethyl and *S*-butylcysteine sulfoxides have been found in common vegetables of the genus *Allium*; the last two compounds are only present in trace amounts. It has been well documented that the total content and relative proportions of the individual *S*-alk(en)ylcysteine sulfoxides in alliaceous plants are significantly affected by a number of genetic and environmental factors (e.g. plant species and variety, climatic conditions, sulfur content in the soil, irrigation, fertilisation, harvest date, amongst other things) and is usually around 0.1–0.8%, which represents more than 10% of the crude protein content. The contents also vary considerably over the growth period. For example, in garlic, the highest amounts are found in spring, in the green parts of the plant, which are the most important sites of cysteine sulfoxide biosynthesis, although some biogenesis may also occur in the bulbs. The cysteine sulfoxide levels in the bulbs start to increase dramatically approximately 5 weeks before harvest. This accumulation in bulbs may be associated with the possible role of cysteine sulfoxides as storage compounds for sulfur and nitrogen during dormancy.

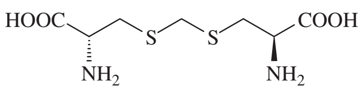
Some vegetables also contain alk(en)ylthio substituted L-cysteine sulfoxides in small amounts. For example, (R_C,S_S)-*S*-methylthiocysteine sulfoxide (R=S–CH_3, **2-30**), (R_C,S_S)-*S*-propylthiocysteine sulfoxide (**2-30**, R=S–CH_2–CH_2–CH_3) and (R_C,S_S,1*E*)-*S*-(prop-1-en-1-ylthiocysteine sulfoxide (**2-30**, R=S–CH=CH–CH_3) occur in onions at concentrations of 0.19, 0.01 and 0.56 g/kg fresh weight, respectively. These amino acids and the corresponding peptides (see Section 2.3.3.1.2) are formed by reaction of thiosulfinates (see Section 8.2.9.1.4) with cysteine residues.

An interesting sulfur containing amino acid derived from cysteine is 2-amino-4,6,8,10,10-pentaoxo-4,6,8,10-tetrathiaundecanoic acid (**2-30**, R=CH_2–CH_2-SO–SO–CH_2–SO_2–CH_3), or deglutamyllentinic acid), which forms from the corresponding γ-glutamyl peptide known as lentinic acid (see Section 2.3.2.1.2) through the action of γ-glutamyl transpeptidase and becomes the precursor of the characteristic sulfur compound (1,2,4,5,6-pentathiepane, commonly known as lenthionine; see Section 8.2.12.9.7) in dried edible shiitake mushrooms (*Lentinula edodes*), one of the most popular edible mushrooms in Japan and other parts of the Far East.

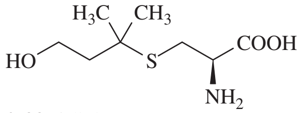
The unusual cysteine derivative L,L-cystathionine (**2-31**) is an intermediate of the biosynthesis of methionine and of other amino acids. The toxic amino acid L,L-djenkolic acid, also known as 3,3′-(methylenedithio)di-L-alanine, consists of two cysteine residues joined by a methylene group between the sulfur atoms (**2-32**). It was first identified in the urine of Indonesians consuming tropical legumes known as jengkol or jering (*Archidendron pauciflorum*, syn. *Pithecellobium lobatum*, Fabaceae). The amino acid L-felinine, 3-hydroxy-1,1-dimethylpropyl-L-cysteine (**2-33**), occurs in the urine of cats and other felines, and is a precursor of the putative cat pheromone 3-mercapto-3-methylbutan-1-ol, which has a practical use in marking territory. Cysteine (or cystine) is also the precursor of dehydroalanine (2-aminoacrylic acid), from which the amino acid lanthionine is formed (see Section 2.5.1.3.4), which is also a component of the microbial peptide nisin (see Sections 2.3 and 11.2.1.2.1). Dehydroalanine is a precursor of other unusual amino acids (such as lysinoalanine). Lysinoalanine and its analogues can be generated as cross-links on heating of proteins and, especially, in proteins after treatment in alkaline solutions (as occurs, for example, in soybean processing). Digestive enzymes do not hydrolyse these cross-links. Other sulfur-containing amino acids include *N*-acetyl-*S*-substituted cysteines (or mercapturates, **2-34**), which form in the body as products of detoxification in reactions of xenobiotics with glutathione and by hydrolysis of the resulting products.



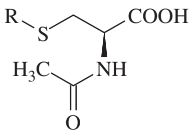
2-31, cystathionine



2-32, djenkolic acid



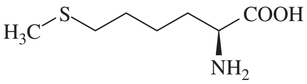
2-33, felinine



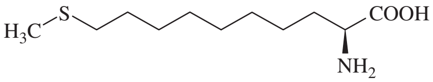
2-34, mercapturic acids

Methionine derivatives

A common amino acid in *Brassica* vegetables, *S*-methyl-L-methionine, was formerly classified as vitamin U (see Section 5.15). Higher homologues of methionine – L-homomethionine, L-dihomomethionine (**2-35**), L-trihomomethionine up to L-hexahomomethionine (**2-36**) – are starting compounds for the biosynthesis of many important glucosinolates (see Section 10.3.2.4.1). For example, homomethionine is the precursor of sinigrin and glucoibervirin, while dihomomethionine is the precursor of progoitrin and gluconapin.



2-35, dihomomethionine



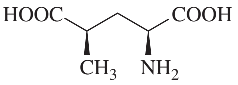
2-36, hexahomomethionine

Selenium amino acids

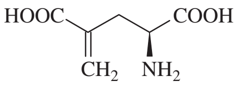
Allium vegetables and various other plants contain small amounts of amino acids derived from cysteine and methionine, in which sulfur is replaced by selenium. These amino acids are the main organic form of selenium and, together with *Se*-containing proteins, represent the main selenium source in foods (see Section 6.2.3.1). Examples of these amino acids are *Se*-alk(en)ylcysteines and their γ-glutamyl derivatives.

2.2.1.2.3 Acidic amino acids and their amides

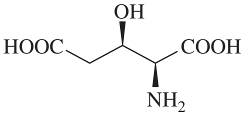
Most non-protein acidic amino acids and their amides are structurally related to L-glutamic acid and L-glutamine. For example, sea pea seeds (*Lathyrus maritimus*, Fabaceae) contain L-4-methylglutamic acid, that is, (2*S*,4*R*)-2-amino-4-methylpentanedioic acid (**2-37**), and the seeds of peanuts (*Arachis hypogaea*, Fabaceae) contain L-4-methyleneglutamic acid (**2-38**) together with L-4-methyleneglutamine. (2*S*,3*R*)-3-Hydroxyglutamic (*threo*-3-hydroxy-L-glutamic) acid (**2-39**) is a precursor of ibotenic acid and other toxic compounds in fly agaric (*Amanita muscaria*) and panther cap (*A. pantherina*). It is also a precursor of the tricholomic acid found in some agarics (*Tricholoma muscarium*) (see Section 10.3.2.9.3). The so-called false rhubarb (*Rheum rhaponticum*), red currant (*Ribes silvestre*, Grossulariaceae) and garden cress (*Lepidium sativum*, Brassicaceae) contain L-3,4-dihydroxyglutamic acid, that is, (2*S*,3*S*,4*R*)-2-amino-3,4-dihydroxypentanedioic acid. Plants also contain other stereoisomers of these amino acids and many other related compounds that exhibit a range of biological effects.



2-37, 4-methylglutamic acid

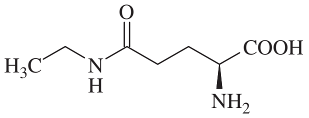


2-38, 4-methyleneglutamic acid



2-39, 3-hydroxyglutamic acid

N-Ethyl-L-glutamine, also known as L-theanine or L-ethanine (**2-40**), is a unique major free amino acid in tea leaves. Depending on the variety of Chinese tea (*Camellia sinensis*, Theaceae), its content in the leaves is normally around 1.3% of dry matter (0.7–2.0%) and is higher in green tea and tea of higher quality (0.8–2.7% in green tea, 0.6–2.1% in black tea, 2.0–9.2% in oolong tea, 0.7–1.8% in decaffeinated black tea). The tea extracts contain about 3% of theanine. The theanine content is used to detect tea extracts in products based on tea (instant and iced tea). Theanine has neuromuscular sedative effects with no side effects and is used in some special food supplements.

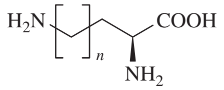


2-40, theanine

The fruiting bodies of common mushrooms *Agaricus bisporus* (also known as button mushrooms, white mushrooms, table mushrooms and champignon mushrooms) contain a mutagenic glutamic acid derived hydrazine β-*N*-(γ-L-glutamyl)-4-(hydroxymethyl)phenylhydrazine known as L-agaritine (10-226) at concentrations of 100–1 700 mg/kg. The metabolic fate of agaritine has been linked with the carcinogenity of this mushroom (see Section 10.3.2.11.4).

2.2.1.2.4 Basic amino acids and related compounds

Plants contain various basic diaminomonocarboxylic acids that are homologues of lysine or derivatives of these homologues. Other arginine derivatives and their homologues are also relatively common. The lowest member of the homologous series of compounds is L-2,3-diaminopropionic acid (**2-41**), occurring in plants of the genus *Mimosa* of the legume family Fabaceae. The toxic N^3-methyl derivative occurs in the cycads (plants of the cycas family Cycadaceae) and the N^2-oxalyl derivative is found in vetchlings (*Lathyrus* spp.) and vetches (*Vicia* spp.) that belong to the legume family Fabaceae. Together with L-2,4-diaminobutyric acid (**2-41**), this compound is the originator of neurodegenerative disease neurolathyrism (see Section 10.3.2.7.1).

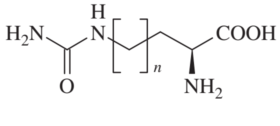


2-41, 2,3-diaminopropionic acid (*n* = 0)
2,4-diaminobutyric acid (*n* = 1)
2,5-diaminovaleric acid (ornithine, *n* = 2)

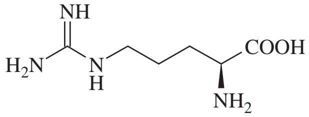
A common basic amino acid is the lower homologue of lysine, L-ornithine (L-2,5-diaminovaleric acid, **2-41**), which is an intermediate in the biosynthesis of arginine and an important amino acid of the ornithine (urea) cycle, which has the function of converting toxic ammonia into less toxic urea in mammals. Ornithine formed in dough through the action of yeast (*Saccharomyces cerevisiae*) is the main precursor of the typical aroma of bread crust, for which 2-acetyl-1-pyrroline together with 6-acetyl-1,2,3,4-tetrahydropyridine and its isomer 6-acetyl-2,3,4,5-tetrahydropyridine are responsible (see Section 8.2.12.4.1).

Reactions of L-lysine (**2-4**) with reducing sugars (known as the Maillard reaction) during the processing and storage of food produce the so-called bound lysine, which is present in the form of unavailable derivatives. Examples of these compounds are the amino acids furosine and pyridosine (see Section 4.7.5.12.3). Plants often contain derivatives of lysine, such as 4-hydroxylysine, which is found in some *Salvia* species of the mint family (Lamiaceae), commonly referred to as sage. N^6-Acetyllysine occurs in beet (*Beta vulgaris* group Altissima, Amaranthaceae, formerly Chenopodiaceae). The metabolic precursor of lysine, L-2-aminoadipic (α-aminoadipic) acid occurs in many legume seeds. For example, the concentration in lentils is 0.17 g/kg and in garden peas 0.18 mg/kg. Aminoadipic acid occurs in lower amounts in commercially available seedlings of leguminous plants sold for human consumption.

A non-protein amino acid related to arginine is the carbamoyl derivative of ornithine, L-citrulline (**2-42**), which is an intermediate in the urea cycle. It was first identified in watermelon (*Citrullus lanatus*, Cucurbitacaeae), where it is present at concentrations of 640–890 mg/kg fresh weight. In plants citrulline forms part of the nitrogen reserves and is a means of transporting nitrogen, as well as numerous amino acids and other nitrogenous compounds. It can also be formed by the decomposition of arginine, for example by yeast *Saccharomyces cerevisiae*. The seeds of some legumes, such as vetchlings (*Lathyrus* spp.) and vetches (*Vicia* spp.), contain its higher homologue, L-homocitrulline (**2-42**), and a number of amino acids containing the guanidino groups. Examples of these amino acids are L-4-hydroxyarginine, L-homoarginine (2-amino-6-guanidinohexanoic acid, **2-43**) and L-4-hydroxyhomoarginine. For example, homoarginine occurs in the seeds of red peas (*Lathyrus cicera*), grass peas (*L. sativus*) and in lentils (*Lens culinaris*).

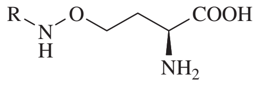


2-42, citrulline (*n* = 2)
homocitrulline (*n* = 3)

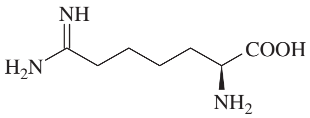


2-43, homoarginine

The subtropical legume jack bean (*Canavalia ensiformis*, Fabaceae), which is grown commercially as a source of the enzyme urease, contains two unusual amino acids derived from homoserine known as L-canaline, or L-2-amino-4-(aminooxy)butanoic acid, and L-canavanine, or L-2-amino-4-(guanidinooxy)butanoic acid (**2-44**). The canavanine concentration in seeds can be as high as 10% of dry matter. Toxic canaline, with a unique aminooxy group, is a structural analogue of ornithine and a lysine antagonist. Canavanine is a structural analogue of arginine and its highly potent antagonist (competitor) that blocks the binding of arginine (agonist) at a receptor molecule. By acting as an antagonist of arginine, canavanine inhibits the growth and development of other organisms and thus has an allelochemical effect. Toxicity is based upon its degradation to canaline (by arginase) and reaction of canaline with aldehydes, for instance with pyridoxal 5′-phosphate in molecules of decarboxylases and aminotransferases yielding stable oximes. Both amino acids show toxic effects to bacteria, insects, fungi, higher plants and predators. Canavanine has also been tested experimentally for cytotoxicity against cancer cells. A specific amino acid L-indospicine (**2-45**) is a hepatotoxin, which is present along with canavanine in seeds of the *Indigofera spicata* tree, which belongs to the same plant family (see Section 10.3.2.7.1). Other species of the genus *Indigofera* have found use as sources of a natural blue dye known as true indigo (*I. tinctoria* and *I. suffruticosa*), many *Indigofera* species have uses in traditional medicine and are also grown as ornamental plants.



2-44, canaline, R = H
canavanine, R = C(=NH)NH_2



2-45, indospicine

The muscle tissues of warm-blooded animals and of fish contain an unusual amino acid, creatine phosphate (or phosphocreatine, **2-46**) in relatively high concentrations (3–6 g/kg). This acts as a phosphate donor (an energy reserve that can be rapidly mobilised) for anaerobic formation of ATP (adenosine triphosphate) from ADP (adenosine diphosphate) in skeletal muscles and the brain following an intense muscular or neuronal effort. It is biosynthesised from glycine and arginine. Natural hydrolysis of phosphocreatine *post mortem* yields creatine (**2-46**), which occurs in raw meat. During thermal processing of meat and meat products, creatine dehydrates spontaneously to form creatinine (see **2-117**), which may become the precursor of toxic imidazopyridines, imidazoquinolines and imidazoquinoxalines in some processed meats and meat products (see Section 12.2.1). Crustaceans employ arginine instead of creatine. Creatine is often used as a food supplement for athletes and bodybuilders. It is claimed that it helps stimulate and maintain instantaneous muscle power.

creatine, R = H

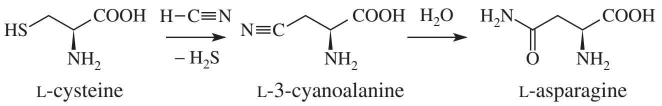

Figure 2.2 Formation of 3-cyanoalanine and asparagine.

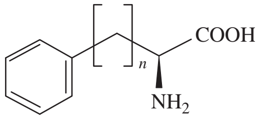
Cyanoamino acids

The production of toxic hydrogen cyanide in plants, called cyanogenesis (see Section 10.3.2.3), requires effective mechanisms, which eliminate this toxic substance. One of these is the biosynthesis of neurotoxic β-substituted alanine derivative β-cyano-L-alanine (L-3-cyanoalanine) from cysteine, which takes place in all vascular plants under the catalysis of β-cyanoalanine synthase (Figure 2.2). β-Cyanoalanine is then converted into asparagine, which is involved in the normal metabolism. This reaction is catalysed by β-cyanoalanine hydratase.[1] Seeds of some vetches (*Vicia* spp.) and vetchlings (*Lathyrus* spp.) of the Fabaceae family contain β-cyanoalanine (together with γ-glutamyl-β-cyanoalanine) at high concentrations. The seeds of common vetch (*Vicia sativa*) contain up to 1.5 g/kg β-cyanoalanine and 0.6 g/kg of the γ-glutamyl derivative. Decarboxylation of β-cyanoalanine and other reactions produce β-aminopropionitrile, which is considered to be a cause of the disease lathyrism (see Section 10.3.2.7.1).

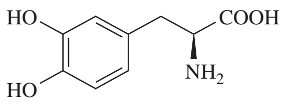
2.2.1.2.5 Aromatic amino acids

Most non-protein aromatic amino acids are derived from L-phenylglycine (**2-47**), L-phenylalanine (**2-4**) or L-tyrosine (**2-4**). For example, various plants contain 3-carboxyphenylalanine, which is accompanied by 3-carboxyphenyltyrosine. Legumes of the genus *Vigna* (Fabaceae) contain 4-aminophenylalanine, the β-phenyl-β-alanine isomer of phenylalanine (**2-47**) occurs in different types of beans (*Phaseolus* spp.).



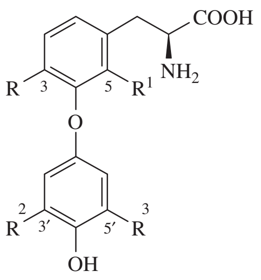
2-47, phenylglycine (*n* = 0)
β-phenyl-β-alanine (*n* = 1)

An important aromatic hydroxyamino acid is L-3,4-dihydroxyphenylalanine, known by the acronym DOPA (from the name **di**hydr**o**xy**p**henyl**a**lanine, **2-48**). It is formed by enzymatic oxidation of tyrosine and becomes the precursor of brown and black pigments (pigments of the eyes, hair, skin or fur of animals) termed melanins (see Section 9.3.1.1). Melanins are formed from DOPA by enzymatic browning reactions that proceed *in vivo*. Clams have this amino acid in special viscous proteins that allow adhesion onto different surfaces.



2-48, 3,4-dihydroxyphenylalanine (DOPA)

Tyrosine is additionally a precursor of the thyroid hormones 3,5,3′,5′-tetraiodothyronine, also known as thyroxine (**2-49**), and 3,5,3′-triiodothyronine, which was previously called iodogorgic acid.



2-49, thyronine, $R = R^1 = R^2 = R^3 = H$
triiodothyronine, $R = R^1 = R^2 = I$, $R^3 = H$
tetraiodothyronine (thyroxine), $R = R^1 = R^2 = R^3 = I$

2.2.1.2.6 Heterocyclic amino acids

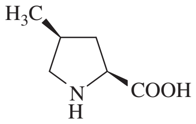
Foods of plant and animal origin often contain amino acids structurally related to proline, the lower and higher homologues and amino acids being derived from histidine and other nitrogen heterocyclic compounds. These amino acids are mainly derivatives of azetidine, pyrazole, pyridine, piperidine, pyrimidine, purine, isoxazole, isoxazoline and other nitrogen heterocycles. Less frequently their ring is derived from oxygen heterocycles (such as pyran-2-ones) or sulfur heterocycles (thiazanes). The side chains are hypothetically derived from glycine, alanine and 2-aminobutyric acid, although the heterocyclic amino acid skeletons are synthesised from other biochemical precursors. Many heterocyclic amino acids have significant biological effects. They often exhibit neurotoxicity, hallucinogenic, insecticidal and other toxic effects.

2.2.1.2.7 Dervivatives of proline, histidine, lysine and cysteine

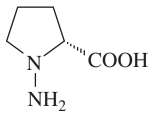
Examples of proline derivatives, which reportedly occur in apples and loquat (Japanese plum; *Eriobotrya japonica*, Rosaceae), are (*S*)-4-methyl-L-proline (**2-50**), (*S*)-4-hydroxymethyl-L-proline and 4-methylene-L-proline. *N*-Amino-D-proline, or linatin (**2-51**), together with the corresponding dipeptide (γ-glutamyl derivative), occurs in linseed (*Linum usitatissimum*, Linaceae). It has antinutritional effects as it acts as an antivitamin B_6. Cucurbitin, (*R*)-3-aminopyrrolidine-3-carboxylic acid (**2-52**), is an unusual compound that is found in the seeds of various squashes. It is responsible for their antihelmintic (vermifugal) effects, which are destructive to parasitic helminth worms. In *Cucurbita pepo*

[1] β-Cyanoalanine can be transformed into γ-glutamyl-β-cyanoalanine by γ-glutamyl transferase. Other enzymes involved in cyanide catabolism are cyanide hydratase and rhodanase. Cyanide hydratase, found in many fungi, catalyses the hydration of cyanide to formamide ($H_2N{-}CH{=}O$). Rhodanase found in bacteria, plants and animals catalyses the conversion of cyanide into thiocyanate ($R{-}S{-}C{\equiv}N$), which is also known as rhodanide.

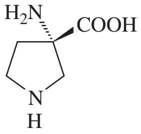
(Cucurbitaceae) squash seeds the concentration ranges from 1.7 to 6.6%, and in *C. maxima* squash seeds it can reach up to 19.4%.



2-50, 4-methylproline

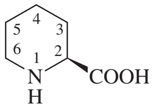


2-51, linatin



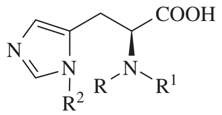
2-52, cucurbitin

The higher homologue of proline, L-pipecolic (L-2-piperidinecarboxylic) acid (**2-53**), is commonly found in many plants. It is a metabolite of L-lysine, which arises from the oxidative deamination of its α-amino group. Pipecolic acid is found at high concentrations in beans (17–44 mg/kg) and cruciferous vegetables (about 12–21 mg/kg). Lower concentrations are found in potatoes (2.5 mg/kg) and fruits (1.3 mg/kg). Some legumes, such as those of the genus *Inga* (originating in tropical America), contain 4-hydroxy-, 5-hydroxy- and 4,5-dihydroxypipecolic acids. Pipecolic acid is also found in animal tissues. In the mammalian brain it acts as a stimulator of γ-aminobutyric acid (**2-11**) receptors. Abnormally high amounts of pipecolic acid in blood plasma (known as hyperpipecolataemia or hyperpipecolic acidaemia) are found in chronic liver diseases and some genetic disorders.

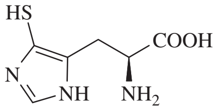


2-53, pipecolic acid

In addition to the previously mentioned 3-methylhistidine derived from 3*H*-imidazole isomer (see Section 2.2.1.1.2), the imidazole skeleton occurs in many other amino acid molecules. The so-called acetylhistidine, diacetylhistidine and triacetylhistidine (**2-54**) are present as free amino acids in spinach (*Spinacia oleracea*, Asteraceae). The free amino acid *N*[1]-methyl-4-mercaptohistidine, known as ovothiol A (**2-55**), can be found in many marine animals. It is one of three mercaptohistidines isolated from the eggs and ovaries of marine invertebrates, where it occurs at high concentrations. Thanks to the imidazole ring, ovothiol A shows a higher reactivity of the thiol group (the active form is thiolate) than glutathione towards free radicals, including reactive oxygen species. In polychaetes (such as *Platynereis dumerilii*) it has the function of a male pheromone. An effective antioxidant is also a 2-thioimidazole betaine known as L-ergothioneine (**2-16**), which is synthesised in Actinomycetales bacteria (such as *Mycobacterium* ssp.) and in various non-yeast-like fungi, including edible genera of the Basidiomycota division, such as *Boletus* ssp. In contrast, no ergothioneine synthesis occurs in higher plants or any animal species. It has been suggested that the incorporation of ergothioneine in plants may result from the absorption of the ergothioneine produced by microorganisms in the soil and in animals through ergothioneine-containing plant and animal foods. Allegedly, King Bolete (*Boletus edulis*) has the highest amount of this amino acid (528 mg/kg fresh weight). Concentrations in other fungi are lower, for instance in oyster mushroom (*Pleurotus ostreatus*, 119 mg/kg), button mushrooms (*Agaricus bisporus*, 0.46 mg/kg), chanterelle (*Cantharellus cibarius*, 0.06 mg/kg fresh weight) and undetectable amounts occur in shiitake (*Lentinula edodes*). Concentrations of ergothioneine in pork liver were 8.71 mg/kg, in pork meat (loin) 1.33 mg/kg, in ham 1.12 mg/kg, in whole grain wheat bread 0.53 mg/kg and in broccoli 0.24 mg/kg.

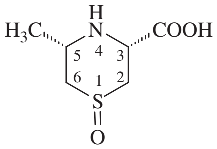


2-54, acetylhistidine, R = $COCH_3$, $R^1 = R^2 = H$
diacetylhistidine, R = $R^1 = COCH_3$, $R^2 = H$
triacetylhistidine, R = $R^1 = R^2 = COCH_3$



2-55, ovothiol A

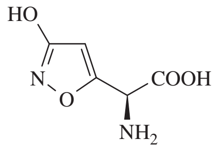
A special sulfur containing heterocyclic amino acid is cycloalliin, (1*S*,3*R*,5*S*)-3-carboxy-5-methyl-1,4-thiazan-*S*-oxide (**2-56**), which is formed in onion and garlic from the amino acid isoalliin (**2-30**). The cycloalliin content in raw onion bulbs and garlic cloves ranges from 0.5 to 1.5 g/kg.



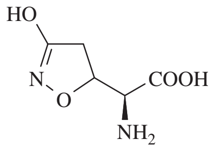
2-56, cycloalliin

2.2.1.2.8 Substituted glycines

Amanitas, such as fly agaric (*Amanita muscaria*), contain a toxic derivative of isoxazole known as ibotenic acid (**2-57**), which is biosynthesised from glutamic acid. Hallucinogenic effects also shows its dihydroderivative tricholomic (dihydroibotenic) acid (**2-58**), which is a component of *Tricholoma muscarium* mushrooms (see Section 10.3.2.9.3).



2-57, ibotenic acid



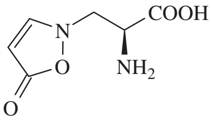
2-58, tricholomic acid

2.2.1.2.9 Substituted alanines

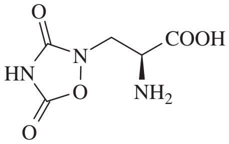
There is a relatively large group of substituted alanines derived from isoxazoline, isoxazolidine and oxazoline. They can be found mainly in germinating seeds and in higher fungi. The donor of the alanyl residue is usually *O*-acetylserine.

An example of these compounds is β-(isoxazolin-5-on-2-yl)-L-alanine also known as 2-(2-amino-2-carboxyethyl)isoxazolin-5-one (**2-59**) which occurs in the seeds and seedlings of many legumes (Fabaceae), vetchlings (*Lathyrus* spp.), vetches (*Vicia* spp.), garden peas (*Pisum* spp.) and lentils (*Lens* spp.). For example, the

amount of β-(isoxazolin-5-on-2-yl)-L-alanine in the seedlings of *L. odoratus* is 0.7–0.8 g/kg fresh weight, in seedlings of lentils 0.17 g/kg and in seedlings of garden peas 1.31 g/kg. Seedlings of lentils also contain a γ-glutamyl derivative of β-(isoxazolin-5-on-2-yl)-L-alanine (0.40 g/kg). β-(Isoxazolin-5-on-2-yl)-L-alanine shows antimycotic effects and, as a structural analogue of glutamic acid (an antagonist), has a neuroexcitatory effect. In vetchlings and vetches, but not in sweet peas, garden peas and lentils, β-(isoxazolin-5-on-2-yl)-L-alanine is a metabolic precursor of 3-aminopropionitrile, L-2,4-diaminobutanoic acid and neurotoxic 3-(*N*-oxalyl)-L-2,3-diaminopropionic acid (β-*N*-oxalyl-L-alanine), which occur in some species of these plants and are responsible for the crippling human disease lathyrism (see Section 10.3.2.7.1). The seeds of the vine *Quisqualis indica* (Combretaceae), known as Rangoon Creeper and native to tropical Asia, contain L-quisqualic acid (**2-60**), which is a stimulant of glutamic acid receptors and has neuroexcitatory activity. Oil extracted from these seeds is used in traditional Chinese medicine as a nematocide and in the treatment of ulcers of the stomach and duodenum. Its leaves, shoots and pods are popular vegetable plants.

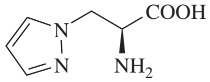


2-59, 2-(2-amino-2-carboxyethyl) isoxazolin-5-one



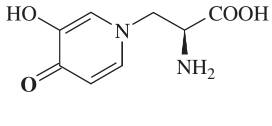
2-60, quisqualic acid

β-Pyrazol-1-yl-L-alanine (**2-61**), derived from pyrazole, occurs in some plants of the *Cucurbitaceae* family. It was first isolated from the seeds of watermelon (*Citrullus lanatus*), where it represents approximately 0.1% of dry matter. It also occurs in the seeds of many other melons, squashes and gourds, together with other heterocyclic amino acids such as 3-aminopyrrolidine-3-carboxylic acid (**2-52**).



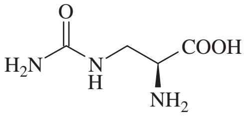
2-61, β-pyrazol-1-ylalanine

The pyridine (dihydropyridine) derived amino acid β-(3-hydroxy-4-pyridon-1-yl)-L-alanine, L-mimosine (**2-62**), is thyreotoxic (causes over-activity of the thyroid gland) to non-ruminant animals. It occurs in the subfamily Mimosoideae of the legume family Fabaceae, in plants of the genera *Mimosa* and *Leucaena*. *Leucaena leucocephala* (syn. *Mimosa glauca*) is native to the tropical and subtropical Americas, known as White Leadtree, and is used as livestock fodder. The mimosine content in seeds can reach up to 5% of dry matter (see Section 10.3.2.7.1). The amino acid pyridosine arising from lysine in the Maillard reaction can also be considered a dihydropyridine derivative (see Section 4.7.5.12.3).



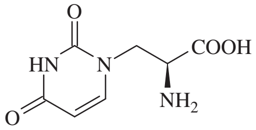
2-62, mimosine

Several other free amino acids derived from purines and pyrimidines have roles as defense agents. Plants of the genus *Mimosa* synthesise 5-aminouracil, which blocks mitotic division and the incorporation of guanosine into nucleic acids. The product of its catabolism is the amino acid L-albizziine (**2-63**), the precursor of L-2,3-diaminopropionic acid (**2-41**) that accumulates in plants.

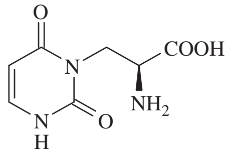


2-63, albizziine

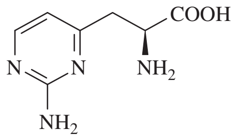
The neuroactive pyrimidine derivative L-willardiine, β-(uracil-1-yl)-L-alanine (**2-64**), occurs in peas (*Pisum sativum*, Fabaceae), the seeds of European beech (*Fagus sylvatica*, Fagaceae) and together with mimosine is present in some acacia (*Acacia* spp., Fabaceae). In subtropical legumes of the genus *Crotalaria* (young pods and leaves of certain species are used as vegetables, others are used as fodder and green manure), it is accompanied by L-isowillardiine, β-(uracil-3-yl)-L-alanine (**2-65**). Amounts of isowillardine in garden pea seedlings, for example, have been reported to be 0.67 g/kg. The amino acid L-lathyrine (**2-66**) occurs in various types of vetchlings (*Lathyrus* spp., Fabaceae). For example, lathyrine makes up 2% of dry matter in seeds of Tangier peas (*Lathyrus tingitanus*). Unlike other *N*-heterocyclic β-substituted alanines, the alanyl residue is derived from L-alanine and not from *O*-acetyl-L-serine.



2-64, willardiine

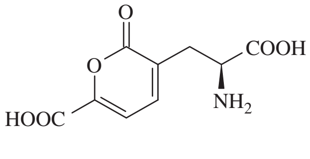


2-65, isowillardiine

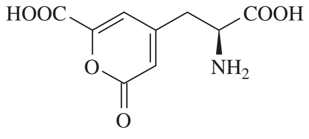


2-66, lathyrine

The fly agaric (*Amanita muscaria*), other Amanitas and some higher plants contain stizolobic acid (L-2-amino-6-carboxy-2-oxo-2*H*-pyrane-4-propionic acid, **2-67**) and stizolobinic acid (L-2-amino-6-carboxy-2-oxo-2*H*-pyrane-3-propionic acid, **2-68**), with DOPA as the precursor. Stizolobic acid is a precursor of the orange betaxanthine muscaaurine II, which is, along with other pigments (see Section 9.3.1.3.1), responsible for the orange–red colour of the hat of this toadstool.



2-67, stizolobic acid

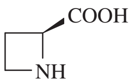


2-68, stizolobinic acid

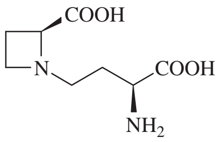
2.2.1.2.10 Substituted aminobutanoic acids

Higher homologues of heterocyclic β-substituted alanines, with another carbon atom in their side chain, can be considered as compounds derived from homoserine or as γ-substituted 2-aminobutanoic acids.

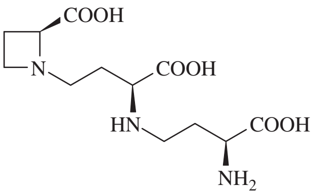
The lower homologue of proline, azetidine-2-carboxylic acid (**2-69**), has antimicrobial effects associated with its incorporation into proteins in place of proline. A small amount of this amino acid is found in some legumes (Fabaceae), plants of the lily family (Lilliaceae), Amaryllidaceae family and red algae (Rhodophycae). Its derivatives with the *N*-alanyl residue, *N*-(3-amino-3-carboxypropyl)azetidine-2-carboxylic acid (**2-70**) and nicotianamine (**2-71**), occur in beechnuts (*Fagus sylvatica*, Fagaceae). Nicotianamine also occurs in Virginia tobacco leaves (*Nicotiana tabacum*, Solanaceae), and the hydroxylated analogue of nicotianamine, mugineic acid (**2-72**), occurs in rice. Tobacco also contains the pyridine derivative L-nicotianine (**2-73**). *N*-(3-Amino-3-carboxypropyl) azetidine-2-carboxylic acid, nicotianamine, mugineic acid and other compounds with similar structures act as phytosiderofores (i.e. they form complexes with iron ions), which allow plants to take in iron from the soil (see Section 6.2.2.1).



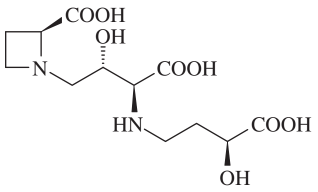
2-69, azetidine-2-carboxylic acid



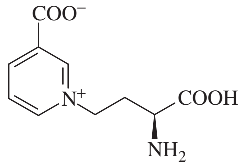
2-70, *N*-(3-amino-3-carboxypropyl)azetidine-2-carboxylic acid



2-71, nicotianamine

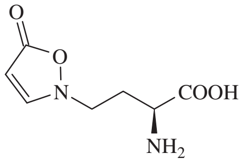


2-72, mugineic acid



2-73, nicotianine

A number of heterocyclic substituted aminobutanoic acids occur in legumes. The sweet pea (*Lathyrus odoratus*) contains 3.5% (dry matter) β-(isoxazolin-5-on-2-yl)alanine, a higher homologue also known as α-amino-γ-(isoxazolin-5-on-1-yl)butanoic acid or 2-(3-amino-3-carboxypropyl)isoxazolin-5-one (**2-74**). This amino acid is neurotoxic. Poisoning shows similar symptoms to poisoning by neurolathyrogenic L-2,4-diaminobutyric acid (see Section 10.3.2.7.1). Other toxic amino acids with a 3-amino-3-carboxypropyl residue are canavanine and canaline (see Section 10.3.2.7.1).



2-74, 2-(3-amino-3-carboxypropyl)isoxazolin-5-one

2.2.2 Physiology and nutrition

All tissues have some capability to biosynthesise the non-essential amino acids, to modify amino acids and to convert non-amino acid carbon skeletons into amino acids. At times of dietary surplus, the potentially toxic nitrogen of amino acids is eliminated via transamination, deamination and urea formation to yield various compounds, which are then used for the biosynthesis of glucose or fatty acids or they may be converted into carbon dioxide and water in the citric acid cycle, which releases energy during times of starvation. Transamination is a process catalysed by amino transferases during which the amino group is transformed into the oxo acid, yielding the oxo acid of the original amino acid and a new amino acid. During oxidative deamination, an amino acid is converted into the corresponding oxo acid by the removal of the amine functional group as ammonia. There are two major pathways for ammonia detoxification by the liver: urea and glutamine synthesis. Approximately 90% of surplus nitrogen in humans enters the urea cycle for irreversible conversion to urea, which is excreted by the kidneys. The major pathway for ammonia fixation in liver is glutamine synthesis. According to the degradation reactions, amino acids are divided into three categories:

- **glucogenic**
- **ketogenic**
- **glucogenic and ketogenic**.

Glucogenic amino acids degrade to pyruvic acid or citric acid cycle intermediates, such as 2-oxoglutaric or oxaloacetic acid, which are precursors of glucose via gluconeogenesis. All amino acids except lysine and leucine are at least partly glucogenic. Lysine and leucine are the only amino acids that are solely ketogenic, giving rise to only acetyl-CoA or acetoacetyl-CoA, which are utilised in the biosynthesis of saturated fatty acids *de novo*. A small group of amino acids, comprising isoleucine, phenylalanine, threonine, tryptophan and tyrosine, give rise to both glucose and fatty acid precursors. Alanine, serine, cysteine and asparagine are converted into oxaloacetic acid. Glutamine, proline, arginine and histidine are converted into 2-oxoglutaric acid via glutamic acid. Succinyl-CoA is a point of entry for non-polar amino acids such as methionine,

valine and isoleucine. Leucine is degraded to acetyl-CoA and acetoacetic acid. Tryptophan, lysine, leucine, phenylalanine, tyrosine and isoleucine donate their carbons to acetyl-CoA.

People with a sufficiently varied and balanced diet (whose energy intake from protein is in the range of 10–15% of their total energy intake and where the ratio of animal and vegetable proteins is in the ratio 1 : 1) usually have a good supply of essential amino acids. Complete proteins contain a balanced set of essential amino acids ideal for humans. Some countries allow enrichment of foods with essential amino acids, especially with limiting amino acids: lysine is usually the limiting amino acid in cereals and **vegetable proteins**; methionine, possibly with cysteine, due to a low content is limiting in beans, meat and dairy proteins; threonine is limiting due to the low content in wheat and rye proteins; and tryptophan, which occurs in low amounts in milk caseins and maize and rice proteins. For example, in Japan and other East Asian countries, lysine and threonine are used to fortify rice; lysine is used for bread fortification and methionine is added to soy products. Problems with the intake of essential amino acids may occur in some unconventional foods, where significant restrictions may lead to a rather monotonous diet. This applies, for example, to vegans and those on macrobiotic diets. These types of diet are inappropriate for children, because the lack of some essential amino acids can lead to serious developmental defects.

The essential amino acids content of livestock feed should be monitored, as the lack of limiting amino acids can significantly decrease the feed consumption and cause weight loss. Essential amino acids are commonly used as feed additives at levels of 0.05–0.2%. Such enhancements are required if plant proteins are to maintain their usage level in animal feeding applications.

Certain risks to human nutrition, and especially to livestock nutrition, may be posed by some toxic amino acids (see Section 10.3.2.7 and Section 10.3.2.9.3).

2.2.3 Properties

2.2.3.1 Acid-base properties

The common amino acids are weak polyprotic acids. The ionisable groups do not show a strong tendency to dissociate, and the degree of dissociation thus depends on the pH of the medium. In the physiological range of pH values, the α-carboxyl groups of amino acids are usually fully dissociated, and the α-amino groups are protonated. Compounds with these properties are called **amphoteric** or **ampholytes** (amphoteric electrolytes). Ampholytes form inner salts, that is dipolar, ambiguous or amphoteric ions called amphions (the German equivalent is zwitterion). An amphion carries a positive or a negative electrical charge (**2-2** and **2-3**), so the resulting electrical charge of the molecule is zero. The predominant forms of almost all amino acids in the physiological environment of animal and plant tissues are amphions. In addition to amphions, in aqueous solutions amino acids may also form (depending on pH) cations (as they react with acids and behave as bases) or anions (when they act as acids, Figure 2.3). Therefore, amino acids are very polar compounds, being fairly soluble in water and in polar solvents; they have high dipole moment values. Also, the melting points (they often melt during decomposition) are high (around 200 °C or higher), therefore they are relatively stable at elevated temperatures.

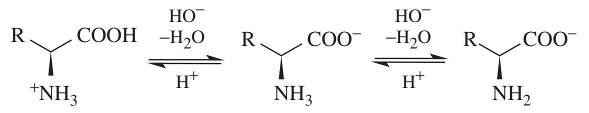


Figure 2.3 Influence of pH on the dissociation of L-amino acids.

2.2.3.1.1 Glycine

The dissociation of the simplest monoaminomonocarboxylic acid glycine as a dependence on the pH is shown schematically in Figure 2.4. In an acidic solution (pH about 2 and below), the predominant form is the ion I_1 (cation) and the net amino acid charge is +1. In a neutral solution (pH value around 6), the ion I_2 (amphion) dominates and the net charge is zero. In alkaline medium (pH approximately 10 and higher), glycine is predominantly present as an I_3 ion (anion) and the net charge of the molecule is −1.

The measure of acidity and basicity of functional groups of amino acids are the **dissociation constants**. The dissociation constant K_1 describes the acidity of the α-carboxyl group of glycine, as shown by the following reaction:

$$^{+}NH_3CH_2COOH + H_2O = {}^{+}NH_3CH_2COO^- + H_3O^+$$

It is therefore defined by the equation (the activities, concentrations of ions and neutral molecules, respectively, are given in parentheses):

$$K_1 = \frac{[^{+}NH_3CH_2COO^-][H_3O^+]}{[^{+}NH_3CH_2COOH][H_2O]}$$

The dissociation constant K_2 describes the basicity of the α-amino group, that is:

$$^{+}NH_3CH_2COO^- + H_2O = NH_2CH_2COO^- + H_3O^+$$

and is defined by the equation:

$$K_2 = \frac{[NH_2CH_2COO^-][H_3O^+]}{[^{+}NH_3CH_2COO^-][H_2O]}$$

The values of the dissociation constants of glycine at 25 °C are: $K_1 = 4.47 \times 10^{-3}$, $K_2 = 1.67 \times 10^{-10}$. Most often these values are shown as negative logarithms, that is as pK_i (−log K_i) values. Then pK_1 = 2.35 and pK_2 = 9.78.

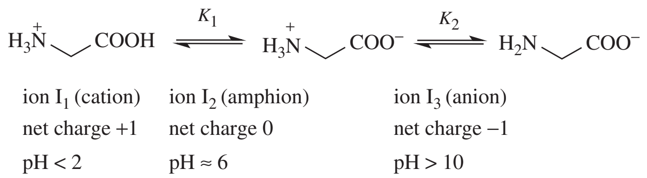

Figure 2.4 Influence of pH on the dissociation of glycine.

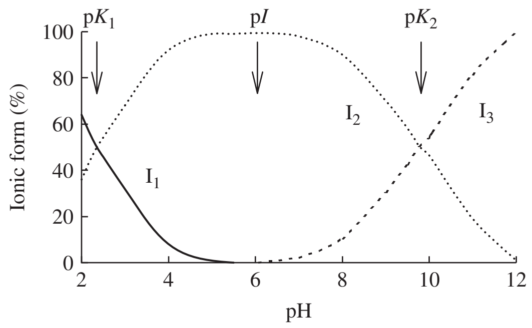

Figure 2.5 Dependence of ionic forms of glycine on pH (see Figure 2.4): — = cation (I_1), - - - - - = amphion (I_2), ········· = anion (I_3).

The pH of the solution at which the maximum concentration of amphions is reached is called the isoelectric point (denoted pI). The value of pI may be calculated as the arithmetic mean of the pK_1 and pK_2 values. The pI value for glycine is:

$$pI = \frac{pK_1 + pK_2}{2} = 6.1$$

At pH = pK_1 the concentrations of the cation and the amphion are equal, and so each of these two forms amounts to 50% of the total amino acid. At pH = pK_2 the concentrations of the amphion and the anion are equal. The dependence of ionic forms of glycine on pH is shown in Figure 2.5.

2.2.3.1.2 Acidic amino acids

A somewhat different situation to that of glycine is found with aspartic and glutamic acids. Owing to the presence of two carboxyl groups in the molecule, these amino acids form four types of ions: cations, amphions and two types of anions. Dissociation of glutamic acid, depending on the pH value of the solution, is given as an example in Figure 2.6. The dependence of the ionic forms of glutamic acid on pH is shown in Figure 2.7.

The amphion again has charge on the α-amino group and on the α-carboxyl, which is more acidic than the distal carboxyl. The value pI (the mean of the pK_1 and pK_3 values) is 3.1. At pH = pI, unlike glycine, the amphion I_2 is not the only ion in solution. It is about 80% of the total amount of glutamic acid present. Cation I_1 is also present at a level of about 10% (this is the main ion in an acidic medium at pH < pK_1), and anion I_3 occurs in the same level. In a neutral solution at pH 7, virtually the only ion present is anion I_3. This ion is a sensory active form of glutamic acid, and is responsible for its unique organoleptic properties. The anion I_3 is the dominant form of glutamic acid in solutions at pH values ranging from pK_2 to pK_3 (pH 4.3–9.5), which in foods is a pH range to which sodium hydrogenglutamate is added as a flavour enhancer (see Section 11.3.5). At pH values around 10 and above, the predominant form of glutamic acid is the anion I_4, which has a net charge of −2. Both carboxyl groups are then dissociated, but dissociation of the amino groups does not normally occur. The other three theoretically possible ionic forms do not actually contribute to the ionic equilibrium. Under suitable conditions (pH and temperature), there is equilibrium between glutamic acid and its lactam L-5-oxopyrrolidine-2-carboxylic acid (see **2-116**). This lactam is in equilibrium with its anion.

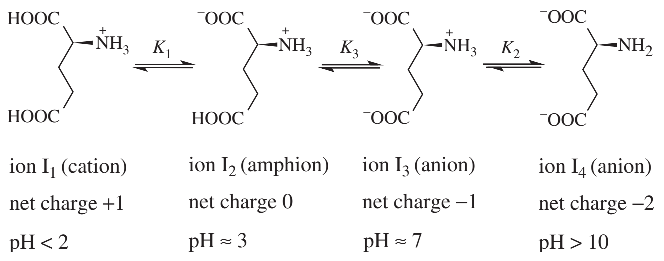

Figure 2.6 Dissociation of glutamic acid as influenced by pH.

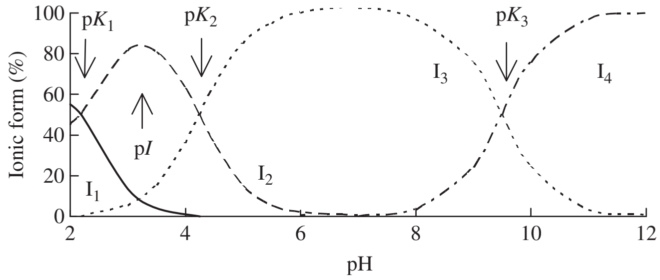

Figure 2.7 Dependence of ionic forms of glutamic acid on pH (see Figure 2.6): — = cation (I_1), - - - - - = amphion (I_2), ········· = anion (I_3), — · — · = anion (I_4).

2.2.3.1.3 Basic amino acids

Just as with glutamic and aspartic acids, lysine also has four types of ions (Figure 2.8). In an acidic solution, two types of cations may occur. At pH < pK_1 (a pH lower than 2), the predominant form is a cation with a net charge of +2, while in the solution around pH 7 the monocation predominates. Its maximum concentration is in solutions of pH equal to the average values of pK_1 and pK_2. The maximum concentration of the amphion is found in solutions of pH around 10, where the pI value is equal to the average values of pK_2 and pK_3. In solutions of pH > pK_3 (pH about 11 and higher), lysine anion predominates (Figure 2.9).

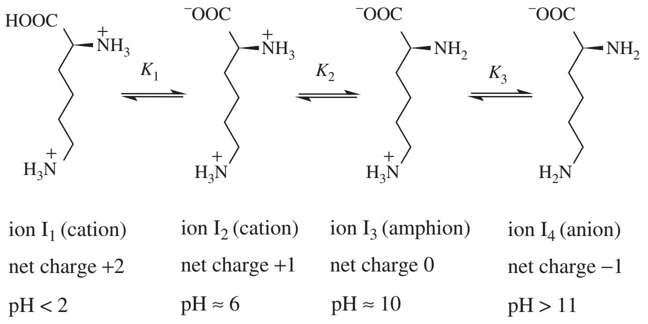

Figure 2.8 Dissociation of lysine as influenced by pH.

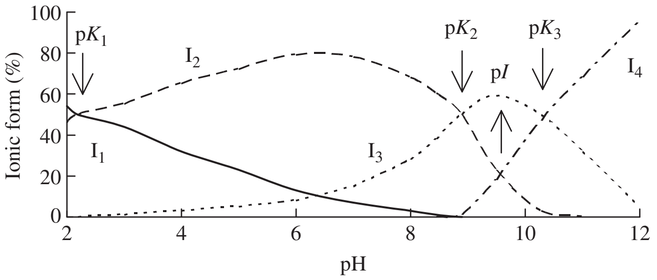

Figure 2.9 Dependence of ionic forms of lysine on pH (see Figure 2.8): — = cation (I_1), - - - - - = cation (I_2), ········· = amphion (I_3), — · — · = anion (I_4).

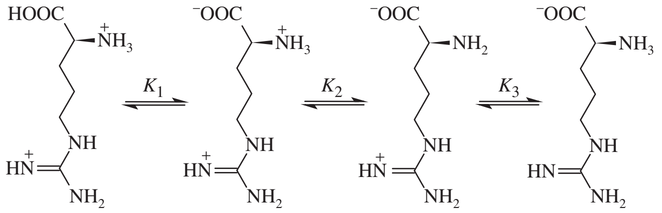

Figure 2.10 Dissociation of arginine as influenced by pH.

As with lysine, four ionic forms can also exist with arginine (Figure 2.10) and histidine (Figure 2.11) depending on the pH. The predominant forms of both amino acids at pH 7 are monocations.

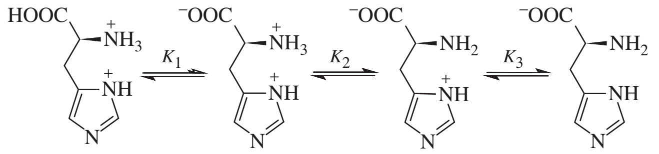

Figure 2.11 Dissociation of histidine as influenced by pH.

2.2.3.1.4 Other amino acids

Other monoaminomonocarboxylic acids behave in an analogous way to glycine. These include alanine, valine, leucine and isoleucine, and include amino acids substituted in the side chain (serine, threonine, methionine, phenylalanine and proline). The cysteine SH-group can also be dissociated at higher pH; therefore, there are four ionic forms. In solutions of pH 7, the main form is the amphion (Figure 2.12), which prevails in tyrosine solutions at pH 7 (analogous to phenylalanine). In an alkaline solution, the hydroxyl group of tyrosine can be deprotonated, forming a phenoxide anion (Figure 2.13). An overview of the pK_i and pI values of proteinogenic and some other common amino acids is given in Table 2.4.

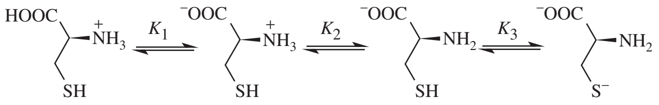

Figure 2.12 Dissociation of cysteine as influenced by pH.

Table 2.4 p*K* and p*I* values of amino acids.

Amino acid	pK_1	pK_2	pK_3[a]	pI	Amino acid	pK_1	pK_2	pK_3[a]	pI
Proteinogenic					Asparagine	2.10	8.84	-	5.5
Glycine	2.34	9.78	-	6.1	Glutamine	2.17	9.13	-	5.7
Alanine	2.35	9.87	-	6.0	Lysine	2.16	9.18	10.79	10.0
Valine	2.29	9.74	-	6.0	Arginine	1.82	8.99	12.48	10.9
Leucine	2.33	9.74	-	6.0	Histidine	1.80	9.33	6.04	7.7
Isoleucine	2.32	9.76	-	6.0	Phenylalanine	2.16	9.18	-	5.7
Serine	2.19	9.21	-	5.7	Tyrosine	2.20	9.11	10.13	5.7
Threonine	2.09	9.10	-	5.6	Tryptofan	2.43	9.44	-	5.9
Cysteine	1.92	10.78	8.33	5.1	Proline	1.99	10.60	-	6.3
Selenocysteine	1.27	8.42	5.24		***Other***				
Methionine	2.28	9.21	-	5.7	4-Hydroxyproline	1.82	9.65	-	5.7
Aspartic acid	1.99	9.90	3.90	3.0	β-Alanine	3.55	10.24	-	6.9
Glutamic acid	2.10	9.47	4.07	3.1	γ-Aminobutyric acid	4.03	10.56	-	7.3

[a] The dissociation constant pK_3 of cysteine (selenocysteine) is the dissociation constant of the –SH (–SeH) group. The dissociation constants of both carboxyl and amino groups of cysteine have values 1.04 and 2.10 and 8.02 and 8.71, respectively. The isoelectric point value is 6.1. The dissociation constant pK_3 of aspartic acid and glutamic acid is the dissociation constant of the distal carboxyl group. The dissociation constant pK_3 of lysine, arginine, histidine and tyrosine is the dissociation constant of the distal amino group (ε-amino group), of the guanidino group, the imino group of imidazole ring and the hydroxyl group, respectively.

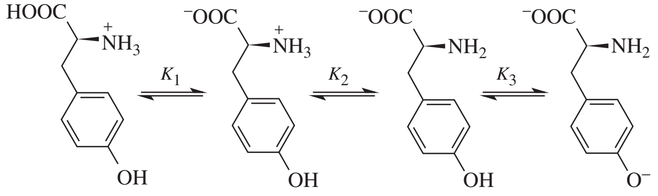

Figure 2.13 Dissociation of tyrosine influenced by pH.

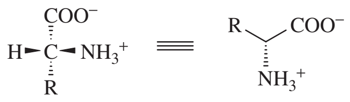
2.2.3.2 Optical activity

With the exception of glycine, all other amino acids contain a chiral carbon atom in the position α to the carboxylic group (**2-2** and **2-3**), which is called a C_α carbon. Therefore each of them exists in two optical isomers (enantiomers). The proteins contain almost exclusively the amino acids of the L-configuration (**2-75**); these amino acids are (*S*)-stereoisomers. The spatial arrangement of substituents around the asymmetric carbon in L-amino acids is the same as in L-glyceraldehyde (see Section 4.2.1.1). The exceptions are L-cysteine and L-selenocysteine that are (*R*)-stereoisomers (the priority of residues $R = CH_2SH$ and $R = CH_2SeH$ is higher than the priority of a carboxyl group COOH). *S*-Substituted cysteine sulfoxides have two chiral centres, at the C_α carbon and the sulfur atom (**2-30**).

2-75, L-amino acid (*S*)-amino acid

Amino acids of the D-series are derived from D-glyceraldehyde and are (*R*)-stereoisomers of amino acids (**2-76**). They are a mirror image of the L-series of amino acids. Compared with L-amino acids, D-amino acids occur relatively rarely in nature. They are mainly bound in a variety of biologically active peptides of plants and animals, occuring in peptidoglycans of microbial cell walls, or as free compounds (such as linatine, **2-51**, in flax seeds). For a long time it was believed that proteins of all living organisms contained only L-amino acids and that D-amino acids were not present in mammals. Recently, D-aspartic acid (synthesised by aspartate racemase) and D-serine (synthesised by serine racemase) were found in proteins of various tissues[2] where they play important roles in living organisms.

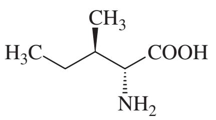
[2] D-Aspartic acid occurs in aorta and lung protein elastin of people with arteriosclerosis, in the protein myelin and peptide β-amyloid of the brains of people with Alzheimer's disease, in the α-crystalline protein in lenses of people with cataracts, in the osteocaleine protein of bones and in the phosphoryne protein of teeth, and D-serine was identified in the β-amyloid of brain of older people as a consequence of aging. D-Aspartic acid and D-serine have important biological functions in brain proteins of living organisms. D-serine functions as a neurotransmitter and modulator, D-aspartic acid plays an important role in the central nervous system and in the regulation of production of hormones in the endocrine glands.



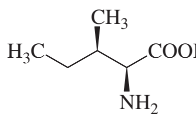
2-76, D-amino acid (*R*)-amino acid

Free D-amino acids found in fresh or heat-processed foods are mostly of microbial origin. They are formed by hydrolysis of peptidoglycans in the cell walls of microorganisms, or by the action of microbial racemases on L-amino acids. Therefore they mainly occur in foods produced by lactic acid fermentation, such as yoghurt and are termed **biogenic** D-amino acids. D-Amino acids may also form through non-enzymatic isomerisation of L-amino acids in foods processed at high temperatures, and especially in foods treated with alkaline reagents. These amino acids are bound in proteins from which they are released by hydrolysis. They are called **abiogenic** D-amino acids.

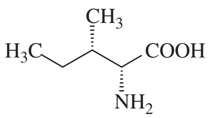
Isoleucine, threonine, 4-hydroxyproline and 3-hydroxyproline also have an asymmetric carbon atom in the side chain (two chiral centres in total). They can therefore occur in four stereoisomeric forms (this number is equal to $2^n = 2^2 = 4$, where $n =$ number of asymmetric carbon atoms) known as L-, D-, L-*allo*- and D-*allo*- according to the configuration of the carbon carrying the amino group. The unique *R*/*S* system is not widely used in biochemistry. The stereoisomers of isoleucine are thus called L-isoleucine or (2*S*,3*S*)-isoleucine (**2-4**), D-isoleucine or (2*R*,3*R*)-isoleucine (**2-77**), L-*allo*-isoleucine or (2*S*,3*R*)-isoleucine (**2-78**) and D-*allo*-isoleucine or (2*R*,3*S*)-isoleucine (**2-79**). Proteins contain only L-isoleucine. The product of enzymatic or thermal isomerisation of L-isoleucine is D-*allo*-isoleucine. Likewise, proteins contain L-threonine or (2*S*,3*R*)-threonine (**2-4**) and L-4-hydroxyproline or (2*S*,4*S*)-4-hydroxyproline (**2-6**). Cystine (as well as lanthionine, see Section 2.5.1.3.4) contains two identical asymmetric carbons in the molecule and, therefore, only exists in three different isomers. Proteins contain just L-cystine (**2-4**), its isomer is D-cystine (**2-80**) and the mesoform *meso*-cystine (**2-81**) is a symmetrical molecule.



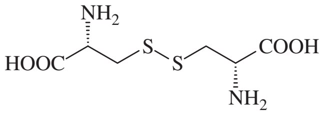
2-77, D-isoleucine



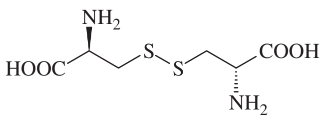
2-78, L-*allo*-isoleucine



2-79, D-*allo*-isoleucine



2-80, D-cystine



2-81, *meso*-cystine

The sorting of amino acids into L- or D- series is not linked to their optical rotation. For example, an aqueous solution of natural alanine or glutamic acid is dextrorotatory, denoted (+)-L-Ala and (+)-L-Glu, respectively. Dextrorotation (turning of polarised light by solutions of certain optically active substances to the right, i.e. clockwise) shows a total of 12 proteinogenic amino acids, while the remaining amino acid shows laevorotation. For example, aqueous solutions of leucine and histidine are laevorotatory, and are denoted (−)-L-Leu and (−)-L-His, respectively. Optical rotation depends greatly on pH. For example, leucine in acidic and alkaline solutions is dextrorotatory; histidine is dextrorotatory in acidic and laevorotatory in neutral and alkaline solutions.

2.2.3.3 Organoleptic properties

Some amino acids are sensorially active substances, which can therefore influence the organoleptic properties of food. For example, glycine has a sweet taste (70% of the sweetness of sucrose) and is sometimes mixed with saccharin as a sweetening agent. According to their organoleptic properties, the proteinogenic amino acids can be classified as:

- **sweet** (glycine, alanine, threonine, proline and hydroxyproline)
- **acidic** (aspartic and glutamic acids)
- **bitter** (amino acids with hydrophobic side chains, i.e. valine, leucine, isoleucine, phenylalanine, tyrosine and tryptophan)
- **indifferent** (other amino acids).

Free amino acids are only found in small amounts in most foods. Therefore, they only influence the flavour of foods when production is based on proteolysis (some cheeses, but also meat and fish). Enzymatic hydrolysates of proteins (such as soy sauces) or hydrolysed vegetable proteins (acid hydrolysates), which contain only amino acids, are used extensively as seasonings.

Glutamic acid and its monosodium salt, sodium hydrogen L-glutamate (**2-82**), have unique organoleptic properties. It is salty, but also has the taste known as **umami** (see Section 8.3.3.1), therefore it is used as a food additive (to intensify the flavour of meat and vegetable dishes) for the production of various spice products. The salts of some other amino acids have more or less comparable taste, for example salts of L-ibotenic acid (**2-57**), L-tricholomic acid (**2-58**), (*S*)-2-amino-4-sulfobutanoic acid known as L-homocysteic acid (**2-83**), L-theanine (**2-40**), 2-methyl-L-glutamic acid, L-5-oxopyrrolidine-2-carboxylic acid (also known as pyroglutamic acid or glutiminic acid or 5-oxoproline; see **2-116**) and some other compounds.

2-83, homocysteic acid sodium salt

2.3 Peptides

Peptides have a number of different functions in organisms and often exhibit significant biological effects. Some are widely distributed in nature and are found in many diverse organisms, whereas others have a restricted occurrence. Many oligopeptides and polypeptides show physiological effects, as they act like hormones (for example, the linear peptides secretin, insulin and thyroliberin and the cyclic peptides oxytocin or vasopressin) and antibiotics (gramicidine, polymyxin, bacitracin and other peptide antibiotics).

Many microbial peptides, collectively known as **bacteriocins**, have antibacterial properties. In practice, one of these peptides, the polycyclic peptide nisin, is used as a food preservative (see Section 11.2.1.2.1). It is produced by the metabolic activity of the bacterium *Lactococcus lactis* and used in dairy technology to stabilise fermented products. Nisin contains five sulfide bridges and 34 amino acid units, including the uncommon amino acids D-alanine, D-2-aminobutyric acid, 2-aminoacrylic acid, known as dehydroalanine (Dha), 2-aminocrotonic acid, or dehydrobutryine (Dhb), 3-methyllanthionine (β-methyllanthionine, MeLan) and *meso*-lanthionine (Lan) cross-links (see Section 2.2.1.2.2). Nisin acts against gram-positive organisms (*Streptococcus* spp. and *Clostridium* spp.) and against the vegetative forms and spores.

Furthermore, peptides include a number of toxins that are highly effective towards microorganisms, such as botulinum toxin produced by the bacteria *Clostridium botulinum* (see Section 12.3.2.1), cyclic toxins of higher fungi, such as fallotoxins and amatoxins of toxic agarics of the genus *Amanita* (see Section 10.3.2.9.2), insect toxins such as apamine and mellitine in bee venom, and toxins of many other insect species (spiders, scorpions, reptiles and amphibians).

Some peptides that are present in foods significantly influence their organoleptic properties, especially the taste.

2.3.1 Structure, nomenclature and classification

Peptides are amino acid polymers in which the carboxyl group of one amino acid bonds to the amino group of the second amino acid via an **amide bond**. The amide bond thus created is called a **peptide bond** because of its specific nature.[3] The combination (condensation) of two α-amino acids yields a dipeptide, three molecules of amino acids produce a tripeptide and so on. The formation of a dipeptide from two amino acids is accompanied by the loss of a water molecule. Each linear peptide contains one amino acid with a free carboxyl group, which is a ***C*-terminal amino acid**, and one amino acid with a free amino group, an ***N*-terminal**

[3]Amide bonds resulting from the condensation of amino groups of α-amino acids with carboxylic groups of organic acids are found in many other compounds but these are not classified as peptides. Examples are some vitamins such as pantothenic acid, tetrahydrofolic acid (folic acid with two or more molecules of glutamic acid are already peptides) and the active form of biotin (biocytin).

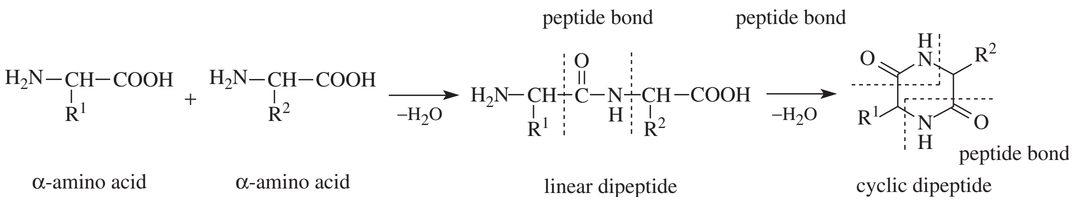

Figure 2.14 Formation of linear and cyclic dipeptides.

amino acid. In addition to linear peptides, the condensation of amino acids also leads to cyclic structures, which have no free carboxyl group and no free amino group. Such compounds are called cyclic peptides. Examples of simple cyclic dipeptides are 3,6-disubstituted 2,5-dioxopiperazines (Figure 2.14).

The peptide bond is essentially a rigid planar structure. In dipeptides, six atoms lie in the same plane: the α-carbon atom and CO group from the first amino acid and the NH group and α-carbon atom from the second amino acid. The peptide bond shows substantial double-bond characteristics, which prevents rotation about this bond (Figure 2.15). Thanks to the rigidity of the bond, peptide groups may be present in *cis* or *trans* conformations (Figure 2.16). The *trans* form is strongly favoured; therefore natural peptides and proteins contain almost exclusively the energetically preferable *trans* conformers, where the neighbouring C_α atoms are situated on opposite sides of the peptide bond. The bond distances between the atoms of the peptide groups of *trans* and *cis* conformers are (in nm): C–N = 0.133 (0.132), C(=O) = 0.124 (0.124), N–H = 0.100 (0.100), NC_α = 0.146 (0.147) and C–C_α = 0.151 (0.153). Typically the *cis* conformation only occurs when the nitrogen atom in the peptide bond is from proline. In the peptide bond region, only substituents on C_α carbons can freely rotate, and thus they determine the conformational structure of the peptide chain. The C_α carbon attachment into the peptide chain involves two single bonds, a C_α–N bond and a C_α–C bond. Other groups of the peptide chain can freely rotate around these bonds. The degree of rotation can

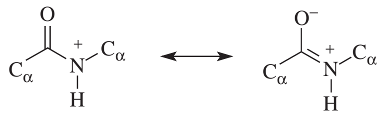

Figure 2.15 Peptide bond (substituents at the C_α are not marked).

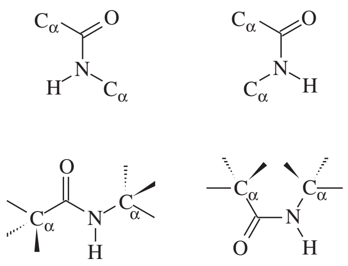

Figure 2.16 Peptide bond *trans* and *cis* conformations.

be specified by dihedral angles of rotation around the bond C_α–N (angle φ; phi) and bond C_α–C (angle ψ; psi), which are sometimes called torsion angles. The different values of these angles give rise to a large number of conformations of peptides and proteins.

Peptides are usually classified according to the molecule size (number of bound amino acids), the shape of the chain and the type of links in the chain, among other things. According to the number of bound amino acids (monomers), peptides are divided into:

- **oligopeptides** (containing typically 2–10 amino acid molecules in the chain)
- **polypeptides** (containing typically 11–100 amino acid molecules or compounds with relative molecular weights of about 10 kDa; polypeptides, formerly known as **macropeptides**, actually produce the proteins).

According to the chain type, peptides are divided into:

- **linear peptides** (which represent the clear majority)
- **cyclic peptides**.

Peptides containing just amino acids (often the less common amino acids) are called **homeomeric peptides**, and peptides containing other compounds are **heteromeric peptides** or **peptoids**. This group includes:

- **nucleopeptides**
- **lipopeptides**
- **glycopeptides**
- **phosphopeptides**
- **chromopeptides**
- **metalopeptides**.

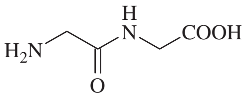
Peptides in which all of the covalent linkages between the constituent amino acids are peptide bonds are termed **homodetic peptides**, whereas those that contain peptide bonds together with other covalent linkages between certain amino acid residues are called **heterodetic peptides**. Examples of these covalent linkages

are disulfide bonds (R–S–S–R′), thioester bonds (R–CO–S–R′) or ester bonds (R–CO–O–R′). The relevant peptides (with one or more ester bonds) are **depsipeptides**. The peptide bonds usually contain bound α-amino groups and α-carboxyl groups. Unlike in proteins, the peptide bonds in peptides sometimes contain the distal functional groups, such as the γ-carboxyl group of glutamic acid in the so-called γ-peptide bond. Unlike proteins, peptides frequently contain D-amino acids and unusual amino acids, for example β-alanine (**2-10**), taurine (see Section 5.15), γ-aminobutyric acid (**2-11**), pyroglutamic acid (see **2-111**) and others.

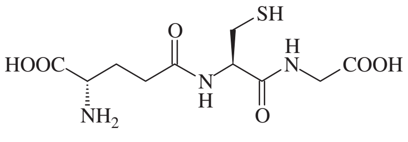
The terminology considers linear peptides as acylated amino acids. Therefore, the amino acid at the carboxyl terminus of the chain is what gives it its name; for the other amino acids, the ending -ine is replaced by the suffix -yl. The practice uses three letters for labelling peptide chains or one letter for symbols for amino acid. The simplest dipeptide composed of two molecules of glycine is called glycylglycine (**2-84**), or for short Gly-Gly or G-G. The important tripeptide with the trivial name of glutathione (**2-85**) is γ-L-glutamyl-L-cysteinylglycine. Using the three letter symbols, glutathione is:

Glu⌊ Cys-Gly or γ Glu⌊ Cys-Gly

using one letter amino acid symbols, glutathione is ECG. The symbol ⌊ indicates the distal carboxyl group linkage. Nomenclature of cyclic peptides is based on either the peptide or the heterocycle. For example, the cyclic dipeptide derived from glycine is cyclo(Gly-Gly) or 2,5-dioxopiperazine (Figure 2.14, R = H). Most naturally occurring cyclic peptides contain a higher number of amino acids.



2-84, glycylglycine



2-85, glutathione

2.3.2 Biochemistry

Peptides are biosynthesised by both ribosomal and non-ribosomal processes from a wide range of amino acids. Ribosomal peptide biosynthesis leads to peptide enzymes, hormones and many other physiologically active substances. Many structures biosynthesised by ribosomal processes are post-translationally modified. Glycopeptides are produced by adding sugar residues via *O*-glycoside linkages to the hydroxyls of serine and threonine residues or via *N*-glycoside linkages to the amino group of asparagine. With phosphopeptides, the hydroxyl groups of serine or threonine are esterified with phosphoric acid. Many peptides contain a pyroglutamic acid residue at the *N*-terminus, which is a consequence of glutamine intramolecular cyclisation between the γ-carboxyl and the α-amino group. The *C*-terminal carboxylic acids may also frequently be converted into an amide. Non-ribosomal processes synthesise many natural peptides that occur in foods. They are responsible for the formation of glutathione, histidine-containing dipeptides of skeletal muscles, peptide toxins and peptide antibiotics. These peptides are formed via a sequence of enzyme-controlled reactions.

2.3.3 Occurrence

Peptides are found in foods as products of metabolism as a result of the genetic dispositions of the animal or plant organisms. In living organisms, peptides arise either from amino acids by simple biosynthesis (in contrast to proteins this is without the use of the proteosynthetic apparatus), or by hydrolysis of precursors produced in protein synthesis (with possible chemical modification). During processing and storage of foods, peptides also form as secondary products through enzymatic and non-enzymatic hydrolysis of proteins. The process is known as **proteolysis**. Peptides can also arise when amino acids are heated to higher temperatures, but this reaction has no significance in practice.

2.3.3.1 Important peptides

2.3.3.1.1 Glutathione

Tripeptide glutathione, γ-L-glutamyl-L-cysteinylglycine (**2-85**), is a common peptide, which is found in animal and plant tissues and microorganisms. It occurs in two forms, a reduced form (denoted G-SH) and an oxidised form (G-S-S-G), which are part of an important redox system, similar to cysteine and cystine:

$$2\text{G-SH} \rightarrow \text{G-S-S-G} + 2\text{H}$$

$$\text{G-S-S-G} \rightarrow 2\text{H} + 2\text{G-SH}$$

Glutathione is the most abundant non-protein thiol in cells and is also a cofactor of some enzymes, such as glyoxylase. In animal cells, glutathione is present in high levels of 300–1500 mg/kg, higher plants contain lower amounts of glutathione (wheat flour 10–15 mg/kg) and microorganisms, such as yeast *Saccharomyces cerevisiae*, about 5 000 mg/kg dry cell weight.

The reactivity of the thiol group makes glutathione particularly suitable for a broad range of biochemical functions in all organisms. The glutathione redox system of reduced and oxidised glutathione has an oxidation reduction potential of –0.23 V, which allows it to act as an effective electron acceptor and donor for numerous chemical and biochemical reactions. Glutathione also modifies protein sulfhydryl groups via a number of reactions: reduction of protein sulfenic acids, formation of protein mixed disulfides and their subsequent reduction. For example, glutathione in flour affects the rheological properties of dough (see Section 5.14.6.1.6). The nucleophilic thiol group of glutathione allows reactions with reactive oxygen and reactive nitrogen radicals, hydrogen peroxide and hydroperoxides of fatty acids, formation of mercaptides with metals and reactions with various electrophiles. Thus glutathione is an ideal substance to protect organisms against oxidative stress, poisoning by metal ions and poisoning by a number of exogenous and endogenous toxic organic substances, including carcinogens.

Oxygen and nitrogen radical species are removed from organisms via non-enzymatic reduction with G-SH, whereas the removal of

hydrogen peroxide and hydroperoxides requires enzymatic catalysis by glutathione peroxidases. Glutathione peroxidases (GPx) are antioxidant selenoenzymes, which protect various organisms from oxidative stresses by catalysing the reduction of hydrogen peroxide and fatty acid hydroperoxides at the expense of G-SH (see Section 6.3.15.1.2). Both reactions ensure removal of lipid hydroperoxides from damaged biological membranes (lipoproteins) and lead to the generation of glutathione disulfide (G-S-S-G), which is reduced back to G-SH through the ascorbate/G-SH cycle in the plastids of plants and in erythrocytes of animals by glutathione reductase that uses NADPH from the pentose phosphate shunt. In plants, glutathione is also essential for the protection of membranes by maintaining α tocopherol and zeaxanthin in the reduced state through reaction with ascorbic acid.

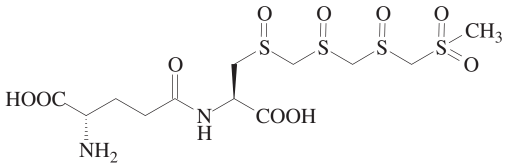
Class III metallothioneins (see Section 6.2.2.2) are metal-binding plant and microbial peptides termed phytochelatins. Phytochelatins are oligomers of glutathione, $(\gamma\text{Glu-Cys})_n$-Gly, which are synthesised by phytochelatin synthase. Phytochelatins are made in the cytosol where they have a high affinity to bind with some metals (e.g. copper and cadmium). These metal–phytochelatin complexes are then transported into vacuoles and the metals are thus sequestered away from sensitive enzymes. In animals, glutathione, either independently or along with nutrients such as zinc or selenium, has an impact on the ability of the body to handle metals such as cadmium, lead, iron and mercury and metalloids such as arsenic, which have the potential to disrupt the metabolism and biological activities of many proteins, because of their high affinity for free sulfhydryl groups.

Glutathione is also closely linked with immunity, protecting the cells and assisting the liver in detoxifying harmful compounds and toxins. Conjugation of G-SH with electrophilic compounds, mediated by the glutathione *S*-transferases (GSTs) enzymes serves to protect cells from toxic chemicals. In plants, these conjugates are transported into vacuoles. In animals, G-SH conjugates are excreted in the urine and faeces. The formation and excretion of G-SH conjugates leads to G-SH depletion, which is attenuated by *de novo* synthesis of G-SH. If glutathione is depleted, an organism can be predisposed to the effects of stress from xenobiotics. When taking glutathione, vitamin C is also recommended because ascorbic acid assists the glutathione to maintain its powerful free radical-suppressing effects.

2.3.3.1.2 Other glutamyl peptides

Both animal and plant tissues contain many different γ-L-glutamyl peptides that have a number of important functions. For example, plant γ-glutamyl peptides play a role in the transport of amino acids through membranes, they protect plant cells against the effects of phytotoxic heavy metals (by acting as phytochelatins; see Section 6.2.2.2), in *Allium* and *Brassica* plants they have a key role as a reserve for nitrogen, sulfur (contain up to 50% of organically bound sulfur) and selenium compounds and are precursors of the biologically active amino acids *S*-alk(en)ylcysteine sulfoxides. They are not cleaved by the enzyme alliinase and are thus not directly involved in the aroma formation in onion, garlic and other vegetables. γ-Glutamyl peptides are formed in reactions catalysed by the enzyme L-γ-glutamyl transferase, which catalyses the splitting of the γ-glutamyl linkages in reduced glutathione (G-SH) and the transfer of the glutamate moiety to amino acid or peptide acceptors.

Plants of the genus *Allium* typically contain more than 20 γ-glutamyl peptides, such as *N*-(γ-glutamyl)-*S*-alk(en)yl glutathiones, *N*-(γ-glutamyl)-*S*-alk(en)yl cysteines and *N*-(γ-glutamyl)-*S*-alk(en)yl cysteine sulfoxides. These peptides occur as intermediates in the biosynthesis of *S*-alk(en)ylcysteine sulfoxides in *Allium* vegetables (Figure 2.17). The main γ-glutamyl peptides in garlic cloves are *N*-(γ-glutamyl)-*S*-(prop-2-en-1-yl)-L-cysteine ($R{=}CH_2{-}CH{=}CH_2$) and (*E*)-*N*-γ-glutamyl-*S*-(prop-1-en-1-yl)-L-cysteine ($R{=}CH{=}CH_2{-}CH_3$), which are present at levels of approximately 2.9–4.6 g/kg of fresh weight and 4.6–5.4 g/kg of fresh weigh, respectively. They are followed by *N*-(γ-glutamyl)-*S*-(2-carboxypropyl)-L-cysteinyl glycine, $R{=}\ CH_2{-}CH(COOH)CH_3$, known as *S*-(2-carboxypropyl)glutathione (0.8–1.2 g/kg of fresh weight), *N*-(γ-glutamyl)-*S*-methyl-L-cysteine (0.04–0.4 g/kg of fresh weight) and *N*-(γ-glutamyl)-*S*-(prop-2-en-1-yl)-L-cysteine sulfoxide ($R{=}CH_2{-}CH{=}CH_2$; 0.04–0.08 g/kg of fresh weight). *S*-(2-Carboxypropyl)glutathione is the main γ-glutamyl peptide of onion bulbs (0.1–0.9 g/kg of fresh weight), where it is accompanied by (*E*)-*N*-γ-glutamyl-*S*-(prop-1-en-1-yl)-L-cysteine sulfoxide ($R{=}CH{=}CH_2{-}CH_3$; 0.2–2.3 g/kg of fresh weight), (*E*)-*N*-γ-glutamyl-*S*-(prop-1-en-1-yl)-L-cysteine (up to 0.1 g/kg of fresh weight) and *N*-(γ-glutamyl)-*S*-methyl-L-cysteine (up to 0.1 g/kg of dry weight). In pre-bulbing onions, levels of (*E*)-γ-glutamyl-*S*-(prop-1-en-1-yl)cysteine sulfoxide and *S*-(2-carboxypropyl)glutathione were found to be below 0.05 g/kg of fresh weight and at the bulbing onion stage they amounted to 2.1 and 4.0 g/kg of fresh weight, respectively. The main γ-glutamyl peptide in beans is *N*-(γ-L-glutamyl)-*S*-methyl-L-cysteine, and an important γ-glutamyl peptide of shiitake mushrooms (*Lentinula edodes*) is known as lentinic acid (**2-86**; see Section 2.1.1.2.2).



2-86, lentinic acid

2.3.3.1.3 Histidine dipeptides

In addition to glutathione, the muscle tissue of animals contains a group of dipeptides derived from L-histidine (its 1*H*- and 3*H*-isomers, respectively). These dipeptides include carnosine (β-alanylhistidine, **2-87**), anserine (β-alanyl-1-methylhistidine, **2-88**), balenine also known as ofidine (β-alanyl-3-methylhistidine, **2-89**) and homocarnosine (γ-aminobutyrylhistidine, **2-90**). The biological role of these dipeptides is not yet fully known. It is assumed that they are involved in the contraction of skeletal muscles, and are associated with some enzymes containing copper in the molecule that show the activity of neurotransmitters, vasodilators and modulators. Their buffering capacity at physiological pH values is also important (they are present as cations with an ionised primary

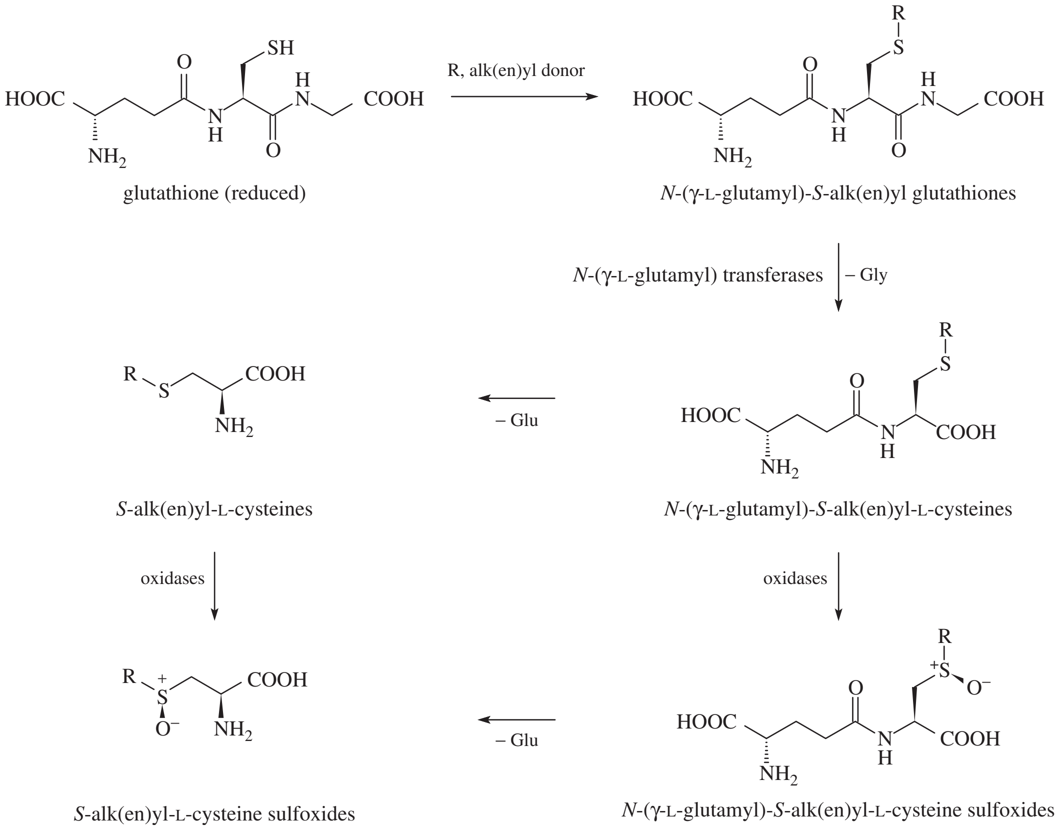


Figure 2.17 Formation of *S*-alk(en)ylcysteine sulfoxides from γ-glutamyl cysteine peptides in *Allium* vegetables.

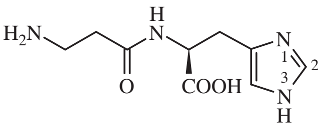
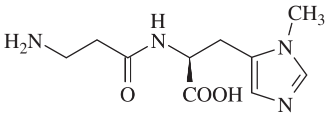
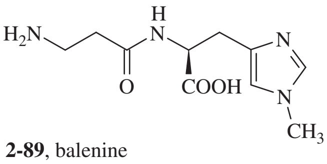
amino group, imidazole ring nitrogen and carboxyl group). Carnosine has recently appeared in some food supplements for athletes, but its use is not yet supported by credible scientific results.



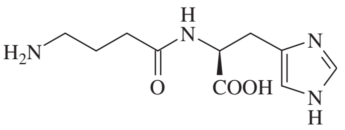
2-87, carnosine



2-88, anserine



2-89, balenine



2-90, homocarnosine

Because of the variations in different types of meat, the dipeptide contents can serve as criteria for determining the origin of meat and meat products (Table 2.5).[4] For example, anserine is the dominant dipeptide in meat from birds, while in animal tissues the main dipeptides are anserine and carnosine (while human tissues contain only carnosine). Determination of these two peptides has been used, for example, to evaluate the amount of chicken meat in pork meat products. Balenine is usually present in small amounts in meat from snakes. In marine mammals such as whales, balenine is the main histidine dipeptide.

The sensory properties of histidine dipeptides and their reaction products may affect the oral sensation of meat products as they contribute to the umami taste (see Section 8.3.3.1) and enhance the flavouring properties of sodium hydrogen glutamate. The key contributors to the typical chicken broth flavour are, for example, anserine, carnosine and β-alanylglycine. During the processing of meat, histidine dipeptides are partly hydrolysed by endogenous peptidases (for example, during curing of ham, about one half of these dipeptides are hydrolysed) and non-enzymatically. They also partly react with protein-bound asparagine and glutamine and are incorporated into proteins during heating. In beef soup stock solution and in model experiments, hydrolysis of proteins with incorporated carnosine yields β-aspartyl-β-alanylhistidine and γ-glutamyl-β-alanylhistidine tripeptides, respectively. During thermal processing of meat, and particularly of fish, histidine dipeptides enter the Maillard reaction (see Section 4.7.5).

[4]The content of individual dipeptides, of course, varies in different muscles and depends on many factors, such as age of the animal and type of processing. Breast muscles of poultry, for example, contain about 5–10 times higher amounts of carnosine and five times higher amounts of anserine than leg muscles (white breast muscles are involved in intense anaerobic metabolism and therefore require a higher buffering capacity).

2.3.3.2 Proteolytic products

Proteolytic enzymes are present in virtually all raw food materials, therefore proteins can be broken down by partial spontaneous

Table 2.5 Histidine dipeptides content of fresh meat.

Meat	Content (mg/kg)			Meat	Content (mg/kg)		
	Carnosine	Anserine	Balenine		Carnosine	Anserine	Balenine
Pork	1 040–4 190	70–160	180	Horse	3 820–4 023	30–48	0
Beef	1 520–3 650	110–552	17	Rabbit	497	4 536	0
Sheep	670–1 898	430–1 992	24	Chicken	100–1 117	550–3 350	-
Goat	520–1 030	750–2 016	0	Turkey	1 600–2 400	6 150	-

hydrolysis during the storage of these materials and during food production, which leads to a mixture of different peptides. In some technologies spontaneous proteolysis is desirable, such as during meat curing and in cheese[5] and malt production.

For example, intense proteolyses of muscle proteins, due to the action of endogenous proteolytic enzymes, have been reported to occur during the processing of dry-cured ham. This gives rise to the formation of free amino acids and short peptides (especially from actin through the action of cathepsin D in meat and from caseines as a result of plasmin and other proteases in cheeses) that contribute directly or indirectly to the flavour characteristics of the final product. In the case of octapeptide Lys-Gly-Asp-Glu-Glu-Ser-Leu-Ala, isolated from beef broth, this reportedly showed umami taste with a threshold value of about 500 mg/l.

Dozens of different peptides have been identified in cheeses. Most of them arise from α_{S1}- and β-caseins and a few are from α_{S2}- and κ-caseins. The proteinases involved in hydrolysis of α_{S1}-casein are mainly cathepsin D originating from milk and cell-envelope proteinase from thermophilic starters, while β- and α_{S2}-caseins are mainly hydrolysed by plasmin. Moreover, peptidases from starters are also active throughout the ripening process, presumably similar to those from non-starter lactic acid bacteria. For example, the bitterness of mature Gouda cheese is caused by calcium and magnesium chlorides, some bitter-tasting free amino acids and is modified by peptides, which arise from the hydrolysis of β-casein (such as decapeptide Tyr-Pro-Phe-Pro-Gly-Pro-Ile-His-Asn-Ser and derived nonanpeptide without the terminal serine) and α_{S1}-casein (tetrapeptide Leu-Pro-Gln-Glu).

Some proteins (especially lipid transfer protein and protein Z, see Section 2.4.5.4.1) and hydrophobic polypeptides resulting from barley proteins in malt, through endogenous proteases and yeast autolysis, are important foam stabilisers in beer.

2.3.3.2.1 Protein hydrolysates and pyrolysates

Linear peptides

Many food products (including soy sauce and other oriental sauces) that are produced by enzymatic hydrolysis of proteins or protein-rich materials contain various peptides. Other materials containing variable amounts of peptides include yeast autolysates and also blood, whey and casein hydrolysates, which are used as food additives of high nutritional value.

During the partial enzymatic hydrolysis of proteins, bitter-tasting peptides are often released, which limits the application of these hydrolysates in food processing. Casein and soy protein hydrolysates in particular have a tendency towards bitterness. The bitter taste is caused by peptides containing hydrophobic amino acids (valine, leucine, isoleucine, phenylalanine, tyrosine and tryptophan). Proline (which commonly occurs in the penultimate position) and pyroglutamic acid are also often present in bitter peptides, while cysteine and methionine are usually absent. Bitter peptides contain varying numbers of bound amino acids, usually between 2 and 23. Several tens of bitter peptides have been characterised. Those isolated from Cheddar cheese, originating from α_{S1}-casein, have the following sequences of amino acids: Arg-Pro-Lys-His-Pro-Ile-Lys-His-Gln-Gly-Leu-Pro-Gln, Leu-Pro-Gln-Glu, Arg-Pro-Lys-His-Pro-Ile-Lys and Lys-Pro-Trp-Ile-Gln-Pro-Lys. The bitter peptide of Cheddar cheese originating from β-casein is the linear nonapeptide Val-Pro-Gly-Glu-Ile-Val-Glu-Ser-Leu. Another example of a bitter peptide occurring in β-casein hydrolysate is the linear pentadecapeptide Tyr-Gln-Gln-Pro-Val-Leu-Gly-Pro-Val-Arg-Gly-Pro-Phe-Pro-Ile. Peptides with a molecular weight higher than 3 000 Da are not bitter because they cannot interact with the taste receptors.

Methods for eliminating bitter peptides in partial protein hydrolysates are known, but they cause a significant loss of essential amino acids. These procedures usually include additional enzymatic hydrolysis under controlled conditions (a shorter time for the hydrolysis leads to higher peptides that are not bitter) and a selection of suitable proteases, such as aminopeptidases, carboxypeptidases and some other proteases. Enzymes of plant and microbial origin have been successfully used for this purpose. For example, the intracellular peptidases from *Lactococcus lactis* ssp. *cremoris* and *Brevibacterium linens*, which have high proteolytic activity, successfully hydrolyse bitter peptides in cheeses.

The bitterness of hydrolysates can be reduced considerably by the plastein reaction. Under certain conditions (temperature, pH, peptidase concentration and other factors) proteases (such as endopeptidases) can synthesise new larger peptides from undesirable bitter peptides; these larger peptides are known as plasteins and are not bitter. The plastein reaction involves a transpeptidation and/or condensation mechanism. The plastein synthesis can also

[5]Proteolysis has three phases (see Section 2.4.5.2.1): proteolysis in milk before cheese manufacture due to indigenous milk protease (plasmin) activity, the enzymatically induced coagulation of the milk in rennet cheeses (hydrolysis of κ-casein by rennin) and proteolysis during ripening of most cheeses, which is the most important reaction having a major impact on flavour and texture.

be used to incorporate nutritionally valuable amino acids (methionine, lysine and tryptophan) into proteins of low biological value, for the removal of undesirable amino acids from proteins (phenylalanine, see Section 10.3.1.1.3) and for the recovery of protein from non-traditional and waste proteinaceous materials.

Cyclic peptides

Cyclic dipeptides, 2,5-dioxopiperazines, are mainly formed by dehydration of linear dipeptides as a result of the hydrolysis of proteins and also partly through stepwise cyclisation from free amino acids. They have been identified in several fermented and thermally treated foods and sometimes contribute to the perceived bitterness. 2,5-Dioxopiperazines are partly responsible for the bitterness of coffee, cacao, roasted cereal grains, roasted malt, beer, aged sake and other foods. For example, in roasted coffee the following proline-based diketopiperazines have been identified: cyclo(Pro-Ile), cyclo(Pro-Leu), cyclo(Pro-Phe), cyclo(Pro-Pro) and cyclo(Pro-Val). Acid hydrolysis (traditionally with hydrochloric acid) of protein-rich material (mostly oilseed meal) is employed for the production of hydrolysed vegetable proteins that are used as seasonings. The resulting hydrolysates contain relatively large amounts (about 25 mg/kg) of 2,5-dioxopiperazines derived from the hydrophobic amino acids valine, leucine, isoleucine and phenylalanine. The main products are cyclo-(Val-Val), cyclo-(Val-Ile), cyclo-Val-Phe, cyclo-(Leu-Phe) and cyclo-(Ile-Ile), which are formed by dehydration of linear dipeptides under acidic conditions. The 2,5-dioxopiperazines (*Z*)-cyclo(Leu-Pro) and (*Z*)-cyclo(Phe-Pro) have also been found in wheat dough and bread. The levels of these cyclic dipeptides increased from approximately 1 to 35 and 25 μg/kg of dough, respectively, after 48 h of incubation. The bread crumbs and crust contained, respectively, almost 100 and 2 000 times the levels found in the dough prior to baking.

Bitter, off-tasting, cyclopeptides can also arise during the storage of cold pressed vegetable oils. For example, fresh linseed oil provides a nutty flavour, but on storage at room temperature it develops a bitter off-taste. The key bitter compound responsible for the bitter taste is the cyclic octapeptide cyclo-(Pro-Leu-Phe-Ile-Met*O*-Leu-Val-Phe), known as cyclolinopeptide E, which contains methionine sulfoxide.

2.3.3.2.2 Bioactive peptides

Some peptides with particular amino acid sequences, which are inactive in the intact protein, may exert biological functions after their release from the intact protein molecule. Such bioactive peptides have been described as peptides with hormone- or drug-like activity that eventually modulate human physiological functions through binding to specific receptors on target cells, leading to induction of physiological responses. Bioactive peptides (protein fragments), generally consisting of 3–20, but sometimes more, amino acids, arise through hydrolysis of many dietary proteins during:

- fermentation processes using proteolytic starter cultures
- during the manufacture of protein hydrolysates
- during digestion of proteins
- by the action of digestive enzymes on proteins *in vitro*.

Depending on their biological properties, bioactive peptides can be divided, for example, into:

- **opioids**
- **antihypertensive peptides**
- **mineral-binding peptides**
- **antimicrobial peptides**
- **immunomodulating and cytomodulating peptides**.

Unlike endorphins (peptide hormones found mainly in the brain that bind to opiate receptors and reduce the sensation of pain and affect emotions), exorphins are the brain's opiates that are found in food, mainly in milk, dairy products and gluten-rich wheat. The most important exorphins are β-casomorphins (BCMs), which are released by the digestion of β-casein in bovine milk and dairy products. They are denoted by a numeral indicating the number of amino acids. The first β-casomorphin, heptapeptide (also known as casomorphin 7, Tyr-Pro-Phe-Tyr-Gly-Tyr-Ile), was isolated from a casein hydrolysate in 1970. Homologous sequences have also been identified in human milk. In 2009, the European Food Safety Agency (EFSA) published a comprehensive review on casomorphins, which are classified as substances with opioid effects. This is why milk, for instance, can help people fall asleep because it contains opioid peptides. Exorphins also arise from other milk proteins (α-casein – α_{S1}-casein exorphin, κ-casein – casoxins A, B and C, α-lactalbumin – α-lactorphin, β-lactoglobulin – β-lactorphin and serum albumin – serorphin), cereal proteins (such as wheat gluten and gliadin), soybeans (α-protein), meat and poultry proteins (albumin, haemoglobin, γ-globulin), eggs (ovalbumin) and other proteins.

Angiotensin-converting enzyme (ACE) inhibitory peptides represent an additional group of bioactive peptides, which inhibit the activity of the angiotensin-converting enzyme, resulting in a reduction of blood pressure. ACE inhibitory peptides with a chain length of 2–10 amino acids were first obtained from milk proteins (caseins and serum proteins), although they have also been found in a number of other animal and plant proteins. For example, one of about 150 bioactive peptides from α_{S1}-casein (of the genetic variant B, see Section 2.4.5.2.1) is hexapeptide, which is composed of Lys-Thr-Thr-Met-Pro-Leu. An antihypertensive hexapeptide isolated from wheat sourdough, traditionally used in bread making, is composed of amino acids Val-Pro-Phe-Gly-Val-Gly, which occur at the 287–292 position of a low molecular weight glutenin subunit.

Similarly to mineral-binding proteins, casein-derived phosphopeptides can form salts with minerals such as calcium due to the binding properties of the phosphoserine residue. These peptides are involved in the increased absorption and bioavailability of calcium and other minerals (zinc, copper, manganese and iron)

in the intestine. An example is a heptapeptide derived from κ-casein (Pro-Val-Ala-Leu-Ile-Asn-Asn).

Peptides with antioxidant properties are effective against enzymatic and non-enzymatic oxidation of lipids, as free radical scavengers and in metal ion chelations. An example is a soybean pentapeptide with the sequence Leu-Leu-Pro-His-His.

Antimicrobial peptides are effective against different bacteria and yeasts. An example of an antimicrobial peptide is lactoferricin, which includes residues 17–41 from lactoferrin. Other peptides with antimicrobial properties are isracidin, derived from α_{S1}-casein (residues 1–23), and casocidin-I, as a result of hydrolysis of α_{S2}-casein (residues 150–188). Lactoferricin also has immuno- and cytomodulatory properties that similarly show a number of peptides arising by hydrolysis of milk caseins and serum proteins.

The resistance of peptides to gastrointestinal digestion is an important prerequisite in order to obtain physiological effects *in vivo* after oral administration of bioactive peptides. Current knowledge indicates that absorption is only possible with dipeptides and tripeptides, which are probably absorbed through passive diffusion through the intestinal mucosa, although the amounts absorbed are extremely small. The absorbed peptides are further degraded by peptidases in the blood. For example, the major constituent in human blood after oral ingestion of gelatin hydrolysates was dipeptide Pro-Hyp, in addition to small amounts of Ala-Hyp, Ala-Hyp-Gly, Pro-Hyp-Gly, Leu-Hyp, Ile-Hyp and Phe-Hyp, which suggests that oral administration of gelatin (collagen) may be involved in some biological activities in the body. In the case of opioids, passage through the blood–brain–barrier is necessary in order for them to act on the central nervous system.

2.3.4 Properties

2.3.4.1 Physical-chemical properties

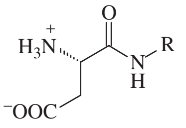
As with amino acids, peptides dissociate in aqueous solutions and form internal salts (zwitterions). The values of the dissociation constants (pK values) and isoelectric points (pI) of some simple peptides are shown in Table 2.6. It is clear (by comparing the values for Gly, Gly-Gly and Gly-Gly-Gly) that the increase in the molecular weight of a peptide reduces the acidity and basicity of the functional groups. The pI values of peptides are lower than those of the corresponding amino acids. The pK and pI values of peptides containing the same amino acids are different depending on the order of the amino acids (in Gly-Asp and Asp-Gly).

2.3.4.2 Organoleptic properties

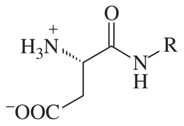
Peptides, like amino acids, can taste bitter, sweet, salty or indifferent. Most natural and synthetic oligopeptides have a bitter taste (see Section 2.3.3.2). A sweet taste indicates dipeptides derived from L-aspartic acid (**2-91**) and others derived from its lower homologue L-aminomalonic acid (**2-92**). R^1 is always a hydrogen atom or a methyl group, substituents R^2 are alkyls or aryls and substituents R^3 are esterified carboxyl groups (usually methyl esters, but some ethyl, propyl, isopropyl and other esters are also sweet). The best known of these compounds is the methyl ester of L-aspartyl-L-phenylalanine, which has long been used as the sweetener aspartame (see **11-27**).

Table 2.6 pK and pI values of peptides.

Peptide	pK_1	pK_2	pK_3	pK_4	pK_5	pI
Gly-Gly	3.12	8.17	-	-	-	5.6
Gly-Gly-Gly	3.26	7.91	-	-	-	5.6
Ala-Ala	3.30	8.14	-	-	-	5.7
Gly-Asp	2.81	4.45	8.60	-	-	3.6
Asp-Gly	2.10	4.53	9.07	-	-	3.3
Lys-Ala	3.22	7.62	10.70	-	-	9.2
Asp-Asp	2.70	3.40	4.70	8.26	-	3.0
Lys-Lys	3.01	7.53	10.05	11.01	-	10.5
Lys-Lys-Lys	3.08	7.34	9.80	10.54	11.32	10.9

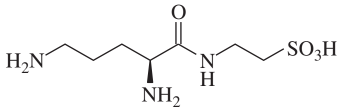


2-91, aspartyl dipeptides

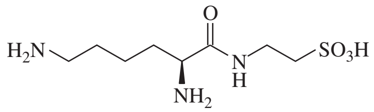


2-92, aminomalonyl dipeptides

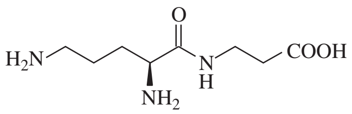
The hydrochlorides of some dipeptides have a salty taste, which suggests the possibility of using them as a replacement for sodium chloride for people who need to cut down their salt intake for health reasons (see Section 8.3.2). L-Ornithyl taurine (**2-93**) and L-lysyl taurine hydrochlorides (**2-94**) also exhibit a salty taste of similar quality and intensity as sodium chloride. A weaker salty taste is found in the hydrochloride of L-ornithyl-β-alanine (**2-95**) and the hydrochloride of L-ornithyl-γ-aminobutyric acid.



2-93, ornithyl taurine



2-94, lysyl taurine



2-95, ornithyl-β-alanine

2.4 Proteins

The process of protein synthesis creates polymers from amino acids. Proteins commonly contain more than 100 amino acids bound into linear chains by covalent peptide bonds. Their relative molecular weight ranges from 10 000 to several million daltons. In addition to peptide bonds that link the amino acids in a protein chain, some other covalent bonds (such as disulfide bonds, between bound cysteine side chains, and ester bonds, allowing connection of serine, threonine, arginine or lysine through phosphoric acid) can be important determinants of protein structure. Apart from covalent bonds, various electrostatic interactions can also be important to the protein structure (ionic, hydrogen and hydrophobic interactions; see Section 7.6.1). Ionic bonds are formed between amino acids bearing opposite electrical charges and are found mainly in the hydrophobic core of the protein. Hydrogen bonds (bridges) can exist between a variety of atoms, for example between two different amino acid side chains, or between an amino acid side chain and a water molecule. Hydrophobic bonds occurring in the hydrophobic protein core are the major forces driving the correct folding of the protein. Protein molecules also bond with water and various inorganic ions. Some proteins contain physically or chemically bound organic compounds, such as lipids, sugars, nucleic acids and various coloured organic compounds.

Apart from water, proteins form the major portion of the mass of living organisms. According to the biological functions they perform in biochemical processes, proteins are often distinguished as:

- **structural** proteins (occurring primarily as structural components of cells and animal and plant tissues)
- **catalytic** proteins (enzymes, hormones)
- **transport** proteins involved in the movement of ions, small molecules or macromolecules (e.g. haemoglobin)
- **mobility** proteins participating in muscle contraction (actin, myosin and actomyosin)
- **defence** proteins (antibodies and immunoglobulins)
- **storage** proteins (e.g. ferritin)
- **sensory** proteins (rhodopsin)
- **regulation** proteins (histones and hormones).

Proteins ultimately perform **nutritional** functions, together with lipids and carbohydrates, and are among the most important components of human dietary requirements. They are our main source of nitrogen, a source of essential amino acids and of material needed for the growth and repair of muscles, bones, skin and other tissues, and are a source of energy. For human nutrition, proteins are derived from various foods. These mainly come from foods of animal origin (meat, milk and eggs), a category that on average represents about 25% of protein in the human diet worldwide. Proteins of vegetable origin (mainly cereals and pulses, but also fruits, vegetables and root crops) contribute about 65% of the per capita supply of protein on a worldwide basis.[6]

Non-conventional sources such as seeds, plant waste and algae (mainly algae of the genera *Chlorella*, *Spirulina* and *Scenedesmus*) can also potentially provide protein for human consumption.

In food raw materials, which are, with some exceptions, post-mortem animal tissues and post-harvest plant tissues, the majority of proteins do not possess the envisioned biological functions. Furthermore, animal and plant tissues of raw materials are often damaged during food processing or cooking, which sometimes results in desirable, but also undesirable, activity of various enzymes. Apart from the enzymes that occur naturally in raw materials, foods may also contain enzymes produced by microorganisms (both naturally occurring and also those whose properties are used in food technology procedures), and also enzymes added for various reasons during processing. In many cases foods are heat processed, during which there are a number of physical and chemical changes to the proteins, which are known by the general term **denaturation**. Thus proteins are often classified according to the state in which they are found in foods as **native** (natural) proteins and **denatured** proteins. Native proteins preserve all the biological functions they have in living organisms, while denatured proteins do not, as the quaternary, tertiary and secondary structures present in their native state are lost. Both native and denatured proteins are the main nutritional sources of protein. The intentional modification of food protein side chains with chemical reagents, currently applied to only a limited extent, produces chemically **modified** proteins with altered properties. The modified proteins, mostly used as food additives for specific purposes, can have improved nutritional quality, physical states (such as texture) and functional properties (e.g. whipping capacity). Whilst many such modifications offer opportunities for improving food proteins and extending their availability from non-conventional sources, careful considerations of their safety and acceptability is required.

2.4.1 Classification and nomenclature

As with all macromolecules, protein nomenclature predominantly uses trivial names. Proteins can be classified from a variety of perspectives, which reflect their importance in nutrition, origin, structure, chemical and biochemical properties and other attributes.

The amount of protein that the body is able to absorb and use from a certain protein source varies, because protein from one food may be absorbed better than a protein from a different source, even if the same amounts of each are provided. According to their bioavailability (see Section 2.4.4.2), the following protein categories can be identified:

- **fully available**, which contain all essential amino acids at levels required for human nutrition (e.g. egg and milk proteins)

[6]Animal (and plant) protein supplies per capita (%) for selected geographic regions in 1989 were: Western Europe 60 (42), North America 73 (34), Latin America 29 (57), Africa 12 (79), Middle East 17 (78), and Far East 11 (81).

- **partly available**, in which some essential amino acids are present in somewhat lower amounts than required (e.g. meat proteins)

- **non-available**, in which essential amino acids are present in much lower amounts than required (e.g. all vegetable proteins and animal proteins from connective tissues).

Depending on their structure (or the presence of non-protein components), native proteins are divided into:

- **simple** proteins

- **conjugated** proteins.

Simple proteins that consist of amino acids only are also traditionally separated into two basic groups according to the shape of the molecule (to a certain extent this classification coincides with a further classification into soluble and insoluble proteins):

- **globular** proteins or spheroproteins (e.g. albumins and globulins), where the molecules have a round to spherical shape, non-polar functional groups are within the molecule, the polar functional groups form the outer core and bind to water molecules, generally soluble in water or dilute salt solutions, forming colloidal solutions (see Section 7.6.3.5) and many act as enzymes;

- **fibrillar** proteins or scleroproteins (for example, practically insoluble structural proteins collagen, keratin and elastin) the molecule of which has the shape of macroscopic fibres.

Depending on the proportion of non-protein compounds covalently bound to the proteins, conjugated proteins are divided into several groups:

- **nucleoproteins**, which contain ester-bound nucleic acids;

- **lipoproteins** are proteins conjugated with neutral lipids, phospholipids, steroids (such as cholesterol) and mostly occur in egg yolk and blood plasma;

- **glycoproteins** containing bound saccharides, mostly oligosaccharides (e.g. the structural protein collagen in meat, κ-casein in milk and some egg white proteins), saccharides are bound by an *O*-glycosidic bond to serine, threonine or 5-hydroxylysine;

- **phosphoproteins** containing bound phosphoric acid (α- and β-caseins in milk and the egg yolk protein phosvitin);

- **chromoproteins** containing bound porphyrin or flavin derivatives (haemoglobin, myoglobin, ferritin, peroxidases, catalases and dehydrogenases with NAD and FAD cofactors);

- **metalloproteins** that contain metals bound by coordinate bonds (examples include the protein ferritin, which is the storage form of iron in the liver, or ceruloplasmin, which contains bound copper, these proteins represent the most important sources of iron and copper in human nutrition).

In the past proteins were classified according to their solubility, but use of this classification is now limited. However, many trivial names of proteins are still based on this classification:

- **soluble** proteins

- **insoluble** proteins, which include fibrillar proteins (scleroproteins).

The soluble proteins are divided into the following six groups:

- **albumins** are neutral proteins soluble in water, salted out from aqueous solutions by ammonium sulfate at a saturation of 60%, at 75 °C, irreversibly coagulating, and include lactalbumin in milk, ovalbumin and conalbumin in egg white, leucosin in wheat, legumelin in lentils and peas and phaseolin in kidney beans;

- **globulins** are weakly acidic proteins insoluble in water, but soluble in dilute salt solutions, e.g. in 5% sodium chloride, in acids and bases, salted out by ammonium sulfate at a saturation of 40% and coagulating on heating; globulins soluble in salt-free water are **pseudoglobulins**, those insoluble in salt-free water are **euglobulins**; examples include muscle proteins myosin and actin (also the product of their interaction, actomyosin), lactoglobulin in milk, ovoglobulin in egg white, edestin in wheat, avenalin in oats, legumin and vicilin of lentils, peas and other legumes, conglycinin and glycinin in soybeans, tuberin in potatoes, almond protein amandin, Brazil nuts protein excelsin and hemp protein edestin;

- **prolamins** are proteins insoluble in water, but soluble in dilute solutions of salts, acids and bases and in 70% ethanol, do not coagulate on heating, and primarily include vegetable lysine-free proteins containing higher amounts of bound proline and glutamine, an examples are gliadin in wheat and rye, secalin in rye, hordein in barley, gliadin in oats, oryzin in rice and zein in maize;

- **glutelins** are insoluble in water but soluble in dilute solutions of salts, acids and bases, differ from prolamins in that they are insoluble in ethanol and coagulate on heating, they contain a considerable amount of glutamic acid; the most common glutelin is glutenin found in wheat, which is responsible for some of the baking properties of bread wheat; examples of other glutelins are rye secalinin, barley hordenin, rice oryzenin and maize zeanin;

- **protamines** are basic proteins soluble in water, dilute acids and in ammonium hydroxide and do not coagulate on heating; they contain large amounts of basic amino acids (about 80% arginine), occur in fish sperm (e.g. cyprimine in carp, salmine in salmon, sturine in sturgeon, clupeine in herring and scombrine in mackerel;

- **histones** are basic proteins soluble in water and dilute acids, but not in ammonium hydroxide and do not coagulate on heating, they contain higher amounts of lysine, arginine and histidine and are present at high levels in the nuclei of animal and plant cells, where they are bound to nucleic acids.

2.4.2 Structure

In practice, to characterise proteins in terms of food and nutrition, information on the overall amino acid composition is usually sufficient. In many cases, however, detailed knowledge of the protein structure is also required. Four levels of the protein structure are recognised: **primary**, **secondary**, **tertiary** and **quaternary**. Detailed descriptions of the structure of proteins can be found in biochemistry textbooks.

2.4.2.1 Primary structure

The primary structure of proteins includes, for example, the data on the structure of covalently bound amino acid molecules, the number and order (sequence) of amino acids in the peptide chain, the character of basic peptide bonds, number, character and position of other covalent bonds (disulfide bridges and other bonds).

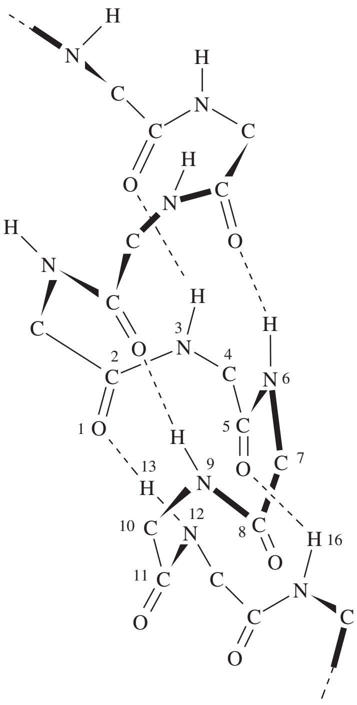


Figure 2.18 α-Helix (C_α atoms are shown without substituents).

2.4.2.2 Secondary structure

The secondary structure of a segment of a polypeptide chain is the local spatial arrangement of its main chain atoms, without considering the conformation of its side chains or its relationship to other segments. The polypeptide chains of native proteins have particular secondary structures in different parts of the chain. A certain spatial arrangement (conformation) of the chain is given by its primary structure (amino acid sequence), fixed by non-covalent interactions of functional groups of the amino acids. Hydrophobic interactions are present when the amino acids have hydrophobic side chains, amino acids with an electric charge in the side chain (acidic and basic hydrophilic amino acids) are involved in electrostatic interactions and other hydrophilic and amphiphilic amino acids can form hydrogen bonds through their functional groups. There are three common secondary structures in proteins, namely **helices**, **sheets** and **turns**.

The most important elements of the secondary structure (conformation of the polypeptide chain) are helical structures arising from the coiling of peptide chains (or part of a chain) in the neighbourhood of the C_α into a spiral known as a helix. Helices have characteristic torsion angles, numbers of amino acid residues per turn and helix heights. These characteristics are described by values of n_m, where n is the number of amino acid residues per turn and m is the number of atoms in the ring, including the hydrogen atom forming a hydrogen bond. Helices are chiral and can be right-handed or left-handed. Only right-handed helices are found in natural proteins (with some exceptions, for instance in collagen).

The major secondary structure of a protein is the right-handed α-**helix** (Figure 2.18). An α-helix is a rigid arrangement of a polypeptide chain, in which intramolecular hydrogen bonds play a significant role. If the helix has a translation of 0.15 nm along the helical axis and a pitch height (the vertical distance between one consecutive turn of the helix) of 0.54 nm, then the helix has 3.6 amino acid residues per turn (0.54/0.15 = 3.6). The average size of an α-helix is 11 amino acid units, which corresponds to about three turns of the helix. The C=O group of the peptide bond of an amino acid with a sequence number n is bound by hydrogen bonding to the N–H group of the peptide bond of an amino acid with a sequence number n+4. This α-helix is also known as a 3.6_{13} helix as the hydrogen bond is between atoms 1 and 13 of the polypeptide chain. This secondary structure can be found in at least part of any polypeptide chain in the majority of proteins (in myoglobin, collagen and other proteins).

A rarer type is a helix 2.2_7 (the hydrogen bond is between atoms 1 and 7 of the polypeptide chain). A right-handed helix 3_{10} (three units per turn, pitch height 0.6 nm), which is narrower and also steeper than an α-helix (the hydrogen bond is between atoms 1 and 10 of the polypeptide chain), sometimes occurs as an α-helix junction with another part of the polypeptide chain. The so-called helix 4.4_{16} (π-helix) only exists at the end of several helices (4.4 units per turn, pitch height 0.52 nm, the hydrogen bond is between atoms 1 and 16 of the polypeptide chain).

β-**Structures** are somewhat less common regular secondary structures of proteins, also known as β-pleated sheets or just β-sheets (Figure 2.19). These are characterised by long extended polypeptide chains in contrast to the compact helices. These structures are formed by combining parallel or antiparallel oriented polypeptide chains (β-strands) that line up and form bridges of extramolecular hydrogen bonds (unlike the helices, which

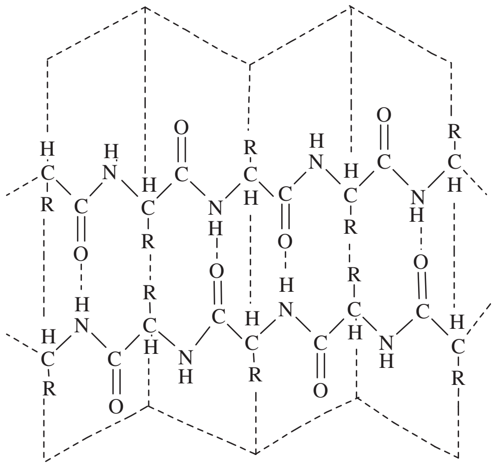

Figure 2.19 Antiparallel β-sheet consisting of two β-strands.

are bound by intramolecular hydrogen bonds), creating a stable β-sheet. On average, a β-sheet consists of six β-strands, and structures with less than five β-strands are rare. Each polypeptide chain contains up to 15 amino acid residues. Some globular proteins rarely produce a parallel structure; an antiparallel structure occurs more frequently, and the polypeptide chains containing proline, such as the collagen polypeptide chain, never form β-structures. A large closed β-sheet (typically having an antiparallel structure) is called a β-barrel. β-Barrels are found in proteins known as porins that occur in the cytoplasmic membrane of gram-negative bacteria and in the outer membranes of mitochondria and plastids.

There are many structural motifs that are formed by the combination of helices and sheets, but the common types of protein secondary structures (helices and pleated sheets) represent about half of the common globular proteins structures. These combinations require turns in the protein structure that reverse the direction of the peptide chain. These so-called β-turns are considered to be a third common secondary structure motif. Approximately one third of all the residues in globular proteins are found in turns. Turns are almost always found on the surface of proteins and often contain Pro and/or Gly. The remaining segments of the molecule have the so-called non-repetitive structure (random coils, turns and bulges), which is also highly organised and characterised in terms of the backbone conformation and hydrogen bonding.

Fibrillar proteins have a specific secondary structure. For example, the basic secondary structure of keratin consists of two pairs of closely linked right-handed α-helices (a superhelix) that are coiled into a left-handed helix. The basic secondary structure of collagen is a triple helix in which the left-handed polypeptide helix is coiled into the right-handed superhelix.

2.4.2.3 Tertiary and quaternary structures

The tertiary structure of a protein molecule is the arrangement of all its atoms in space (conformation) without regard to its relationship with neighbouring molecules or subunits. It describes the packing of the individual sections of the peptide chains (α-helices, β-sheets and random coils) in the whole polypeptide chain with respect to each other, as these secondary structure units are not planar, but may be bent, coiled and connected together in different ways. Various types of covalent bonds (such as disulfide bridges) and non-covalent interactions between functional groups of amino acids (hydrophobic and electrostatic interactions, see Section 7.6.1) participate in the binding of individual protein sections and in the full fixation of the tertiary structure.

The tertiary structures of many proteins are now known. One example is the myoglobin molecule, which is composed of 153 amino acids, of which about 80% are involved in α-helical structures (Figure 2.20). Its tertiary structure is that of a typical water soluble globular protein. The polypeptide chain is coiled into eight separate right-handed α-helices (designated A through H) that are connected by short non-helical regions. The size of each helix ranges from 7 (helix D) to 26 amino acid residues. In total, 121 amino acids out of 153 occur in helical structures. The last coils of helices A, C, E and G are reinforced by helices 3_{10}. The hydrophobic cleft (hydrophobic pocket), containing one haem prosthetic group with an iron atom, is formed largely by helices E and F and is then in contact with helices B, C, G and H and turns CD and FG. The fifth ligand of the coordination bond of Fe^{2+} is histidine F8, the eighth amino acid in the α-helix F, which is known as proximal histidine. The so-called distal histidine (histidine E7) bonds oxygen to oxymyoglobine via a hydrogen bond (see Section 9.2.1.1). In deoxymyoglobine the sixth binding positions of Fe is vacant.

Many protein molecules do not consist of just one but of several identical or different polypeptide chains that form a complex structure, which is known as the quaternary structure of a protein. The quaternary structure is the arrangement of protein subunits in space and the association of its inter-subunit contacts and interactions,

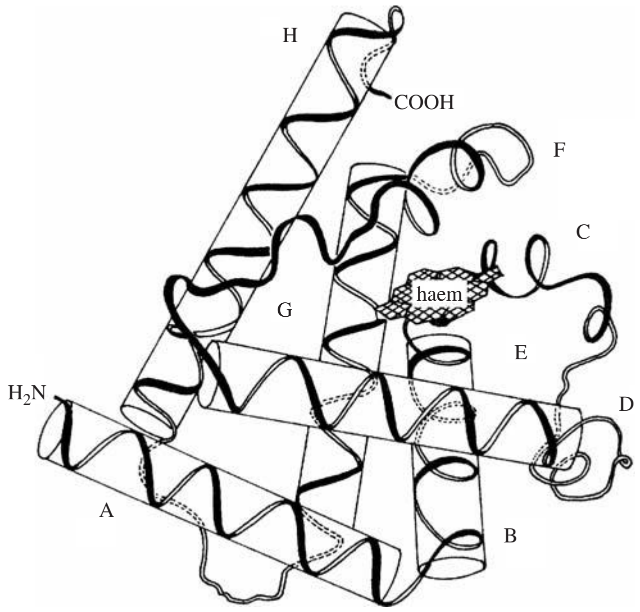

Figure 2.20 Structure of muscle tissue protein myoglobin.

without regard to the interior geometry of the subunits. The subunits in a quaternary structure must be in non-covalent association. Therefore, a quaternary structure only exists if there is more than one polypeptide chain present in a complex protein. For example, avidin in eggs (68 300 kDa) and haemoglobin in blood (64 500 kDa) consist of four subunits, while β-lactoglobulin in milk (36 000 kDa) is composed of two subunits (monomers).

Each subunit of a haemoglobin tetramer has a haem prosthetic group with Fe^{2+}, which is identical to that described for myoglobin. The common peptide subunits are designated α, β, γ and δ. Both the α and β subunits have structural characteristics similar to that of myoglobin.

The subunit structure of β-lactoglobulin of cows' milk is shown in Figure 2.21. This protein (18 kDa) occurs in milk and in a solution of pH 5–7.5 it is generally a dimer, in a solution of pH 3.5–5 it is an octamer and in a solution of pH 3.5 it is a monomer. The monomer polypeptide chain consists of 162 amino acid residues. It contains two disulfide bridges (Cys 66-Cys 160 and Cys 106-Cys 119), one free thiol group (Cys 121), the *N*-terminal amino acid is leucine and the *C*-terminal amino acid is isoleucine. In the milk of other mammals, there are genetic variants of several amino acids, which differ in structure. The polypeptide skeleton is composed of nine β-strands (they are marked with arrows pointing to the *C*-terminus of the molecule), which form a cylindrical β-barrel. The strands contain the following amino acid residues: A 16–27, B 39–44, C 47–58, D 62–76, E 80–84, F 89–97, G 102–109, H 115–124 and I 145–150. The connection between the strands H and I is made through an α-helix, which contains amino acid residues 130–140. Strand I participates in dimer formation, which is based on an antiparallel hydrophobic interaction with another monomer, between isoleucine 29 of one monomer and isoleucine 147 of a second monomer.

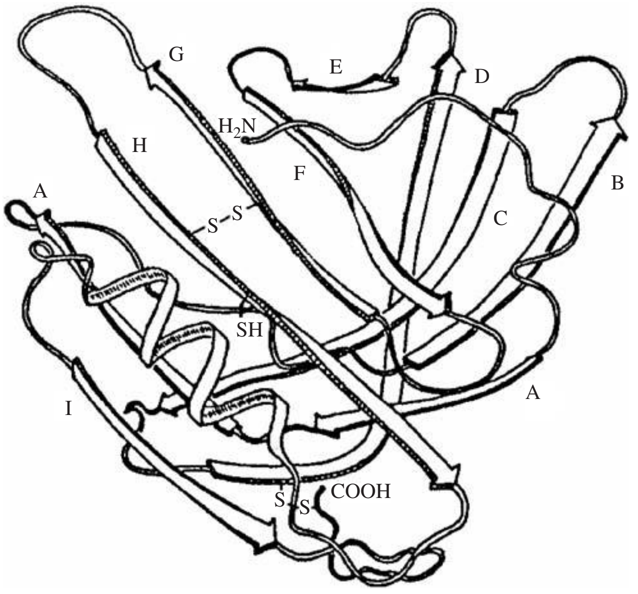

Figure 2.21 Structure of β-lactoglobulin of cow's milk.

2.4.3 Properties

2.4.3.1 Dissociation and hydration

Globular proteins are soluble in polar solvents such as water and in aqueous solutions of acids and bases. Structural fibrous proteins are insoluble in water. Prolamins also dissolve in less polar solvents such as ethanol. In addition to the protein structure, solubility depends on the relative permittivity of the solvent, the pH value of the solution (the minimum solubility is at, or in the vicinity of, the isoelectric point), its ionic strength (a low concentration of salt increases the solubility by the salting-in effect, higher concentrations of salt reduces the solubility by the salting-out effect; see Section 7.6.3.2.3), temperature and other factors.

Proteins dissociate in solutions, as do amino acids or peptides, to form macromolecular polyions. Therefore, proteins are polyampholytes. Depending on the pH of a solution, protein molecules are positively or negatively charged ions as a result of the dissociation of the functional groups of the various amino acids, especially basic amino acids (such as lysine) and acidic functional groups (aspartic and glutamic acids) in the side chains. The net charge (the difference between the number of positive and negative charges) is therefore positive or negative depending on the pH value. The pH at which the protein has no net charge is the isoelectric point (the negative logarithm is the p*I* value). It depends on the type of protein and lies in the pH range 2–11. It should be noted that the protein still contains charged side chains at its isoelectric point; however, at the isoelectric point, the number of positively charged side chains is equal to the number of negatively charged side chains.

Hydration dictates a range of processes, including protein folding, ligand binding, macromolecular assembly and enzyme kinetics. For example, solutions of globular proteins are colloidal dispersions (see Section 7.6.3.2). The protein molecule has the character of a molecular micelle with hydrophobic amino acids arranged towards the interior of the molecule, whereas hydrophilic amino acids are bound outwards. The polar core is hydrated in aqueous solutions, which explains the solubility of globulins. The amount of bound water (monomolecular layer; see Section 7.6.4.2) is about 0.2–0.5 g per 1 g of protein. Dispersions of proteins are therefore hydrophilic colloids. Other layers of water are now bound less tightly. Proteins in aqueous solutions are usually molecular dispersions as the dispersed phases are neutral molecules or ions. Most protein solutions are monodisperse colloidal systems, they contain single molecules, but some proteins are oligodisperse colloidal systems that contain dimers and higher oligomers. For example, β-lactoglobulin molecules form in a solution of pH 3.5–5 octamers and in a solution of pH 5–7.5 dimers. Some proteins form aggregates of molecules, known as micellar colloids (e.g. α-, β- and κ-casein in milk). The mechanical, kinetic, optical and electrical properties of disperse systems of proteins (sols and gels) are described in Section 7.6.3.2.4.

2.4.3.2 Denaturation

Native proteins are precisely folded polypeptidic chains. The denaturation of proteins involves the disruption and possible destruction

of the secondary, tertiary and quaternary structures under the mild effects of various physical factors and in the presence of chemical agents. Since denaturation reactions are not strong enough to break the peptide bonds, the primary structure (sequence of amino acids) remains the same after the denaturation process. However, the long-term and severe effects of some factors that led to the denaturation can also cause changes to the primary structure (degradation of the polypeptide chain to shorter units and possibly to free amino acids during the cooking of meat). The conformational changes may be reversible or irreversible. Native and denatured proteins are in equilibrium and the original conformations can sometimes be restored, returning the protein to its original condition. This process is call renaturation (Figure 2.22). Changes in protein conformation, however, are usually irreversible. Loss of biological activity and the original function of the protein is thus a result of these changes.

Denaturation disrupts the normal α-helices and β-sheets in a protein and uncoils it into less organised and random shape structures. New (previously unavailable) functional groups can interact with water and therefore many proteins in the denatured state have an increased ability to bind water (30–45%). Denaturation is often accompanied by protein coagulation, which is due to aggregation of protein molecules, because functional groups of the proteins react with themselves, thus reducing the number of functional groups available to enter into interactions with water. Hence, the ability of proteins to bind water decreases (see Section 7.6.3.5). For example, the proteins in eggs denature and coagulate during cooking. Denatured proteins can also react with other food components, for example with saccharides in the Maillard reaction.

Various physical factors can cause denaturation (mostly changes in temperature, pressure, exposure to ultrasound and penetrating electromagnetic radiation). Denaturation as a result of chemical agents occurs, for example, in the presence of salts, acids and bases or in the presence of surfactants. For example, heat can be effectively used to disrupt hydrogen bonds and non-polar hydrophobic interactions. This occurs because heat increases the kinetic energy and causes the molecules to vibrate so rapidly and violently that the bonds are disrupted. The activation energy of denaturation by heat is dependent on temperature and on other factors such as the amount of water present, and is very high compared with enzymatic reactions. For example, the activation energy of thermal denaturation of the milk proteins β-lactoglobulin and α-lactalbumin during pasteurisation (at 80 °C) is approximately 270 kJ/mol. During sterilisation (at >100 °C), the activation energy of denaturation is about 60 kJ/mol. The denaturation of fibrillar proteins in meat requires a significantly higher activation energy and proceeds in a different way. An example is the thermal denaturation of collagen in the production of gelatine, which requires long, intense heating procedure in the presence of water.

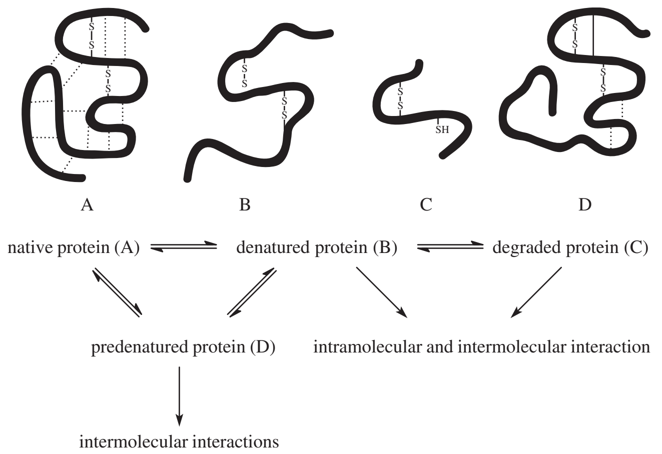

Figure 2.22 Termal denaturation of proteins.

The denaturation of proteins does not just occur during thermal processing of foods, but also can be the result of low temperatures (when food is exposed to freezing temperatures of between 0 and −15 °C). As a result, crystals of ice are produced, which can break the cell membranes, followed by denaturation due to surface phenomena at the interface of the two phases (protein solution and ice crystals), or possibly due to the freezing of water needed to maintain the native conformation of the protein. Loss of water also leads to an increase in the salt concentration and osmotic pressure, which can accelerate protein denaturation. Lipoproteins are particularly sensitive to denaturation (e.g. those in egg yolk). The extent of the denaturation is limited in rapid freezing at very low temperatures, however, as smaller ice crystals are formed.

Denaturation of globular proteins also occurs at the interface of a protein with another phase (solid, liquid or gaseous). As a result of conformation changes, the molecule unfolds, the hydrophilic groups are oriented into the aqueous phase and hydrophobic groups into the less polar phase. This leads to partial denaturation of proteins in the presence of surfactants, for example in emulsions and foams (see Section 7.6.3.2.3). When whipping egg whites, partial denaturation occurs due to the mechanical stress, through the action of shear forces.

From the nutritional point of view, denaturation is usually desirable since denatured proteins are more amenable to digestive enzymes than the native proteins. Denaturation, therefore, increases the bioavailability of proteins (e.g. sulfur-containing amino acids in cereals and legumes). Some antinutritional and natural toxic substances are also denatured, such as protease inhibitors (see Section 10.2.1.1), lectins (see Section 10.2.2.6), enzymes and other unwanted proteins and undesirable microorganisms.

2.4.4 Physiology and nutrition

2.4.4.1 Fate of proteins in human organisms

The human organism is not able to use dietary proteins as such. They must be hydrolysed into single amino acid molecules before they can be absorbed. The hydrolysis of proteins (mostly denatured proteins) is catalysed by proteolytic enzymes called proteases (proteinases or peptidases), which have relatively high substrate specificity. They catalyse the hydrolysis of interior peptide bonds to form peptides of different sizes (endopeptidases such as pepsin, trypsin and chymotrypsin) or attack the terminal amino acids (exopeptidases). Hydrolysis of the *N*-terminal amino acids is

catalysed by aminopeptidases while carboxypeptidases hydrolyse amino acids from the *C*-terminus.

Protein digestion begins in the stomach. The gastric juices contain the endopeptidase pepsin created by the peptic cells of the gastric mucosa. Pepsin is released from the proenzyme pepsinogen in the acid medium of the stomach (pH 2), which is provided by the hydrochloric acid also secreted by the gastric mucosa. The major component of pepsin in adult mammals is pepsin A.[7] Protein hydrolysis by pepsin just gives smaller units, polypeptides. Digestion of polypeptides continues in the upper portion of the small intestine, the duodenum, through the action of the proteolytic enzymes trypsin and chymotrypsin, which are produced in the pancreas as the inactive proenzymes known as trypsinogen and chymotrypsinogen, respectively. They act in an alkaline medium in the small intestine and break down polypeptides into smaller peptides, which are hydrolysed to their component amino acids by a mixture of aminopeptidases and dipeptidases (known as erepsin) released by the mucosa. Free amino acids are absorbed across the intestinal mucosa into the lymphatic circulatory system and from there into the bloodstream.

The bloodstream provides a readily available pool of amino acids, which can be taken up by the liver and cells of various organs to support the reactions that are essential for life. The liver is the major site for synthesis of tissue proteins and for the conversion of excess amino acids into many other products. After deamination, the carbon skeleton enters the citric acid cycle and is used for the production of glucose (gluconeogenesis) and fatty acids and to generate energy through the oxidation of acetate into carbon dioxide and water. The resulting ammonia is converted into urea and excreted by the kidneys. This process overloads the body; therefore excessive protein intake, which could be used as a source of energy, is disadvantageous.

D-Amino acids that occur in dietary proteins and peptides are eliminated from the body in urine (10–20%) and the remaining D-amino acids are catabolised by the flavoenzyme D-amino acid oxidase to 2-oxo acids in the liver, kidneys and brain.

Tissue proteins are hydrolysed by thiol proteases called cathepsins (denoted by the letters B, D, L, H, S, M and T). They also act in post-mortem autolysis of proteins during meat curing.

Proteases have found practical application in various food and other technologies; for instance, rennin is used in the dairy industry for the manufacture of hard cheeses, while plant proteases, such as papain, are employed in the prevention of protein hazes in beer.

2.4.4.2 Nutrition

Dietary proteins are essential nutrients that provide adequate amounts of amino acids to allow the body to synthesise its own proteins and other nitrogen-containing compounds and serve as a source of energy. On average, proteins contain 16% nitrogen by weight.[8] Dietary protein requirements are determined by the need for essential amino acids and nitrogen, intake of other nutrients (carbohydrates and fat for energy intake), body weight, physical activity and so on. Specific needs include growth, pregnancy, lactation, illness or injury. The Recommended Dietary Allowances (RDA values) are: 1.5 g/kg/day for infants, 1.1 g/kg/day for 1–3 year old children, 0.95 g/kg/day for 4–13 year old children, 0.85 g/kg/day for 14–18 year old adolescents, 0.8 g/kg/day for adults and 1.1 g/kg/day for pregnant and lactating women. On average, based on the RDA data, the average male who weighs 70 kg should consume approximately 56 g of protein per day, while the average female who weighs 50 kg should consume approximately 40 g of protein per day. Many nutritional experts feel the RDA for protein is far too low and is only suitable for sedentary adults. For teenagers, active adults and some other people, the amount of dietary protein should be higher (1.2–1.8 g/kg). Research does not support protein intake in excess of 2.0 g/kg body weight. Excess protein intake is associated with body dehydration and may be related to excessive urinary calcium losses and inadequate carbohydrate intake. Inadequate protein intake can lead to disturbances in mental and physical development, decreased resistance to infection, deterioration of wound healing after injury and other problems.

The **energy yield** from proteins is 17 kJ/g (4 kcal/g), roughly the same as for carbohydrates (with the exception of sugar alcohols). The energy yield from fat (triacylglycerols) is about 37 kJ/g (9 kcal/g). Sugar alcohols, some organic acids and ethanol can also be used as a source of energy by the human body.

Nutrition recommendations indicate how much protein is needed by considering daily energy intake and the percentage of energy that should come from protein. Although carbohydrates are the body's preferred fuel source, approximately 20–30% of energy requirements should be derived from proteins. The U.S National Academy of Sciences has recommended that between 45 and 65% of energy should be derived from carbohydrates, 20–35% from fat and 10–35% from protein, with no more than 25% of the total energy being from added sugars. Recommendations by the American Heart Association and the American Diabetes Association fall well within these broad guidelines: approximately 50% of energy from carbohydrates, 30% from fat and 20% from protein. In other words, if the average male who weighs 70 kg consumes 9350 kJ (2200 kcal) per day and 20% of the energy is derived from protein, this amount of energy corresponds to 110 g of protein daily (1.6 g/kg body weight). The ratio of animal and vegetable protein should be about 1:1.

2.4.4.3 Protein nutritional value

The nutritional value of a food is mainly determined by the amount of protein it contains and the quality of that protein. Dietary protein quality depends on how well the essential amino acid content

[7] Rennin (chymosin) is another proteolytic enzyme secreted by the stomach of newborn mammals. Its role in digestion is to curdle (coagulate) milk in the stomach, which is a process of considerable importance in a very young animal. Aside from its physiological role, chymosin is also a very important industrial enzyme because it is widely used in cheese making.

[8] The amino acid contents of foods is often related to 16 g of nitrogen (i.e. 100 g of pure protein containing 16% of nitrogen). The nitrogen content of pure proteins and foods is in fact slightly different, meat and eggs contain 16% of nitrogen, egg white has a nitrogen content of 15%, gelatine 18%, milk and dairy products 15.7%, cereals (wheat, rye, barley and oats) 17.2%.

matches the requirements of the human body, on the availability of peptide bonds to digestive enzymes (protein digestibility) and how efficiently the amino acids are absorbed into the body for utilisation. Proteins from animal sources provide all of the essential amino acids in adequate amounts and are called **complete** (**whole**) **proteins**. Proteins of plant origin tend to be deficient in one or more of the essential amino acids and are termed **incomplete proteins**. The human body uses dietary essential amino acids in specific ratios to each other, so if a person does not get enough of one amino acid compared with the others, these other acids can only be used at a level comparable to that of the lower acid.

Proteins have different biological availabilities in the human body and a number of methods have been introduced to evaluate and measure protein utilisation and retention. Two types of measurements are used to estimate protein quality: biological assays and chemical analysis. The most common measures of protein quality included Biological Value (BV), Protein Efficiency Ratio (PER), Net Protein Utilisation (NPU), Amino Acid Score (AAS; also known as chemical score, CS), Essential Amino Acid Index (EAAI) and Protein Digestibility Corrected Amino Acids Score (PDCAAS), amongst other procedures and modifications.

The biological value is the proportion of nitrogen retained in the body compared with that of the nitrogen absorbed (taking no account of digestibility). A dietary protein that is completely utilisable (a complete or whole protein), that is, ingested, absorbed and incorporated into body proteins (such as eggs and human milk) has a BV = 90–100, while gelatine has BV = 0 as it does not contain the essential amino acid tryptophan (Table 2.7). The protein efficiency ratio is determined by dividing the weight gain of a test subject who had been given certain proteins by the intake of that particular protein during the test period. The net protein utilisation is the ratio of nitrogen retained (converted into proteins) to nitrogen supplied.

Table 2.7 Comparison of various methods for the evaluation of nutritional value.

Food	BV	NPU	PER	PDCAAS
Beef meat	74-80	67-73	2.7-2.9	0.92-0.94
Fish	76-83	78-80	2.7	0.9-1.0
Milk (cow)	84-91	81-82	2.5	1.00
Eggs (whole)	93-100	88-94	3.1-3.9	1.00
Whey protein	96	92	3.0	1.00
Casein	77-80	76	2.5	1.00
Wheat	54-64	67	0.8	0.37-0.54
Rice	83	40	1.5	0.54-0.78
Soybeans	73-74	48-61	2.3	0.91
Potatoes	73	60	1.8	0.71-0.82
Gelatine	0	0	0	0

[a]Colostrum (milk produced by the mammary glands in late pregnancy) has a different composition.
[b]EAA = essential amino acids.
[c]AA = amino acids.
[d]EAAI = essential amino acid index.
[e]AAS = amino acid score (for limiting amino acids).

The amino acid (chemical) score is expressed in milligrams of an amino acid in 1 g of the test protein divided by milligrams of the same amino acid in a reference protein. The essential (limiting) amino acid that has the lowest AAS value thus determines the nutritional value of a protein. The reference protein is a protein of high nutritional value (such as β-lactalbumin) with balanced amounts of all essential amino acids. The AAS value for each of them is 100%. The composition of the reference protein is shown in Table 2.8, which also gives the recommended daily intake of essential amino acids in adult humans. These values depend on nutritional and health status, age and other individual factors, and have undergone considerable revision in recent years. The AAS value only takes one amino acid into account. More accurate data on the nutritional value of proteins are provided by the index of essential amino acids, which includes the contributions of all the essential amino acids as the geometric mean of the AAS values. The calculated AAS and EAAI values for meat, chicken and fish are given in Table 2.9, for milk in Table 2.10, for eggs in Table 2.11, for cereals and pseudocereals in Table 2.12, and for legumes, oilseeds and nuts in Table 2.13. The protein digestibility corrected amino acids score is a more recent method to evaluate protein quality. It is based on both the amino acid requirements of humans and their ability to digest it. It is expressed in milligrams of limiting amino acid in 1 g of test protein divided by milligrams of the same amino acid in 1 g of the reference protein (which corresponds to AAS), and multiplied by faecal digestibility percentage (Table 2.7).

In human nutrition, which assumes a varied and well balanced diet, the evaluation of the nutritional quality of proteins is not

particularly important. An exception may be some extreme diets (such as those of vegans), which might not supply some essential amino acids in sufficient quantities. The evaluation of protein quality in feeds for livestock and poultry is important in cases requiring rapid muscle growth or high yields of milk or eggs. In these cases, feed is often enriched (fortified) with limiting amino acids, mostly lysine and methionine, which increase its nutritional value.

2.4.5 Occurrence, composition and changes

Foods differ considerably in their protein contents, and the protein contents vary in their amino acid compositions and quality. The protein contents can effectively vary anywhere between 0 and 100% of the dry matter The richest sources of protein are mainly foods of animal origin (Table 2.14). For example, the amount of protein in dried egg whites approaches 100% whereas refined vegetable oil does not contain any protein at all. However, some products from plant origins, especially legumes (peas, beans, lentils) and oilseeds (soybeans, peanuts, poppy seeds, nuts) are also good protein sources. Cereals and cereal products have medium protein content, while vegetables, fruits and root crops have a low protein content (Table 2.15). Vegetable oils, vinegar and sugar contain only traces or no protein at all.

2.4.5.1 Meat, meat products, poultry and fish

Animal cells produce four main types of tissue:

- **epithelial** tissue
- **connective** (supporting) tissue

- **muscle** tissue
- **nervous** tissue.

Epithelial tissues cover the whole surface of the body and the digestive tract. Connective tissues are present in cartilages and bones; adipose tissue is also a connective tissue. Muscle tissue covers the bones and is the building material of the gut. Nervous tissue is a major part of the nervous system, which is divided to the central nervous system (nervous tissue of the brain and spinal cord) and the peripheral nervous system. Blood is often classified as an additional tissue. Almost all tissues of animals are used as food for humans, especially the meat of mammals, poultry and fish. The term meat generally means the skeletal muscle and associated fat and tissues, but it may also describe other edible tissues such as organs and offal of mammals, poultry and fish. A typical consumer connects the very vague term meat with a product that, besides muscle tissue, contains a certain proportion of epithelial and connective tissue (such as skin, fat, cartilage and bones). The main types of muscles that are used as food are skeletal muscles, the smooth muscles of the digestive tract and internal organs and cardiac muscle tissue.

In addition to water and proteins, meat commonly contains about 1.5% fat (although in some meats this can be much more, such as pork belly which can contain >50% fat), about 1% minerals and small or trace amounts of carbohydrates. The glycogen content in muscle tissue is 1–2%, but its amount decreases very rapidly post-mortem and meat usually contains only a small part of the original amount, a typical concentration is about 0.2%. Meat also contains sugar phosphates (mainly glucose 6-phosphate,

see Section 4.2.2.1) in small amounts (0.05–0.2%) and some free sugars (mainly glucose).

Muscle proteins in typical mammalian muscle tissue constitute around 20% of the muscle weight. The major proportion of muscle is made up of muscle fibre proteins (elongated, threadlike cells) called **myofibrillar proteins**. Smaller amounts of soluble **sarcoplasmatic proteins** and insoluble **structural proteins** from connective tissue are also present (Table 2.16). Myofibrillar and sarcoplasmatic proteins are almost complete (whole) proteins, while the nutritional value of structural proteins is very low as they are almost indigestible. Table 2.17 gives the amino acid composition of some pure animal proteins; Table 2.9 presents the amino acid compositions for the main types of meat proteins.

In addition to proteins, the other nitrogen compounds present in meat are free amino acids. The level of the individual amino acids is about 0.005% (their total amount is 0.1–0.3%); alanine (about 0.01%), glutamic acid (about 0.05%) and taurine (0.02–0.1%) occur in somewhat higher concentrations, followed by histidine dipeptides and guanidine compounds such as creatine and creatinine. Important groups of nitrogenous compounds are purine and

pyrimidine nucleotides, nucleosides and free bases (0.1–0.25%). Rigor mortis usually sets in between 2 and 4 hours after death and within approximately 1 hour post-mortem the main nucleotide in meat is ATP. After rigor mortis dissipates, 5′-inosinic acid (also known as 5′-inosine monophosphate or 5′-IMP) predominates at a level of 0.02–0.2%, this being formed by the enzymatic decomposition of ATP. The inosinic acid then gradually decomposes during the storage of meat to inosine and hypoxanthine. In addition to IMP, ATP and its breakdown products, ADP and AMP, and other purines and pyrimidines (mainly NAD, 5′-GMP, 5′-CMP and 5′-UMP) occur in small quantities. The other compounds present in significant amounts are numerous organic acids. The main acid is lactic acid, and in fresh meat the content ranges from 0.2 to 0.8%. Glycolic acid (about 0.1%) and succinic acid (about 0.05%) are also present at relatively higher levels, and other acids of the citric acid cycle in lower amounts. Another important group of nutrients present in meat are vitamins. In general, meat is a good source of all vitamins, particularly of water soluble vitamins.

2.4.5.1.1 Myofibrillar proteins

The basic structural unit of skeletal muscle is a muscle fibre composed of long, cylindrical cells of 10–100 μm in diameter and lengths of up to several tens of mm (usually 20–30 mm). Each muscle fibre is actually a muscle cell containing 100–200 nuclei and normal cell organelles. The muscle fibre is covered by a thin, extensible, semi-permeable membrane, the sarcolemma (or myolemma), which transmits electrical impulses from the nerves. It consists of a cell membrane (plasma membrane) and an outer coat made up of a thin layer of polysaccharide material with numerous thin collagen fibrils. The sarcoplasm of a muscle fibre is comparable to the gel-like cytoplasm of other cells.

Muscle cells contain contractile elements, **myofibrils**, which are essentially bundles of proteins found in the sarcoplasm (Figure 2.23). Muscle myofibrils contain isotropic sections (I-bands about 0.8 μm long) and anisotropic sections (A-bands about 1.5 μm long). The I-band is interrupted by a Z-line about 80 nm wide. The low-density central part of the A-band of is the H-zone. The M-line is situated in the centre of the H-zone. The entire structural unit of myofibrils, which is the span between two Z-lines, is called the sarcomere. In a relaxed state (relaxed muscle), it is about 2.5 μm long. During muscle contraction (shortening) it is shorter, 1.7–1.8 μm.

Myofibrils are composed of two types of protein microfilaments (microfibers). Strong microfilaments have a diameter of 12–16 nm and a length of 1.5 μm. They are composed of the protein myosin, which exhibits ATPase activity. Thin filaments, with a diameter of 8 nm and a length of 1 μm, are predominantly composed of the protein actin (Figure 2.24). Other components of microfilaments are proteins with regulatory functions such as tropomyosin, troponin and other proteins that are important for the stability of the sarcomer structure (Table 2.11).

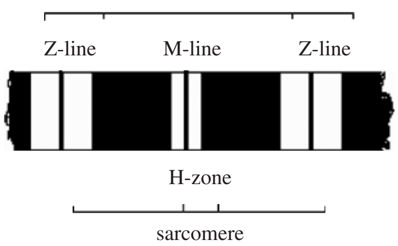

Figure 2.23 Muscle myofibril.

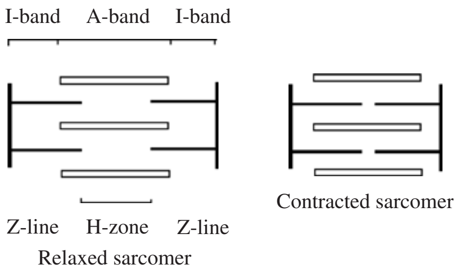

Figure 2.24 Arrangement of actin and myosin (— = actin, ▭ = myosin).

Myosin has a relative molecular weight of about 470 kDa. The molecule contains a fibrillar section, formed by two identical polypeptide chains, largely found in the α-helix conformation. The fibrillar portion of the molecule is connected to a globular head, consisting of four chains with a relative molecular weight of about 20 kDa, which is responsible for ATPase activity of the protein.

Actin is a one-chain globular protein with a relative molecular weight of 43.5 kDa (G-actin, where G stands for globular). This monomeric form polymerises to yield a fibrous form of actin (F-actin, where stands F for fibrous). The units of G-actin are organised into a helix composed of two monomers. This polymer binds to the protein tropomyosin (relative molecular weight 70 kDa), which has a similar structure to the fibrillar part of myosin (two unequal polypeptide chains, essentially curled into an α-helix). The actin is further connected to the regulatory troponins proteins (troponin complexes C, I and T) with relative molecular weights of 18, 24 and 37 kDa, respectively.

In muscle, actin and myosin molecules are able to associate to form a protein complex, actomyosin. Calcium ions lead to this association, and ATP causes the dissociation of the actomyosin. These are the fundamental processes required for muscle activity (contraction and relaxation). The primary process during muscle contraction is the release of calcium ions (e.g. from the sarcoplasmic reticulum) initiated by a nerve impulse. Calcium ions bind to troponin, changing the formation of the molecule, which causes a formational change of tropomyosin and consequently of the actin molecule. Actin then reacts with myosin, forming actomyosin, which results in a shortening of the sarcoma, that is, shortening (contraction) of the whole muscle. During the process of muscle relaxation, the actomyosin complex dissociates through the action of ATP, to give actin and a myosin–ATP complex, which hydrolyses to myosin, ADP and inorganic phosphate. Under normal conditions, ATP is synthesised from pyruvic acid, through the process of glycolysis. In extreme cases (during short, intense exercise or post-mortem), formation of ATP is less efficient, as it is a product of anaerobic glycolysis (from glucose or glycogen) via lactic acid.

2.4.5.1.2 Sarcoplasmic proteins

The sarcoplasm of muscle tissue contains on average 1% myoglobin (9-5) in the dry state (Table 2.16). Its main role is to facilitate the transport of oxygen by diffusion in muscle *in vivo*. In the muscles of aquatic mammals, where its content is about ten times higher than in the muscles of terrestrial mammals, myoglobin also acts as an oxygen reserve. The levels of myoglobin generally depend on the type and origin of the muscle. Besides myoglobin, sarcoplasm contains various enzymes, especially glycolytic enzymes and enzymes from the pentose cycle along with numerous other compounds, such as glycogen, ATP, ATP degradation products and so on.

2.4.5.1.3 Structural proteins

The structural proteins form a specific group of extracellular proteins with protective or supporting roles. They include fibrillar proteins, the most important of which are collagens, elastins and keratins. Their nutritional value is usually low (collagen) or almost nil (elastin, keratin) due to their poor digestibility and inappropriate composition of amino acids.

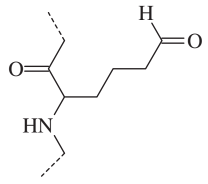
Collagens

Collagens are insoluble extracellular glycoproteins that can be found in all animals. They are the most abundant proteins in the human body (29 different types can be identified). Collagens occur in nearly all connective tissues (skin, cartilage, tendons, filaments and bones). Type I collagen is the main component of tendons, ligaments, skin and bones. Type II collagen is the main component of cartilage.

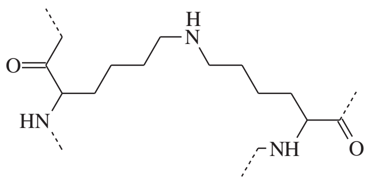
The fundamental structural unit of collagen is the tropocollagen molecule (relative molecular weight about 300 kDa, thickness 1–2 nm and length of ≤300 nm), which consists of a helical structure of three polypeptides, each with molecular weight of about 95 kD. Type I collagen is the most abundant and consists of two chains of α_1 collagen and one chain of α_2 collagen, each having a left-handed helix formation. These three helices are twisted together into a unique right-handed triple helical structure (a heterotrimer known as a super helix), which is stabilised by hydrogen bonds. With type I collagen, each triple helix of tropocollagen naturally aggregates with other triple helices to form a collagen microfibril (thickness <5 nm and length ≤500 nm), which is a right-handed super-super-coil. Cross-linking of collagen microfibrils (catalysed by lysyl oxidase) produces collagen fibres (thickness ≤500 nm and length ≤10 mm). Type I collagen molecules give tissues their mechanical strength and provide the major scaffolding units for the attachment of cells and macromolecules (such as integrins, fibronectin, fibromodulin and decorin). In bones and dentin, the type I collagen is mineralised with hydroxyapatite crystals.

The amino acid composition of collagen is anomalous in comparison with other proteins. Collagen contains high amounts of glycine (30%), proline (about 12%) and also contains hydroxyproline (10%) and 5-hydroxylysine (about 0.5%, Table 2.17). The amino acid sequence is composed of repeating units of Gly-XY, where X is often proline and Y is hydroxyproline or hydroxylysine. The free hydroxyl groups of the peptide chains (derived primarily from hydroxylysine) contain glucose or galactose bound by glycosidic bonds. For example, one fragment of the molecule is 2-*O*-α-D-glucosyl-*O*-β-D-galactosylhydroxylysine. Sugars represent between 0.4 and 12% of collagen molecules by weight. Collagens in connective tissues are accompanied by proteoglycans.

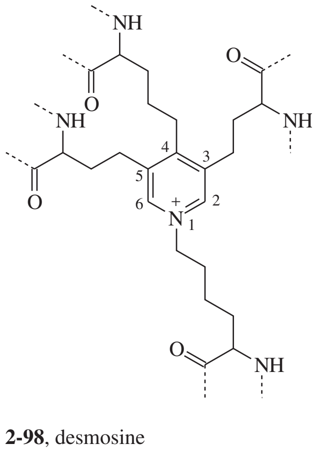
With age, the structure of collagen is stabilised by covalent cross-links. These are formed not only by disulfide bridges (collagen contains low amounts of cysteine, unlike keratin), but also by cross-links from the side chains of lysine, hydroxylysine and histidine. For example, the enzyme lysyl oxidase[9] catalyses the oxidation of lysine (hydroxylysine is oxidised analogously) to the corresponding ω-aldehyde, that is, adipic acid monoaldehyde, or allysine (**2-96**). Two molecules of allysine generate an aldol, which then reacts with the side chains of lysine and histidine to produce imine; these compounds are then stabilised by a reduction or an oxidation. For example, the reaction with lysine followed by imine reduction yields lysinonorleucine (**2-97**). Condensation of three allysine structures in a side chains with the side chain of bound lysine produces cyclic structures derived from pyridine (substituted in positions 1, 3, 4 and 5 of the nucleus). Such structures are desmosine (**2-98**), dihydrodesmosine, tetrahydrodesmosin or pyridines substituted in other positions. The formation of these structures is one of the causes of toughness in meat. Desmosine is also present in elastin.



2-96, allysine



2-97, lysinonorleucine



2-98, desmosine

[9]Lysyl oxidase is inhibited by β-aminopropionitrile formed in some vetchling seeds (*Lathyrus* spp.), which leads to disturbances in the collagen structure with characteristic distortion of limbs and damage to blood vessels. These diseases are known as osteolathyrism and angiolathyrism, respectively (see Section 10.3.2.7.1).

Collagen is hydrolysed by proteases known as collagenases. Collagen denatured in muscle by lactic acid is hydrolysed during the maturation of meat by other enzymes, such as cysteine proteinase (kathepsin B_1). Heat-denatured collagen is hydrolysed by pepsin and trypsin.

Collagen does not dissolve in cold water, salt solutions or dilute solutions of acids and bases. Its characteristic feature is the contraction (shortening of the molecule) when heated to a certain temperature, which is also observed on cooking meat. This form is sometimes referred to as collagen B, while native collagen is known as collagen A. The temperature at which collagen shrinkage occurs depends on its origin. For example, the shrinkage of fish collagen starts at about 45 °C, but mammalian collagen shrinkage occurs at 60–65 °C.

At higher temperatures (approximately 90 °C), the structure of the molecule breaks, the bonds between the polypeptide chains disrupt and each tropocollagen molecule is released to form a soluble sol of gelatine. The sol consists of mixtures of the original polypeptides together with their oligomers and breakdown products. Upon cooling (depending on the concentration of the gelatine and the temperature gradient), a more or less organised structure re-forms again. The new bonds are restored randomly between different parts of the same string or between two strings. The coil–helix transition, followed by aggregation of the helices, leads to the formation of collagen-like right-handed triple-helical proline/hydroxyproline-rich junction zones, similar to the original collagen structure, composed of three polypeptide chains. These structures capture large amounts of water and the gelatine sol forms a gel. Higher concentrations of the proline/hydroxyproline-rich junction zones form stronger gels (see Section 7.6.3.2.3).

Gelatine can also be produced from collagen during cooking, baking and other thermal processing of meat. The extent of gelatinisation depends on the number of cross-links present in the collagen, and therefore also on the age of the animal and the parameters of the thermal process (temperature, time, pressure). Long-term effects of higher temperatures lead to changes in the primary structure of collagen or gelatine (namely, their partial hydrolysis).

Edible gelatine is made from collagen after partial extraction with water, and partial acid (type A gelatine) or alkaline (type B gelatine) hydrolysis. The acid treatment uses pig skin, whereas the alkaline treatment makes use of cattle hides and bones. This gives rise to products with different molecular weights and properties (the alkaline treatment converts asparagine and glutamine residues into their respective acids and results in gelatine with a higher viscosity). Gelatine is primarily used as a gelling agent, forming transparent elastic thermoreversible gels on cooling. In addition, the amphiphilic nature of the molecules endows them with useful emulsification (e.g. in whipped cream) and foam-stabilising properties (as in mallow foam). On dehydration, irreversible conformational changes take place that may be used in the formation of surface films. Gelatine is also used as a clarifiyng agent for wine and fruit juices.

Collagen from the skin dermis is used for the production of collagen casings used in the edible packaging material of sausages. Collagen casings are mainly produced from the corium layer (splits) of cattle hides that consist essentially of collagen (although collagen can also be derived from pigs, poultry and fish). The hides are chopped in water and mixed with lactic acid, which causes them to swell and form a slurry. The acid-swollen slurry is homogenised and filtered to tease the collagen fibres apart. The resultant slurry containing separated collagen fibres is extruded into the casing form. The proteins are then coagulated in a solution of an inorganic salt, plasticised with glycerol, dried, partially re-humidified, wound on reels and shirred.

Elastins

Elastins are insoluble rubber-like proteins conferring elasticity on tissues and organs. Elastin accompanies collagen in a number of connective tissues, undergoing reversible deformations in tendons, blood vessel walls, lung parenchyma, ligaments, skin, tissue membranes and cartilage; it is not hydrolysed by common proteolytic enzymes, but only by the action of specific elastases.

Unlike collagen, elastin is a very flexible net-like structure found in organisms in the form of fibres. The fundamental building component of elastin is the soluble protein tropoelastin that has a relative molecular weight of about 70 kDa and is formed from the soluble precursor, proelastin. Tropoelastin accumulates on the cell surface in small particles that grow into larger spherules (about 1 μm in diameter). The net-like structure of insoluble elastin is based on the association of many cross-linked tropoelastin molecules that are oxidised by lysyl oxidase enzymes at bound lysine molecules, which subsequently undergo aldol condensation and imine formation. One of these cross-links is desmosine (**2-98**) and its isomer isodesmosine (unlike in desmosine, the side chains are in positions 1, 2, 3 and 5 of the pyridine ring). The process of elastic fibre formation includes a number of other molecules. The elastin that is produced is introduced into microfibrils in the extracellular matrix as the central part and interacts with proteins known as fibulins, which form the sheath of these fibres.

Keratins

Keratins are products of epithelial cells. They occur in the outer skin layer (epidermis), and in some skin structures (fur, horns and hooves). The main group are the so-called α-keratins, based on a right-handed polypeptide with an α-helical structure and molecular weight of 10–50 kDa, stabilised by disulfide bridges and hydrogen bonds. Three polypeptides form left-handed helices called protofibrils and 11 protofibrils (two inside and nine outside) create microfibrils. Several hundred microfibrils create macrofibrils that finally form the keratin fibre (e.g. hairs and wool fibres).

Keratins have limited uses in the food industry. In combination with vegetable protein-rich materials, keratin is sometimes used for the production of acid protein hydrolysates (hydrolysed vegetable proteins used as food seasonings). Outside the food industry, alkaline hydrolysis of keratin is used for the production of glues.

2.4.5.1.4 Blood proteins

Blood is a distinct liquid tissue of higher animals, ensuring the transfer of nutrients and metabolic products, gas exchange, metabolic and heat balance. It is also important in the defence reactions of the organism used in self-protection, such as immunological response and coagulation involved in clotting. Blood represents about 5%

of live weight of cattle (cows, calves), 3.3% for pigs and 8% for poultry. In fresh weight, it contains about 80% water (80.5% in beef blood, 79.2% in pork blood) and around 18% protein (17.8% in beef blood and 18.5% in pork blood). About 40% of blood consists of blood cells of which about 94% are erythrocytes containing the blood pigment haemoglobin, 6% thrombocytes and 0.1% leukocytes. About 60% of blood is plasma, which has a dry matter content of 10%. About 6.5–8.5% of this dry matter is albumins and globulins that are present in a ratio of 1.5:1, and 0.3–0.4% of the dry matter is fibrinogen. Blood contains about 0.1% lipids, 1% minerals (mainly phosphates and chlorides of sodium and potassium ions; calcium, magnesium, iron and other ions are present at lower concentrations), small amounts of sugars (0.06–0.07%), free amino acids, vitamins and other low molecular weight nitrogenous substances (urea, creatine and creatinine).

Blood from farm animals is an important raw material for food, feed and industrial use. Clotting of the blood is prevented by binding the calcium ions using citric or phosphoric acids. In the food industry blood drawn aseptically from slaughtered pigs is used to produce some speciality products (e.g. blood sausages and black puddings). Dried blood plasma is used to replace egg whites in baking and in the confectionery industry, while protein fibrin resulting from fibroin can be used for making soup spice preparations (such as acid protein hydrolysates and stock cubes). Dried or cooked blood is also used as feed for livestock and in the production of various veterinary and human medicines and for other technological purposes.

2.4.5.1.5 Changes during storage and processing

After death (post-mortem), a sequence of important biochemical, structural and functional changes occur in the bodies of slaughtered animals when muscle tissue is converted into meat. Although the post-mortem changes proceed in a relatively orderly fashion, a variety of external factors and intrinsic characteristics may accelerate or retard meat maturation and have a marked effect on the quality of the meat. Other important changes occur during thermal processing of meat and during the manufacturing of meat products.

Post-mortem changes and meat maturation

In contrast to tissues *in vivo*, only anaerobic glycolysis takes place in muscles post-mortem, until the muscle glycogen store is depleted and the glycolytic enzymes are inactive. The lactic acid that is formed accumulates in the muscle tissue, which results in a decrease in muscle pH from the initial value of about 6.8 to about 5.8. The glycolytic enzymes are inhibited in this acidic medium and a small proportion of glycogen therefore remains preserved in the muscle. Even after the death of an animal, calcium ions still lead to the interaction of actin with myosin and hydrolysis of ATP to ADP and inorganic phosphate; however, ATP for dissociation of the resulting actomyosin is no longer available. The muscles therefore contain actomyosin, they are shortened (contracted) and the posthumous stiffening (rigor mortis) begins. A muscle, which is soft immediately after the death of the animal, hardens within a few hours. In cattle at normal room temperatures, rigor mortis takes 10–24 hours post-mortem, and this is 4–18 hours in pigs and 2–4 hours in chickens. Rigor mortis then gradually subsides, for example, after 2–3 days post-mortem in beef, or more slowly at lower temperatures. Immediately after killing the animal the meat is dry, and binds its own water and any added water well, as it has a high water binding capacity. In rigor mortis, when lactic acid acidifies the meat, the muscle proteins are present in an environment with a pH around their isoelectric points. The meat is moist-to-wet and its binding capacity is often half or lower than immediately after killing the animal. It is therefore advantageous to produce some meat products before the onset of rigor mortis (in the so-called warm state), otherwise the meat can only be processed after rigor mortis subsides and after maturation, when the pH and binding capacity will increase slightly. To increase the binding capacity of meat, different food additives are used (see Section 11.3.3.1). In practice, meat in rigor mortis cannot be cooked as it remains rigid and does not have the desirable organoleptic properties. During maturation, the cleavage of actomyosin and of other meat proteins is due to the action of specific proteases that include a variety of endogenous enzymes of sarcomers and lysosomal enzymes (cathepsin B, D and L), while colagenases break down collagen fibres. The meat acquires its desirable properties, its texture improves and it becomes suitable for industrial and culinary processing.

Meat defects

Irregularities (defects) of meat known as PSE (pale-soft-exudative meat) and DFD meat (dark-firm-dry meat) occur in pork meat as a result of sensitive animals being subjected to stress. There are a variety of environmental conditions that can cause stress in animals. Some of these include extremes in temperature, humidity, light, sound and confinement. Other stress factors are excitement, fatigue, pain, hunger and thirst. These two defects can occur simultaneously in different types of muscle in the same animal. In beef, although the PSE defect does not occur, a defect similar to DFD meat is seen, known as DCB (dark-cutting-beef), where meat is dark on the cut.

PSE meat is more acidic than normal meat (the pH 1 hour post-mortem is around 5.6 instead of 5.8 and this value lasts much longer than 24 hours). The reason is faster and more extensive glycolysis, resulting in a faster and higher production of lactic acid (glycogen is synthesised from proteins by various mechanisms catalysed by hormones). In the acidic environment the muscle proteins are partially denatured. As suggested by the name, the affected meat has a lighter colour, and its ability to bind water decreases (it contains less protein and more thiol groups and disulfide bridges). The fluid is released from the tissue and may drip from the surface, which leads to weight loss during storage and thawing of frozen meat.

In the DFD and DCB meats, the acidification 1 hour post-mortem results in a pH around 6.5 instead of 5.8 (the pH 24 hours post-mortem is about 6.3), which is explained by the loss of lactic acid in the blood while bleeding the animal. The result is meat with a high water binding capacity, but the meat consistency is stiff and the meat is dark. An additional problem with this type of meat is that it is more susceptible to spoiling since it lacks lactic acid, which normally impedes the growth of microorganisms after slaughter.

Appropriate handling of animals before and during slaughter can greatly reduce their discomfort and stress. This includes proper feeding and rest, as well as the use of suitable techniques for moving and transporting animals.

Thermal processing

During heat processing of meat, the first conformation changes to proteins occur at temperatures around 35 °C, when proteins in the sarcoplasm associate into unstable structures, reducing the water binding capacity of the meat and increasing its rigidity. The first visible changes occur at around 45 °C as a result of shortening of the muscles caused by myosin denaturation. At 50–55 °C actomyosin denatures, and between 55 and 65 °C the sarcoplasmic proteins denature (including globins bound to myoglobin and haemoglobin). Depending on the intensity and duration of the thermal processing, more severe changes in the structure of haematin occur (the central iron atom splits off and the porphyrin skeleton is degraded). As a result, the red colour of meat changes to reddish–brown and finally to grey–brown. Myoglobin is often stabilised by adding sodium nitrite to many meat products (see Section 9.2.1.5.3).

Denaturation of actomyosin and sarcoplasmatic proteins creates stable associated structures and a firm, solid gel (partial denaturation may also occur during local overheating, such as during meat grinding). Changes to the colour of meat are caused by oxidation of haem to haematin. The coagulation of proteins reaches a maximum at temperatures of 60–65 °C, which is followed by conformational changes (shrinkage to about a third or a quarter of the original length) of the collagen molecules (for fish this occurs even at 45 °C). At temperatures above 80 °C, virtually all myofibrillar and sarcoplasmic proteins are coagulated, and free thiol groups of actomyosin are oxidised to disulfide groups. Around 90 °C, collagen gelatinises and the water binding capacity of meat increases. At temperatures around 100 °C (during boiling of meat), there are also some chemical changes to the protein molecules. Significant reactions include desulfuration and deamination of proteins, yielding hydrogen sulfide and ammonia, which have an important impact on the development of the aromatic and taste properties of meat. These reactions are accompanied by a certain loss of cysteine/cysine and lysine.

Thermal processing of foods at temperatures around 150 °C (e.g. during baking) is much more complex than the reactions at 100 °C. The result is a certain loss of all amino acids, but also the formation of typical flavour substances. Processing at temperatures around 200 °C and higher in the surface layers of roasted, fried and grilled meat leads, in a greater extent, to the isomerisation of native L-amino acids bound in proteins to the corresponding D-amino acids and to less usual cross-links, such as lysinoalanine (see **2-121**). Some amino acids (such as tryptophan) and other nitrogenous compounds (such as creatinine) can produce toxic products (see Section 12.2.1.1), which are present at significant concentrations in grilled meat.

Drying meat and meat products (such as durable salami) leads to a significant aggregation of actomyosin molecules that partially denature, if they have not previously been denatured by heat, and the toughness of the meat or meat products increases. Freezing meat also induces significant changes in the structure of proteins. Myosin gradually denatures and associates with actin. This greatly strengthens the structure and decreases the water binding capacity of meat. However, these reactions do not significantly affect the nutritional value of meat. The texture and nutritional value of long-term stored frozen meat is, however, considerably influenced by reactions of proteins with oxidised lipids. Significant changes to proteins occur in the surface layers of smoked meat due to reactions with reactive aldehydes, such as formaldehyde and glyoxal, which form cross-links between polypeptide chains. Smoked products (e.g. meat and sausages) thus obtain a smooth and rigid surface.

2.4.5.2 Milk and dairy products

The main component of milk is water. Its content can vary considerably, according to the origin. Cow's milk contains 87–91% water. The basic chemical composition of cows', goat's and sheep milk in comparison with human milk is shown in Table 2.18. The amino acid composition of milk is given in Table 2.10.

Milk is a very complicated dispersed system (see Section 7.6.3.2.1) in which casein molecules form a micellar dispersion, globular whey proteins a colloidal dispersion, fat present in the form of fat droplets (milk microsomes) forms an emulsion, particles of lipoproteins form a colloidal suspension and low molecular weight substances (lactose and other sugars, amino acids, minerals and water soluble vitamins) form true solutions. Milk's typical white colour is related to the scattering and absorption of light by the fat particles and casein micelles. The yellowish colour that is sometimes seen is caused by carotenoid compounds dissolved in the fat phase (cream and butter), while the greenish colour of whey is caused by riboflavin.

The protein composition of cows' milk is shown in Table 2.19. Milk proteins are a mixture of two main types of proteins:

- **caseins** (approximately 80% of milk proteins)
- **whey** (**serum**) **proteins** (about 20% of milk proteins).

Table 2.18 Nutrient contents of milk.

Component	Content (%)			
	Cow's milk	Goat's milk	Sheep milk	Human milk
Total protein	3.2	3.2	4.6	0.9[a]
Caseins	2.6	2.6	3.9	0.4
Whey protein	0.6	0.6	0.7	0.5
Fat	3.9	4.5	7.2	4.5
Saccharides	4.6	4.3	4.8	7.1
Minerals	0.7	0.8	0.9	0.2

[a] The protein content increases during lactation to 1.6%.

Table 2.19 Protein composition of cow's milk.

Protein	Proportion (%)	Content (g/l)	Protein	Proportion (%)	Content (g/l)
Total caseins	80	25.6	***Total whey proteins***	20	6.4
α_S-Casein	42	13.4	α-Lactalbumin	4	1.3
β-Casein	25	8.0	Serum albumin	1	0.3
γ-Casein	4	1.3	β-Lactoglobulin	9	2.9
κ-Casein	9	2.9	Immunoglobulins	2	0.6
			Polypeptides (proteoses, peptones)	4	1.3

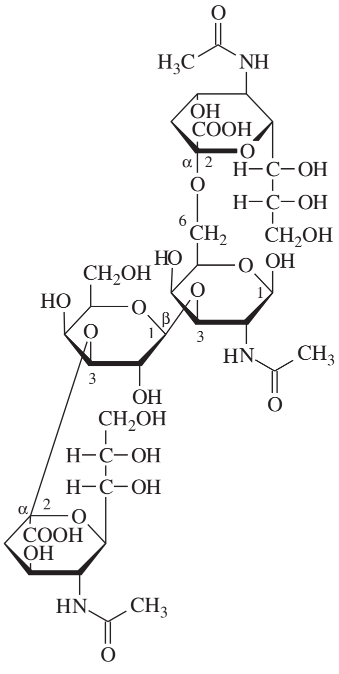
2.4.5.2.1 Caseins

The main components of the casein fraction in bovine milk are α_S-caseins. Bovine milk contains phosphoprotein α_{S1}-casein and α_{S2}-casein, both occurring in four genetic variants, identified by the letters A, B, C and D, which differ somewhat in their primary structure. The most common variant is B, which is a polypeptide chain composed of 199 amino acids (molecular weight 23.6 kDa, pI = 4.92–5.35). α_S-Caseins comprise from 44 to 55% of the total caseins and α_{S1}-casein comprises approximately 80% of the total α_S-caseins. The polypeptide chain contains eight phosphoserine residues located mainly at positions 43–80, which makes this part of the molecule polar. Non-polar side chains of amino acids are located in positions 100–199. α_{S1}-Casein forms insoluble calcium salts in the presence of calcium ions. Fragments of α_{S1}-casein are considered to be λ-casein. α_{S2}-Casein has a similar structure (molecular weight 25.2 kDa), but is less sensitive to the presence of calcium ions.

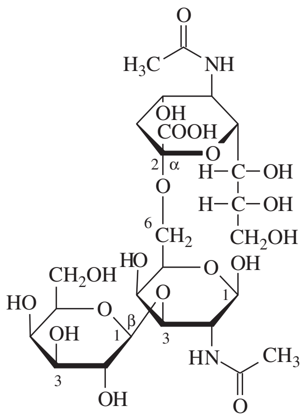
β-Casein comprises from 25 to 35% of the total casein. Polypeptide chains of β-casein consist of 209 amino acid residues (molecular weight 24 kDa, pI = 5.20–5.85). Each variant fits into one of two main categories known as A1 and A2. In cattle, A1-type β-caseins have the amino acid histidine at position 67, whereas the A2-type β-caseins have the amino acid proline at this position. They are also phosphoproteins, as they contain five phosphoserine residues (in positions 1–40). Non-polar side chains of amino acids are concentrated in positions 136–209. β-Caseins form soluble salts with calcium ions at temperatures of 1 °C and lower, which is insoluble at higher temperatures. Human β-casein is the major protein found in human milk.

The group of caseins (amounting to 3–7%) were in the past known as γ-caseins. γ-Caseins (pI = 5.8–6.0) are degradation products of β-caseins as a result of the action of indigenous milk proteinase (plasmin). Plasmin causes hydrolysis of β-casein, especially in late lactation and prior to milking. Splitting off the residue with amino acids 1–28 yields γ_1-casein (with a molecular weight of 20.5 kDa) and proteose-peptone-labeled PP8F, γ_2-casein (with a molecular weight of 11.8 kDa) is created by splitting off the amino acid residues 1–105 and γ_3-casein (with a molecular weight of 11.6 kDa) is formed by splitting off the amino acid residues 1–107.

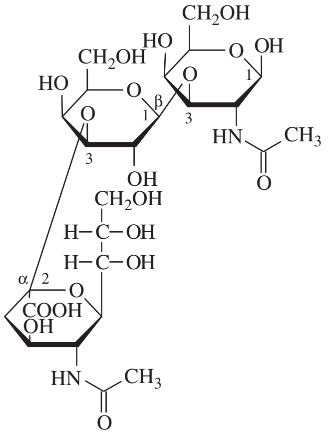
κ-Caseins occur in two genetic variants (A and B) in cow's milk, which represents about 8–15% of caseins. The molecule of the more common variant B is composed of 169 amino acid residues (molecular weight 18 kDa, pI = 5.37). The molecules occur as trimers and higher oligomers connected by disulfide bridges. Unlike the previous caseins α and β, κ-caseins are glycoproteins containing bound oligosaccharides composed of D-galactopyranose (D-Gal*p*), *N*-acetyl-D-galactosamine (D-Gal*p*NAc) and *N*-acetylneuraminic acid (NeuAc). The main component of κ-caseins (56.0%) is a branched tetrasaccharide (**2-99**), κ-caseins coupled with branched trisaccharides (18.5%, **2-100**), linear trisaccharides (18.4%, **2-101**), disaccharides (6.3%, **2-102**) and *N*-acetyl-D-galactosamine (0.8%) are found in smaller amounts. Sugars are bound to the protein via threonine at position 133 of the peptide chain through the glycosidic bond of *N*-acetyl-β-D-galactosamine (**2-103**). Calcium ions form soluble salts with κ-caseins that stabilise α_{S1}- and β-caseins in milk.



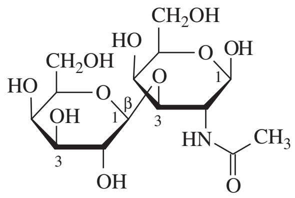
2-99, α-NeuAc-(2→3)-β-D-Gal*p*-(1→3)-β-D-Gal*p*NAc-(6→2)-α-NeuAc



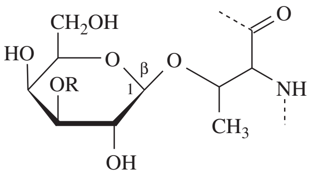
2-100, β-D-Gal*p*-(1→3)-β-D-Gal*p*NAc-(6→2)-α-NeuAc



2-101, α-NeuAc-(2→3)-β-D-Gal*p*-(1→3)-β-D-Gal*p*NAc



2-102, β-D-Gal*p*-(1→3)-β-D-Gal*p*NAc



2-103, β-D-galactosamine residue in κ-caseins bound to threonine

Caseins in milk do not occur as monomers, but are aggregated into casein complexes and spherical particles called **micelles** (see Section 7.6.3.2.1). Caseins β and γ can easily associate into polymeric structures at about 20 °C, while at temperatures <8 °C they dissociate back to the monomers. The aggregation of molecules of α_S-, β- and κ-caseins into micelles occurs at temperatures >5 °C. Molecules of α_S-, β- and κ-caseins are first arranged into particles called **submicelles**, which have the shape of a rotating ellipsoid, and contain 25–30 protein molecules (Figure 2.25). The non-polar parts of molecules of caseins are oriented to the submicelle centre and bound through hydrophobic interactions. The polar molecules of caseins, that is, phosphoserine residues of α_S- and β-caseins and the threonine residue with bound oligosaccharides, interact with calcium ions and water. The individual submicelles are connected to each other via phosphate (phosphoserine) groups of α_S- and β-caseins (the κ-casein molecule does not have a bonding region) and calcium ions, either directly or through free phosphates and citrates (Figure 2.26).

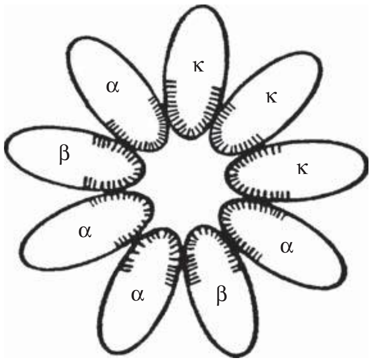


Figure 2.25 Cross section of a typical submicelle (hydrophobic parts of molecule are indicated by dashes). Coultate T.P (1989) p. 144, Reproduced by permission of the Royal Society of Chemistry.

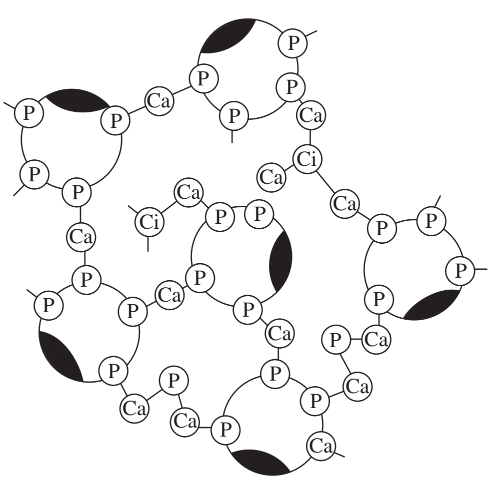

Figure 2.26 Interconnection of submicelles through phosphate (P), calcium ions (Ca) and citrate (Ci) (whole of the non-bonding areas with molecules of κ-casein are indicated). Coultate T.P (1989) p. 144. Reproduced by permission of the Royal Society of Chemistry.

A typical micelle of cows' milk contains approximately 20 000 casein molecules. About 93% (by weight of the micelle) are caseins, about 3% calcium ions, 3% inorganic (free) phosphates, 2% phosphates bound to phosphoserine, 0.4% citrates and 0.5% sodium, potassium and magnesium ions. The micelle diameter is 50–300 nm (the average is generally 150 nm). Their size depends on the α_S- and κ-caseins content. The smallest particles contain about 50% of

α-casein and 15% of κ-casein, while the largest particles contain about 42% α-casein, 26% κ-casein and about 30% β-casein. Milk contains about 1.10^{12} micelles in 1 ml.

2.4.5.2.2 Whey proteins

The globular protein β-lactoglobulin (Figure 2.21) constitutes about 50% of whey (serum) proteins. The relative molecular weight is 18 kDa and its polypeptide chain consists of 162 amino acids (pI = 5.35–5.41). β-Lactoglobulin occurs in three genetic variants, the main ones being labelled A and B. In milk it is present as a dimer that denatures irreversibly on heating (also in the presence of high concentrations of calcium ions in solutions of pH > 8.6). Thermally partially denatured protein reacts with other milk proteins (κ-casein and α-lactalbumin) through one accessible thiol group to form dimers linked by disulfide bonds.

Immunoglobulins, which are globular glycoproteins, are biologically important proteins with antibody efficacy, occurring in whey at low concentrations. They include IgG_1 (162 kDa, pI = 5.5–6.8), IgG2 (152 kDa, pI = 7.5–8.3), IgA (400 kDa as a dimer) and IgM (950 kDa as a pentamer). The clustering of fat globules in raw milk, which results in the formation of larger particles and finally in the formation of a layer of cream on the surface of the milk, is not caused by coalescence of globules, but is due to the action of a specific minor protein, **macroglobulin**, which creates cross-links between the globule membranes. Heating for several minutes to a temperature higher than 100 °C causes coagulation of this protein and prevents formation of a cream layer on the surface of pasteurised and otherwise heat-treated milk. Another important whey protein is α-lactalbumin, which has a biological function as a component of some enzymes. This protein occurs in two genetic variants (A and B), with a relative molecular weight of 14 kDa (pI = 4.2–4.5) and constitutes about 30% of whey proteins. Whey albumin (serum albumin) is present in smaller amounts, with a molecular weight of 66 kDa (pI = 5.13). Peptides and low molecular weight proteins called peptoses and peptones have relative molecular weights of 4–41 kDa (pI = 3.3–3.7).

2.4.5.2.3 Changes during storage and processing

Changes in the composition, structure and properties of milk proteins (caseins and whey proteins) occur during pasteurisation, sterilisation and especially during fermentation, drying and thickening of milk and in cheese making.

Thermal processing

Particularly labile milk proteins are the whey protein immunoglobulins, serum albumin, β-lactoglobulin and α-lactalbumin. During milk pasteurisation[10] at a temperature of 72–74 °C (20–40 s), about 50–90% of whey proteins are denatured and most enzymes present are inactivated. At temperatures >75 °C, the disulfide bonds in whey protein molecules are partly reduced to sulfhydryl groups and hydrogen sulfide is eliminated (mainly from β-lactoglobulin). The partial degradation of methionine yields thiols and disulfides, which also contribute to the so-called cooked flavour of milk. This defect is most obvious immediately after heating, but dissipates within 1 or 2 days. Sterilisation at 140 °C (for 4 s) denatures 100% of the milk proteins. Denatured milk proteins have a slightly higher nutritional value compared with the proteins of raw milk. The denatured β-lactoglobulin in canned milk can interact with κ-casein, which results in increased viscosity and sometimes even flocculation of sterilised milk.

Caseins in pasteurised and sterilised milk do not denature, but thermal processes lead, to a certain extent, to their dephosphorylation (phosphoserine hydrolysis), to proteolysis and aggregation of molecules. Casein could be completely dephosphorylated by incubation at 37 °C with 1% sodium hydroxide for a period of 24 hours. Under extreme conditions, such as during heating of sodium caseinate (see the next section) at 120 °C for 1 hour, about 50% of phosphoproteins are dephosphorylated and after 5 hours of heating the dephosphorylation reaches 100% and the extent of the caseinate hydrolysis is from 10 to 20%.

Lactose is the main milk sugar, which reacts with whey proteins, leading to loss of lysine. This reaction (the Maillard reaction) is particularly intense during milk evaporation or drying (see Section 4.7.5.12.3).

Precipitation and proteolysis of caseins

The pH of fresh milk is 6.5–6.75. When the pH decreases to 4.6, due to lactic acid formation, caseins precipitate, leaving a yellowish solution of whey (serum). The acidification (fermentation of lactose to lactic acid) is not only the spontaneous activity of contaminating microorganisms during storage of milk, but also a result of the activity of a range of cultural microorganisms used in dairy industry.

Partial precipitation of caseins occurs in the production of yoghurt and cottage cheese using appropriate strains of bacteria (such as *Streptococcus thermophillus* and *Lactobacillus bulgaricus*). Yoghurt gets its characteristic gel texture as a result of associations of casein micelles.

In the production of some hard and semi-hard rennet cheeses (e.g. Edam, Gouda, Cheddar and so on), the action of various cultural bacteria belonging to the genera *Streptococcus* and *Lactobacillus* acidify milk to a pH of around 5.5, which partly transforms lactose into lactic acid. At this stage, the proteolytic enzyme rennet (also called rennin, but the term chymosin is preferred) is added, which accomplishes the coagulation of milk. Chymosin is extracted from the stomachs of calves, but today it is often replaced by proteases from fungi of the genus *Mucor* and by pepsin obtained from the stomachs of chickens or pigs. Chymosin specifically hydrolyses κ-casein almost exclusively at the phenylalanine (105)–methionine (106) bond (Figure 2.27), and the molecule splits into two parts:

- ***para*-κ-casein**
- **κ-casein macropeptide**.

[10] Pasteurisation, in order to extend shelf life and inactivate pathogenic microorganisms, is carried out at temperatures of 85 °C (2 s), 71–74 °C (14–40 s) or 62–65 °C (30 min). UHT (ultra high temperature) milk is obtained by indirect heating at temperatures of 135–140 °C (6–10 s) or by direct steam heating at 140–150 °C (2–4 s).

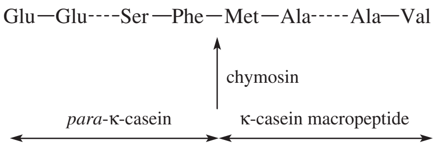

Figure 2.27 Hydrolysis of κ-casein by rennet.

The significance of the primary, secondary and tertiary structures of κ-casein on the sensitivity of this bond has now been established, as have pH, ionic strength, temperature, heat treatment of milk, environmental and processing variables. The resulting *para*-κ-casein (protein composed of 105 amino acids) contains the original hydrophobic part of the κ-casein molecule and, therefore, remains part of the casein micelles, but unlike native κ-casein it no longer has the micelle stabilising function. With the participation of Ca^{2+} ions, the bonds that develop between the micelles cause casein coagulation (curdling). κ-Casein macropeptide is a glycopeptide composed of 64 amino acid residues corresponding to the *C*-terminal 106–169 residues of κ-casein. Owing to the bound oligosaccharides, κ-casein macropeptide is hydrophilic and passes later into the whey.

After several hours of storage, the casein curds reach the desired firmness and are cut into small pieces, which causes the curds to shrink and allows the whey to be released. Heat drives the shrinking (syneresis) process even further. The increase in temperature causes the protein to shrink due to increased hydrophobic interactions and also increases the rate of fermentation of lactose to lactic acid. The increased acidity also contributes to shrinkage of the curd particles. When the curds have reached the desired moisture and acidity they are separated from the whey. Curd handling from this point on is very specific for each type of cheese. After salting (salting of brine is used in Gouda, salting in a vat in Cheddar and salting of the cheese surface in Feta production) and other operations (such as pressing and milling), the curds are left to mature (ripen) at low temperature until the characteristic flavour, body and texture profile is achieved. This final stage varies from weeks to years according to the particular cheese. During maturation, proteins are partly hydrolysed by chymosin and by microbial proteases and milk fat is partly hydrolysed by milk lipase. Proteolytic and lipolytic reactions are necessary to obtain the desired texture, taste and smell of the cheese. Proteolysis is probably the most important biochemical reaction during the ripening of most cheeses, having a major impact on their flavour and texture.

Use of whey and casein

Whey is the cloudy, yellowish liquid that is left after milk has curdled. Sweet whey (pH 6.5–6.7) is a by-product when milk is curdled with chymosin in cheese production. Acid or sour whey (pH 4.3–4.6) results from milk to which an acid has been added to aid in the curdling process (in the production of some types of Mozzarella cheeses). Whey has often been used to feed livestock, but the presence of proteins and other nutritionally important constituents led the food industry to take advantage of this in a wide range of whey and whey constituents applications. For example, acid whey is used as a raw material for the production of lactose and other sugars (see Section 4.4.3.1.2). Sweet whey is a raw material in the production of some cheeses (including the Italian cheese ricotta). Dried whey is added to some food products (infant formulae, breads, pancakes and biscuits) to enhance their nutritional value and functional properties. Whey protein concentrate is used to improve athletic performance and as an alternative to milk for people with lactose intolerance and so on.

About 50 years ago, the major uses of casein were in technogical applications, but nowadays casein products are regularly used as food additives, for example as ingredients that enhance some physical properties of foods, such as whipping, foaming, water binding, thickening and emulsification and nutritional properties.

Insoluble sweet casein (pH 6.5–6.7) obtained by precipitation of milk with chymosin is still used for technological purposes, for instance in the production of imitation tortoise shell and ivory (combs, hairclips, knife handles, piano keys and other products). The insoluble acid casein (pH 4.3–4.6), obtained by precipitation of milk using mineral acids or lactic acid, is a raw material for the production of caseinates. Caseinates are produced by reaction of acid casein curd or dry acid casein with dilute alkali. The resulting solution can be spray dried to produce a caseinate powder. The most common alkali used in the manufacture of spray dried sodium caseinate is sodium hydroxide, where a solution is mixed with a slurry of the casein powder in water. The pH of sodium caseinate ranges from 6.5 to 6.9. The manufacture of other caseinates is very similar to that of sodium caseinate. Caseinates are used in chemical and other industries. Soluble caseinates (sodium, potassium and ammonium caseinates; solubility 100%) and dispersible calcium (solubility 90–98%) and magnesium caseinates are used in various branches of the food industry as additives for binding water and emulsifying agents. For example, sodium caseinate is used as an emulsifying and foaming agent in the production of mayonnaise, ice creams, processed cheeses, coffee whiteners, instant breakfasts and beverages and meat products, potassium caseinate is used in the manufacture of confectionery, a mixture of sodium, potassium and calcium caseinates is employed in the production of confectionary products, to stabilise and fortify meat products, yoghurts and breads. Technological uses of acid casein include, for example, production of synthetic fibres, paints, adhesives for wood, paper and foil laminates, coatings for paper and cardboard.

The so-called insoluble co-precipitates contain all of the milk proteins (caseins and serum proteins). They are obtained from milk by precipitation with acids, the addition of salts and by heating. Like caseinates, co-precipitates are used as food additives for some meat products.

2.4.5.3 Eggs

The eggs of birds and reptiles have been eaten by mankind since time immemorial. The most commonly consumed eggs are those of hens,

[c]Including shell membrane.

ducks, geese, quails and ostriches.[11] Eggs contain a considerable amount of protein in a concentrated form (about 13% of the edible part), which has high nutritional value. The basic chemical composition of a hen's egg (average weight is around 58 g) is summarised in Table 2.20. The egg white proteins constitute about 53% and yolk proteins 47% of the total protein. The levels of the individual proteins in the egg white and yolk are shown in Table 2.21. The amino acid composition of egg proteins is shown in Table 2.11.

2.4.5.3.1 Egg white proteins

The egg white constitutes about two-thirds of the weight of a whole fresh hen's egg (minus its shell), and contains more than 40 different proteins, which are classified as globulins, glycoproteins and phosphoproteins. Glycoproteins contain various oligosaccharides composed of galactose (Gal), mannose (Man), acetylderivatives of glucosamine (Glc*N*Ac), galactosamine (Gal*N*Ac) and neuraminic acid (NeuAc) (Table 2.22).

The main protein of egg white is a group of related compounds known as ovalbumin A, or ovoalbumin A (relative molecular weight of 44.5 kDa, pI = 4.6–4.8; coagulation temperature ≥57.5 °C depending on pH). In addition to sugars, ovalbumin A contains two molecules of bound phosphoserine and four thiol groups (two of which form a disulfide bridge). During storage of eggs, reactions of thiol groups and of the disulfide group in ovalbumin A produce ovalbumin S, which is more thermoresistant and coagulates at 92.5 °C (in solutions of pH 7), but denatures relatively easily when the egg white is whipped. Of particular importance for the stability of whipped foam are ovoglobulins G_2 (40 kDa, pI = 5.5) and G_3 (58 kDa, pI = 4.8).

Ovotransferrin, also known as ovoconalbumin or conalbumin (76 kDa, pI = 6.1), which in hens is identical with serum transferrin, shows antimicrobial effects. This protein coagulates at a lower temperature than ovalbumin (coagulation temperature is 53 °C) and forms complexes with divalent and trivalent metal ions. Complexes with iron can cause a pink discolouration of products containing egg white.

Ovomucoid and ovomucin are the proteins responsible for the viscosity and gel-like consistency of egg white. Ovomucoid (28 kDa, pI = 4.4–4.6) is composed of three components which differ in carbohydrate composition on the *N*-terminus of the molecule. Ovomucoid inhibits trypsin and other proteolytic enzymes and is a strong allergen. The stability to thermal denaturation (in an acidic medium) is associated with nine disulfide bonds in the molecule.

[11]Also eaten, although rarely, are the eggs of some wild birds, such as those of lapwings (e.g. in Great Britain and the Netherlands). The large-scale collection of such eggs for food is now prohibited as it has contributed to a decline in the numbers of birds.

[a]Contains sulfuric acid bound as ester.
[b]Sum of galactose and mannose content.
[c]Basic unit (16 kDa), Gal = D-galactose, Man = D-mannose, Glc*N*Ac = *N*-acetyl-D-glucosamine, Gal*N*Ac = *N*-acetyl-D-galactosamine, NeuAc = *N*-acetylneuraminic acid.

Ovomucin is also thermostable and exists in two forms differing in their content of *N*-acetylneuraminic acid (α-form 220 kDa, β-form 720 kDa, $pI = 4.5–5.0$).

The basic protein ovoglobulin G_1 (lysozyme;14.3 kDa, $pI = 10.7$) contains four disulfide bonds. It occurs in many animal tissues and secretions (e.g. tears), in the latex of some plants and in microorganisms. This protein possesses the activity of *N*-acetylmuramidase, hydrolyses the β-glycosidic linkage between *N*-acetylmuramic acid and *N*-acetyl glucosamine in the peptidoglycan murein, which is the construction material of cell walls in gram-positive bacteria (see Section 4.3.3.7). Lysozyme is therefore used as an antimicrobial agent.

Native ovoflavoprotein (49 kDa, $pI = 5.1$) has, as does ovomucoid, certain antinutritional effects, as it inhibits serine proteases (trypsin, chymotrypsin and also microbial proteases) and has antiviral activity. Ovomacroglobulin (ovostatin) is an inhibitor of serine, cysteine, thiol and metalloproteases and shows antimicrobial activity. Some antinutritional effects are also seen in the basic glycoprotein avidin in raw egg white (relative molecular weight of the monomer is 15.6 kDa). It contains four identical subunits ($pI = 9.5$), each of which binds one molecule of biotin to give an unavailable complex. However, the denatured avidin, for example in hard-boiled eggs, does not interact with biotin. The interaction of riboflavin with flavoprotein (32 kDa, $pI = 4.0$) has, on the contrary, a positive influence on vitamin stability. Cystatin acts as cysteine protease inhibitor, and shows antimicrobial, antitumor and immunomodulating activities.

2.4.5.3.2 Egg yolk proteins

The egg yolk is an emulsion of fat in water, which makes up about 36% of the weight of a whole fresh hen's egg. The dry matter consists of roughly one-third protein and two-thirds lipid. Egg yolk contains a range of droplets (20–40 μm in diameter), similar to fat droplets, which are enveloped by a lipoprotein membrane composed mainly of LDL lipoproteins (Table 2.21). It also contains granules (1–1.3 μm in diameter) consisting of proteins, lipids, minerals and a plasma. Egg yolk proteins are various glycoproteins, lipoproteins, glycophosphoproteins and glycophospholipoproteins. The major granule proteins are lipovitellin and phosvitin, and lipovitellenin and livetin are mainly present in the plasma.

Granule proteins

The most important lipoprotein (HDL) is lipovitellin, which contains neutral triacylglycerols (35%), polar phospholipids (about 60%) along with cholesterol and its esters (5%). α-Lipovitellin and β-lipovitellin differ in their phosphorus content. In the yolk, lipovitellin forms complexes with phosvitin. This name includes two aggregates of related molecules, α-phosvitin (160 kDa) and β-phosvitin (190 kDa). α-Phosvitin is composed of three basic units (37.5, 42.5 and 45 kDa, respectively) while β-phosvitin has only one unit (45 kDa). Phosvitin is glycophosphoprotein (Table 2.22) with a high content of phosphoric acid (10%) bound in the form of phosphoserine, which provides efficient metal-binding sites for calcium, iron and other cations. This sequestering activity of phosvitin is related to its biological functions (the availability of metal ions for the developing embryo).

Plasma proteins

The name lipovitellenin refers to lipoproteins of the LDL type, where the lipid portion represents approximately 84–90% of the molecule weight. This lipid portion is composed of triacylglycerols (74%) and phospholipids (26%). Livetins are the water-soluble fraction of globular proteins, and includes α-livetin (albumin), β-livetin (glycoprotein), γ-livetin (globulin) and δ-livetin (polypeptide). These proteins are identical to serum proteins of hens, namely serum albumin, α_S-glycoprotein and γ-globulin, respectively. Immunoglobulin IgY (167 Da, $pI = 5.7–7.6$) represents the main antibody of egg plasma and blood serum, and is analogous to mammalian immunoglobulin G (IgG). It is transmitted from the blood into the yolk and contributes to the development of immunity in the chicken in its early stages of life. The isolated protein is used in human and veterinary medicine.

2.4.5.3.3 Changes during storage and processing

Eggs are usually eaten fresh or refrigerated. Further industrial processing produces a variety of egg products, such as pasteurised, frozen or dried egg whites, egg yolks or the whole egg contents. Smell and taste defects affect the long-term storage of raw eggs. Sulfur and nitrogen compounds (such as hydrogen sulfide, thiols, sulfides and amines) arising from cysteine and methionine and indoles derived from tryptophan are particularly responsible for these changes.

The mechanical denaturation of proteins occurs, for example, when whipping egg whites. Denatured proteins located at the interface with the air have a positive effect on foam stability. During the heat treatment of eggs, white protein denaturation begins at temperatures around 57 °C. In the temperature range 60–65 °C,

most egg white proteins are denatured (with the exception of ovomucoid, ovomucin and complexes of avidin with biotin) and at temperatures of 65–70 °C most of the yolk protein (except for phosvitin) is denatured. Egg proteins play a major role in the development of the typical aroma of boiled and fried eggs. When drying egg whites, yolks or whole egg contents, glucose in egg white reacts with lysine bound in proteins and with phosphatidylethanolamine bound in egg yolk lipoproteins, which leads to undesirable colour and flavour changes in the product. Before drying, glucose in egg whites is therefore removed by fermentation using bacteria of the genera *Aerobacter* or *Streptococcus* or the *Saccharomyces cerevisiae* yeasts. Another possibility is oxidation of glucose to gluconic acid using the oxidoreductase glucose oxidase (in the presence of catalase). Cold storage of pasteurised egg whites slightly increases the viscosity of the material, but the functional properties remain practically unchanged. For yolks and whole egg contents, cold storage leads to a substantial increase in viscosity due to the formation of products of a gel consistency. Slow freezing (critical temperature is –6 °C) leads to changes to the conformation of the lipoprotein complex and probably irreversible partial dehydration of the protein portion of the lipoproteins.

2.4.5.4 Foods of plant origin

Plant protein sources provide 65% of the world's supply of protein, with cereal grains (47%) and pulses, nuts and oilseeds (8%) as the other major sources. Of the cereals, wheat (43%), rice (39%) and maize (12%) are the main contributors. Other limited sources of plant protein are fruits, leaves, tubers and other parts of plants included under the terms fruits, vegetables or root crops. Plant protein sources can differ from animal protein sources in terms of digestibility, amino acid composition, the presence of antinutritional (such as enzyme inhibitors) and toxic factors (e.g. saponins, cyanogens and lectins), which adversely influence protein digestibility, nutritional value and food safety.

The amino acid composition of cereal grains and other seeds is different to that in foods of animal origin. Seed proteins usually contain a large amount of aspartic and glutamic acids and their amides, but some essential amino acids occur in lower levels and become the limiting amino acids. With some exceptions (such as soybeans), lysine levels are uniformly lower in wheat, rice, maize, potatoes and other crops. Soybeans have lower levels of the sulfur amino acids, there is a lower level of tryptophan in maize, and a lower level of threonine in cassava. As a consequence, the nutritional value of plant protein is lower than that of animal protein; nevertheless, plants can cover all human protein needs. An appropriate combination of plant materials gives a mixture of proteins with high nutritional value, which can provide the protein for the diet of vegetarians. However, the question is whether this is only achievable with the carefully selected diets consumed by vegetarians, or whether it could also be achievable with the cereal or other staple diets available to poor or developing communities. In addition to protein, the body receives a number of other nutritionally valuable components such as fibre, carbohydrates, vitamins and minerals from plants.

2.4.5.4.1 Cereals and pseudocereals

The most important sources of vegetable protein for human nutrition are cereal grains, primarily wheat, which is the third most produced cereal after maize and rice. The protein content of the sub-aleurone layer of wheat, located between the white centre of the grain and the brown fibrous outer layer, is higher than in the central part. Therefore, the protein content in flour significantly depends on the degree of milling (flour extraction rate) and, of course, on the plant species, variety and other factors. Dark wholemeal flour has a higher protein content than white flour; the difference is about 4%. The basic chemical composition of common cereals and pseudocereals is shown in Table 2.23. The basic proteins of cereals are albumins, globulins, prolamins and glutelins. Their trivial

Table 2.23 Average basic chemical composition of cereals and pseudocereals (%).

Cereals[a]	Water	Proteins	Total lipids	Total sugars	Starch	Total dietary fiber	Minerals (ash)

[a] Average values from various sources, therefore their sum may exceed 100%. Non-starch carbohydrates are calculated by difference.

names are based on the Latin names of the plants they come from (see Section 2.4.1).

Wheat proteins

Wheat usually contains 7–13% protein, but can contain up to 15%, with lysine as the limiting amino acid. Distribution of proteins within the wheat kernel differs significantly. About 72% of total protein is in the endosperm, 15.5% in the aleurone layer, 4.5% in the pericarp, 4.5% in the scutellum and 3.5% in the embryo, while starch only occurs in the endosperm. The major factors influencing the protein content of wheat are genetic (species and variety) and environmental conditions (timing and amount of growing season precipitation, temperature during the growing season, soil nitrogen reserve levels and applied nitrogen fertilisers). Wheat proteins are composed of albumins known as leucosin (about 14%), globulins known as edestin (8%), prolamins known as gliadin (33%) and glutelins known as glutenin (46%). In other words, about 20–25% of wheat proteins are represented by water-soluble cytoplasmic proteins that predominantly have structural, metabolic and protective functions (e.g. enzymes with activity of α- and β-amylases, proteases, lipases, phytases and lipoxygenases) and 75–80% of proteins are water-insoluble storage proteins, prolamins and glutelins. The total number of wheat proteins is about 40.

The reserve, water-insoluble proteins are the major proteins of wheat. Prolamins (gliadins) and glutelins (glutenins) are represented by a number of related proteins, each with slightly differing amino acid compositions (there are several dozen gliadins in each of the wheat varieties). Gliadins have a relative molecular weight of between 30 to more than 100 kDa (usually between 60 and 80 kDa). Three basic fractions are identified: high molecular weight gliadins (relative molecular weight is >100 kDa), ω-gliadins (60–80 kDa) and low molecular weight gliadins (30–40 kDa). The ω-gliadin fraction contains the so-called α-, β- and γ-gliadins. Gliadins contain a large amount of glutamine (36–45%), proline (14–30%), somewhat less aspartic and glutamic acids and unusually low amounts of the basic amino acids arginine, lysine and histidine. The relatively low content of acidic and basic amino acids with polar side chains is linked to low gliadin solubility. Glutenins have a higher relative molecular weight, which typically ranges from 40 to 20 000 kDa, (usually about 2000 kDa), as they are made up of polypeptide chains linked by disulfide bridges.

The high proline content virtually prevents the formation of helical secondary structures in both types of proteins. Gliadin and glutenin molecules therefore contain only short helical sections associated with segments of the unorganised secondary structure. The ω-gliadin molecules (stabilised by strong hydrophobic interactions) are rich in segments known as β-turns. Their number increases with rising temperature. In contrast, the α-, β- and γ-gliadins contain α-helices (30–35%) and β-sheets (about 10% in α-gliadins) stabilised by disulfide bridges and hydrogen bonds. Heating causes an increase in the unorganised structures and partial loss of the α-helical structures.

Bread flour is obtained from wheat varieties with higher protein content (12–14%) and is also known as strong flour. This term relates to the properties of the dough, which is elastic and stiffer and therefore requires more intense mixing, retains the carbon dioxide produced by yeast and air well and provides voluminous products. The milling and baking properties of flour are linked not only to the protein content, but also to its composition. Flours referred to as weak flours usually contain less than 10% protein. They are suitable for the production of biscuits, pastries, confectionery and other products (along with baking powder), but not for making bread.

Wheat flour gives a dough with water, which is basically (in addition to starch) a viscoelastic sticky material composed of two-thirds water and one-third hydrated gliadins and glutenins, **gluten**. The formation of the large quaternary structure of gluten during dough-mixing and bread-making processes is extremely complex and not well characterised. It has been established that the glutenin subunits, directly affects dough formation and bread-making quality, the typical viscoelastic properties of gluten, as their molecules are able to generate a three-dimensional network stabilised by different types of bonds between the glutenin molecules. The aggregated glutenin polymers range in relative molecular weight from about 1 000 000 to 10 000 000 Da and consist of three, four or five glutenin subunits, together with an uncertain number of subunits of low molecular weight. Hydrogen bonds are important for their stabilisation and are mediated mainly by glutamine residues, ionic and hydrophobic interactions of amino acids, as well as disulfide bonds present in the gluten structure that contribute to the process of dough formation through a disulfide/sulfhydryl exchange. Tyrosine bonds (bityrosine derivatives) formed in wheat dough during the processes of mixing and baking also contribute to the structure of the gluten network (see Section 2.5.1.1.3). The main factor that determines the quality of flour is the ratio between glutenins and gliadins. Gliadin molecules have a modifying effect on the viscoelastic properties of dough. Gluten proteins in some individuals cause an autoimmune disorder of the small intestine called celiac disease (see Section 10.3.1.1.2). The amino acid composition of wheat protein can be seen in Table 2.12.

Proteins of other cereals and pseudocereals

Rye albumins (44%) and globulins (10%), representing about 55% of rye proteins, have similar properties to albumins and globulins of wheat. About 45% of rye proteins are prolamins, known as secalin (21%), and glutelins, known as secalinin (25%). The trivial names of insoluble proteins of rye and other grains are seldom used, but have become known by the collective name gluten, as in the case of wheat proteins. However, this so-called rye gluten differs from wheat gluten in the proportion of prolamins and glutelins, the content of some amino acids and, especially, in its viscoelastic properties. Wheat gluten is ductile, while rye gluten tears, but rye is still the only cereal grain, in addition to wheat, from which a typical bread can be produced. Nevertheless, rye bread has a completely different texture and consistency (it is compact and sticky) from wheat bread, and also a different content of other flour components, in particular pentosans (see Section 4.5.1.5.2).

The main components of barley and oat proteins are prolamins (hordein in barley, 25%; gliadin in oats, 15%) and glutelins (hordenin in barley, 55%; avenin in oats, 54%), albumins (12%

in barley, 20% in oats) and globulins (8% in barley and 12% in oats known as avenalin), which are minor proteins. Important constituents of barley albumins are the lipid transfer protein (about 9 kDa; responsible for the shuttling of phospholipids and other fatty acid esters between cell membranes) and protein Z (43 kDa; a major barley endosperm albumin) that survive the malting and brewing processes and play roles as foam-promoting agents during these processes. Rice proteins are mainly composed of glutelins known as oryzenin (about 80%), while prolamins known as oryzin (2%) and other proteins (albumins 11% and globulins 10%) are minor components. Maize proteins are composed of small amounts of albumins (4%), globulins (3%), gliadins called zein (about 50%) and glutelins (20–45%). The typical limiting amino acids in maize gluten are lysine and tryptophan.

Increasingly, previously little known or almost forgotten grains are appearing in human nutrition, such as millet, sorghum and the pseudocereals, which include buckwheat and amaranth. Some cereals with increased protein content have also been newly introduced. An example might be the interspecies hybrid of wheat and rye called triticale (the name comes from Latin names *Triticum* for wheat and *Secale* for rye). The grains contain 15–20% protein. The protein content in the interspecies hybrid of wheat and barley, which is called tritordeum (the Latin name for barley is *Hordeum*), is 19–22%. The amino acid composition of the major cereals and pseudocereals is shown in Table 2.12.

2.4.5.4.2 Legumes and oilseeds

Legumes and oilseeds are important sources of proteins, lipids and other nutrients in the diet. Legumes are plants of the Fabaceae family that are cultivated for their seeds used for human and animal consumption and as forage crops (e.g. alfalfa and clover). The most important edible legume seeds (pulses) are soybeans, peas, beans, lentils and peanuts, in addition to some other relatively less frequently used legumes (e.g. chickpeas, vigna and lupin seeds). Legumes are high in protein (a typical protein content is 20–45%) and the limiting amino acids are usually sulfur amino acids.

Proteins in soybeans, peas and other legumes are mostly composed of globulins, while minor components are low molecular weight albumins. For example, soybean protein contains about 80% globulins. Globulins in many legumes are further divided into legumins and vitilins, but soybean globulins are known as glycinin and conglycinin, respectively. Legumins have higher relative molecular weight, are less soluble and have better thermal stability than vitilins. Peanuts contain about the same amount of globulin arachin and related conarachins, 15% of albumins and 10% of glutelins. Pea protein contains about 70% globulins (legumin and vicilin), 20% albumins and 10% glutelins. Recent, more precise characterisation of legume proteins is based on their sedimentation coefficients during ultracentrifugation. In this way, soybean proteins can be separated into four fractions designated 2S, 7S, 11S and 15S.[12] The 2S fraction termed α-conglycinin contains 8–22% of soybean protein and consists of a number of enzymes (the Bowman–Birk and Kunitz trypsine inhibitors and cytochrome c). The 7S globulin fraction, known as β- and γ-conglycinins, accounts for 35–37% of the total protein (containing haemaglutinin, lipoxygenase, β-amylase and globulins labelled a, a_1 and b). The 11S fraction that accounts for 31–52% of the total protein is known as glycinin, and the 15S fraction, which has no trivial name, accounts for 5–11% of the total protein and is poorly characterised. It is thought to be composed of polymers of other soy proteins.

The typical basic chemical composition of some legumes and oilseeds is summarised in Table 2.24. The content of the individual nutrients and other components, however, varies broadly and depends on the seed origin (plant variety), maturity and many other factors. For example, the protein content of common mature pea seeds varies between 14.2 and 36.1% and dietary fibre content is 16.7–25.5% and water content is 11%. Green peas, however, contain 78.9% water, 5.4% protein and 5.1% dietary fibre. Furthermore, oilseeds accumulate oil rather than starch. The amino acid composition of important legumes is given in Table 2.24.

Some legume seeds that contain significant amount of lipids, such as soybeans and peanuts, are used as oilseeds. The protein content of oilseeds usually ranges from 20 to 50%. Other important oilseeds include rapeseed, sunflower seed and many other plant

[12] S denotes the so-called Svedberg's units in which the sedimentation rate is expressed. It is equal to 1×10^{-13} s.

Table 2.24 Average basic chemical composition of some legumes and oilseeds (%).

Mature seeds[a]	Water	Proteins	Total lipids	Total sugars	Starch	Total dietary fibre	Minerals (ash)
Soybeans	8.5	40.2	20.5	7.3	0.5–2.0	9.3	4.5
Peanuts	6.5	27.6	49.6	4.0	1.0	6.0	2.8
Peas	11.3	26.3	2.2	15.8	40	15.9	2.9
Beans (kidney)	11.8	27.2	1.0	2.1	40	11.9	3.8
Chickpeas	11.5	20.7	5.7	10.7	47	13.9	3.6

[a] Average values from various sources, therefore their sum may exceed 100%. Non-starch carbohydrates are calculated by difference.

seeds described in Section 3.4.3.4.1. Almonds and nuts have high protein contents (about 20%). Owing to their low consumption, these commodities cannot be considered significant sources of protein. The amino acid composition of major oil seeds and nuts is given in Table 2.13.

However, legumes and oilseeds often contain various antinutritional factors or even toxic substances. Examples of such substances are different allergens, protease inhibitors, lectins, saponins, indigestible sugars such as raffinose and its homologues, phytic acid and others (see Section 10.3.2.6).

2.4.5.4.3 Changes during storage and processing

Denaturation of proteins can occur during grain drying and milling, but on a very small scale. The extent of protein denaturation depends on water activity, temperature and time of drying and milling. When completely denatured, gluten lacks its typical viscoelastic properties. Bread flour improves its baking properties during storage of up to about a year, but with longer storage these properties deteriorate. The improved baking properties of flour are caused by natural bleaching, which is based on autoxidation of unsaturated fatty acids (see Section 3.8.1.8.2) and their enzymatic oxidation by lipoxygenases. The resulting hydroperoxides of fatty acids are strong oxidising agents that oxidise the free thiol groups of gluten proteins. Their polypeptide chains are connected by disulfide bridges to high-molecular weight units, which have a positive effect on the volume of a loaf and the texture of the crust. At the same time, degradation of carotenoid pigments (see Section 9.9.5.1) results in a more attractive flour of lighter colour. Bread flour is sometimes conditioned with ascorbic acid, which increases the bread volume and creates a better texture. The mechanism of this reaction is described in Section 5.14.6.1.6. Attempts to simulate the aging process has led to the use of flour additives (oxidising agents) in some countries, such as chlorine dioxide, dibenzoyl peroxide, bromates and iodates of alkali metals (see Section 11.4.2.2.1, Section 5.2.6.2 and Section 5.14.4.4).

During the mixing of wheat flour with water, yeast and other ingredients, the dough is worked mechanically (the process is known as kneading). Flour proteins gliadin and glutenin are hydrated, and air and carbon dioxide (produced by yeast) are incorporated, which is the basis for the structure of the bread. On baking, water evaporates from the crust, the starch begins to gelatinise at about 50 °C, and proteins are denatured at about 70 °C, releasing water that is absorbed by the starch and which increases the loaf volume. As the temperature increases, the loaf shape is fixed, and gluten creates the typical three-dimensional net structure, which surrounds all the other ingredients. The colour of the crust begin to develop. Baking bread and other cereal products results in a relatively large Maillard reaction, which is desirable in order to develop the typical colour and flavour. However, it has a negative effect on the nutritional value of proteins, because the bound essential amino acid lysine primarily enters this reaction and thus becomes unavailable (blocked).

Significant changes to the structure of proteins also occur during other methods of thermal processing of cereals. For example, extrusion leads to texturised proteins that lose their prevailing globular structure, they gain a fibrous structure and are denatured, which is accompanied by the disruption of existing non-covalent interactions and disulfide bridges, and the emergence of new bonds between filamentous molecules.

2.4.5.5 Non-traditional protein sources

Since the middle of the last century, unicellular and multicellular organisms have been studied as possible non-traditional sources of protein for human nutrition and livestock. Special interest has been paid to yeast proteins (e.g. the genera *Candida* or *Torula*), and also to bacteria, fungi and algae (e.g. the green sweet water algae of the genus *Chlorella*, which contain about 45% protein dry matter) and to higher plants (oilseed meals, the leaves of certain plants and some vegetables and foliage). These protein sources have not found significant use in human nutrition, but are often used as animal feed.

However, various technologies have been developed that utilise extractions from oilseed meals and pulses as the raw material for the production of flours, protein isolates and protein concentrates. These technologies are mainly used in the processing of soybeans and, to a lesser extent, in the processing of peanuts, cotton, lupine and other oilseed meals. Additional sources of protein are whey, fishmeal and others. The final products can be various mixtures rich in proteins (often enriched by minerals and vitamins), which are mainly used in less-developed countries.

Protein concentrates generally tend to contain around 50% protein, although a higher protein content (90%) is found in **protein isolates**. Concentrates are mostly prepared from oilseed meals (such as soybean meals). The proteins are first denatured by heating, and soluble substances are extracted with water. Protein isolates are prepared by extracting proteins and other substances soluble in dilute aqueous solutions of sodium or calcium hydroxides. The extract obtained is purified and its pH is adjusted to the value of the isoelectric point, when the proteins precipitate. This procedure gives a relatively clean proteinaceous material, which can then be used as a dietary supplement or as an intermediate for further processing. The texture of protein preparations can be further modified to resemble meat. Well known examples are so-called soy meat, soy curd (tofu) or soy cheese (sufu). Modifications include addition of fat, flavouring agents, dyes and binders, and the finished products are mostly processed by extrusion.

2.4.5.6 Modified proteins

The modification of native protein structure is based on the nutritional, hygienic and toxicological and technological requirements. This can be carried out chemically or enzymatically, with the aim of improving:

- desirable physico-chemical properties of proteins (solubility, dispersibility, elasticity, viscosity, adhesivity, cohesivity, the ability to bind water, form gels, emulsions and foams and stabilise these dispersion systems)

- nutritional value (by inactivation of antinutritional and toxic substances, through improved availability of essential amino acid content)

- their organoleptic properties (texture and taste)

- the use of non-traditional raw materials for food purposes (e.g. yeast proteins).

Functional groups of bound amino acids can be chemically modified in various ways. Amino groups can be derived by acylation or methylation (reaction with formaldehyde and reduction of the resulting hydroxymethyl derivatives). Carboxyl and hydroxyl groups can be derived by esterification, amide bonds (including peptide bonds) by hydrolysis, thiol groups by oxidation to disulfides and vice versa. For example, succinylated casein is, unlike native caseins, practically insoluble in solutions of pH 2–3 and soluble in solutions of pH 4.5. Succinylated yeast protein is soluble in solutions of pH 4–6, is more resistant to heat denaturation and has a higher emulsifying strength. Alkylated proteins, for example, do not react with reducing sugars in the Maillard reaction. The enzyme modifications are mainly based on the protein dephosphorylation and plastein reaction (see Section 2.3.2.2). For example, in the presence of calcium ions, the dephosphorylated β-casein is more soluble than the native protein. The plastein reaction has found use in the debittering of protein hydrolysates and for the incorporation of nutritionally valuable essential amino acids into proteins of low nutritional value (e.g. tryptophan, threonine and lysine into maize zein).

2.5 Reactions

Biochemical (enzymatic) reactions *in vivo* transform free and bound amino acids into a wide range of products that can be involved in the biosynthesis of many secondary metabolites and affect various biological processes. In food raw materials, which mainly include animal tissues (meat, fish and poultry) post-mortem and plant tissues during post-harvest storage, a variety of biochemical and chemical reactions take place that involve free amino acids and amino acids bound in proteins and peptides and which influence the nutritional, sensory, technological and hygienic and toxicological quality of foods. Other reactions of these compounds are caused by the action of various physical factors (such as heat, mechanical force, hydrostatic pressure and radiation) and chemical agents (acids, bases, salts and surfactants) during processing and cooking. These reactions often result in oxidation of side chains, peptide chain fragmentation, aggregation, enzymatic inactivation and conformational changes known as denaturation (changes to the native conformation stabilised by non-bonding interactions) and even in changes to the primary structure of proteins due to hydrolysis of peptide bonds. Proteins, peptides and amino acids react with each other and with other natural food components, particularly with oxidised lipids, reducing sugars in the Maillard reaction, oxidised phenolic compounds, some food additives (acids and alkalis, nitrites and sulfites), oxidising agents and some contaminants (e.g. with halogenated solvents). The extent and type of reactions that take place during food storage and processing depend on the particular food (its chemical composition), conditions during storage and processing (water activity, temperature, pH, oxygen and other factors), and the reaction partners present.

The positive consequences of these changes, interactions and reactions are the inactivation of undesirable enzymes and microorganisms, denaturation of protein antinutritional factors and toxins, which results generally in higher digestibility, production of desired flavour-active compounds, desired colour changes and increased food shelf life. The negative consequence is some reduction of the nutritional value of the food (reduced amounts of certain essential amino acids, reduced digestibility of proteins and reduced utilisation of some reaction products). Sometimes, the formation of undesirable flavour compounds and undesirable discoloration may also occur. Some reactions may also negatively affect the hygienic–toxicological quality of food products, because some reaction products have specific biological effects and are classified as technological (process-induced) contaminants (see Section 12.2).

2.5.1 Intramolecular and intermolecular reactions

Amino acids in living organisms undergo oxidation during normal biosynthesis when a diet is rich in protein and during starvation, which contributes significantly to the generation of energy. In animal tissues (meat, fish and poultry) post-mortem and plant tissues during post-harvest storage, amino acids undergo enzymatic and chemical oxidation along with other reactions, such as decarboxylation, transamination, oxidative decarboxylation and reactions with other food components (lipids, sugars and their decomposition products), which produce a variety of products.

2.5.1.1 Oxidation

Proteins and free amino acids contain numerous reactive functional groups and can become substrates for oxidoreductases or may react with reactive oxygen species, such as hydroxyl radicals ($HO^{\bullet}$), superoxide radicals ($O_2^{\bullet-}$), singlet oxygen ($^1O_2$), fatty acid hydroperoxides (R–O–OH), alkoxyl ($RO^{\bullet}$) and peroxyl ($ROO^{\bullet}$) radicals, atmospheric oxygen and other oxidising agents, often under the catalysis of transition metal ions.

Oxidation of the polypeptide chain of proteins can lead to various di(oligo)mers or hydroxy derivatives. The reaction of proteins with the most reactive oxygen species, hydroxyl radicals, results in abstraction of the hydrogen atom from the α-carbon, from the polypeptide chain and also from the side chains of hydrophobic amino acids residues (Figure 2.28). The reaction is analogous to the autoxidation of fatty acids (see Section 3.8.1.8.2). Abstraction of a hydrogen atom by a hydroxyl radical yields a carbon radical, which reacts with oxygen with the formation of a hydroperoxyl radical. This radical is stabilised by reaction with a hydrogen donor (and also with a protonated superoxide radical or Fe^{2+} and H^+ ions),

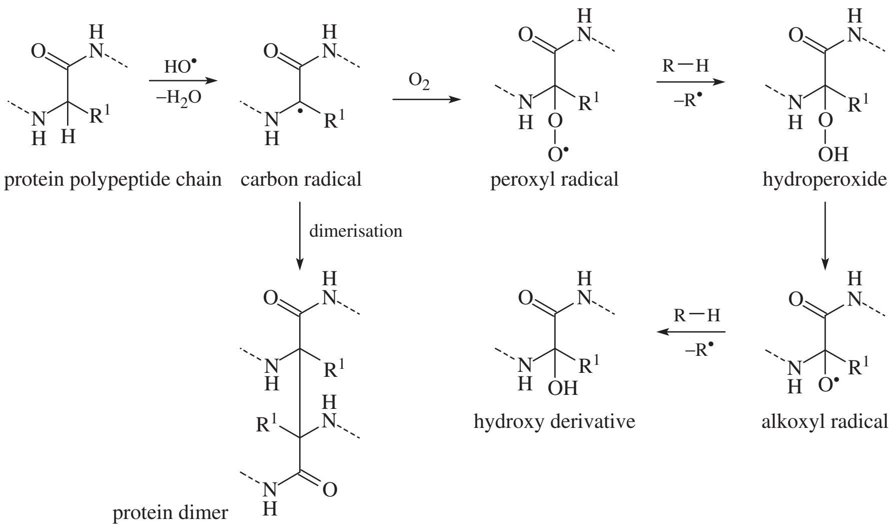

Figure 2.28 Oxidation of protein polypeptide chain by reactive oxygen species.

which yields unstable hydroperoxide that is decomposed to an alkoxyl radical (in the presence of a protonated superoxide radical or Fe^{2+} ions). Dimerisation of the carbon radical in the absence of oxygen produces a protein dimer and the reaction of the alkoxyl radical with a hydrogen donor (protonated superoxide radical or Fe^{3+} and H^+ ions) gives a hydroxylated protein.

Free peroxyl radicals react with proteins with the formation of protein free radicals, which react with other protein free radicals to yield protein dimers, or with lipid free radicals to yield copolymers. The occurrence of a lipoprotein with covalent bonds and protein oligomers during oxidation of proteins (PH) by alkoxyl ($RO^\bullet$) and peroxyl ($ROO^\bullet$) radicals is shown in the following equations. A protein radical ($P^\bullet$) forms most frequently by splitting off the labile hydrogen atom on C_α, an alkoxyl radical yields a hydroxy acid and a peroxyl radical yields hydroperoxide:

$$\text{P–H} + \text{R–O}^\bullet \rightarrow \text{P}^\bullet + \text{R–OH}$$
$$\text{P–H} + \text{R–O–O}^\bullet \rightarrow \text{P}^\bullet + \text{R–O–OH}$$

Recombination of protein radicals subsequently yields protein oligomers:

$$\text{P}^\bullet + \text{P} \rightarrow \text{P–P}^\bullet$$
$$\text{P–P}^\bullet + \text{P} \rightarrow \text{P–P–P}^\bullet \text{ etc.}$$

$$\text{P}^\bullet + \text{P}^\bullet \rightarrow \text{P–P}$$
$$\text{P–P}^\bullet + \text{P}^\bullet \rightarrow \text{P–P–P etc.}$$

Cross links of the lipid–protein type are produced mostly by the following reactions:

$$\text{P}^\bullet + \text{R–O–O}^\bullet \rightarrow \text{P–R} + \text{O}_2$$
$$\text{P}^\bullet + \text{R} - \text{O}^\bullet \rightarrow \text{P–O–R}$$
$$\text{P}^\bullet + \text{R}^\bullet \rightarrow \text{P–R}$$

Oxidation of the polypeptide chain of proteins can also lead to the cleavage of peptide bonds. Two different mechanisms are proposed, α-amidation and diamide pathways (Figure 2.29). In both pathways, the polypeptide chain is shortened and the *N*- and *C*-amino acid residues of the resulting fragments are modified (aspartyl, glutamyl and prolyl residue produce specific *N*- and *C*-terminal fragments).

Sulfur-containing amino acids (cysteine and methionine), aromatic and heterocyclic amino acids (phenylalanine, tyrosine, histidine and tryptophan) are relatively oxylabile compounds. In addition to these amino acids, the side chains of some proteins are also readily oxidised. Some oxidation products are not available, as the source of the amino acids and some products are undesirable

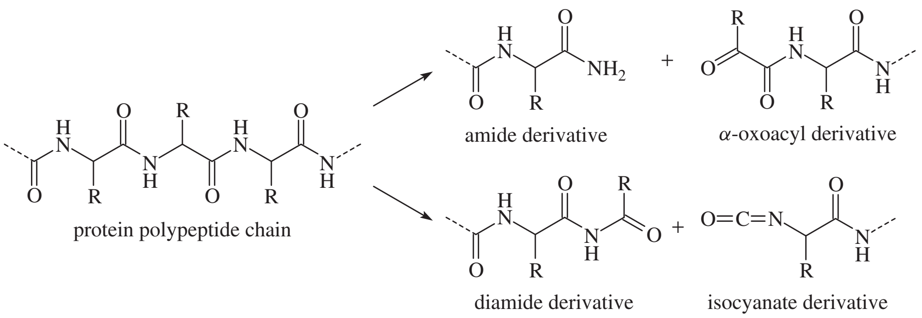

Figure 2.29 Oxidative cleavage of protein polypeptide chain. Stadtman and Levine 2003. With kind permission from Springer Science and Business Media.

as off-flavours and because of hygienic and toxicological aspects. Oxidation of proteins resulting from oxidative stress, which modifies their structure and affects their function, is related to organism aging and pathogenic changes in some diseases.

2.5.1.1.1 Cysteine and cystine

Oxidation of the thiol group (–SH) to the disulfide group (–S–S–) proceeds typically through the action of dehydrogenases, reactive oxygen species (such as singlet oxygen), fatty acid hydroperoxides and even by atmospheric oxygen (autoxidation). Cysteine (free or bound in peptides and proteins) yields cystine (Figure 2.30). The reaction is reversible and the cleavage of the disulfide bond in cystine may proceed, according to the conditions, by homolytic (photolysis and other reactions) or heterolytic mechanisms.

It is assumed that the first stage of cysteine autoxidation by homolytic cleavage is the formation of the alkylthiolate (RS^- anion) through the reaction of the thiol with a hydroxyl ion (reaction therefore takes place faster in alkaline media). Alkylthiolates react with oxygen to form a thiyl radical ($RS^•$) and anion of superoxide radical ($O_2^{-•}$) (see Section 3.8.1.13.2). Homolytic cleavage of thiols by reactive oxygen species also produces thiyl radicals (Figure 2.31). Volatile thiols, which are components of many food flavours, are oxidised in the same way (see Section 8.2.9.1.2).

Cysteine is oxidised to cystine more effectively by fatty acid hydroperoxides, hydrogen peroxide and reactive oxygen species. Fatty acid hydroperoxides simultaneously oxidise sulfur atoms and cystine yields thiosulfinates (monooxides) and also products containing two sulfoxide groups (disulfoxides), a sulfonic group (dioxide or thiosulfonate), a sulfoxide and sulfone group (sulfoxidosulfones or trioxides), or two sulfonic groups (disulfones or tetraoxides; Figure 2.32). In foods, the degree of oxidation does not usually exceed the level of thiosulfinate and dioxide. These compounds are the main products of cysteine and cystine oxidation. Their bioavailablity is about 20–50% that of cysteine. The product of cysteine oxidation by fatty acids hydroperoxides (and hydrogen peroxide) is, in addition to cystine, the unstable cysteine sulfenic acid, cysteine sulfinic acid and cysteine sulfonic acid known as cysteic acid (Figure 2.33). Both of the latter acids are completely unavailable as a source of cysteine.

The glutathione sulfhydryl groups are oxidised to disulfide groups or can be converted into the corresponding sulfenic, sulfinic and sulfonic acids.

Figure 2.33 Oxidation of cysteine to acids, R = $CH_2CH(NH_2)COOH$.

2.5.1.1.2 Methionine

Methionine can be oxidised by reactive oxygen species, fatty acid hydroperoxides and oxidised polyphenols. The primary oxidation product, methionine sulfoxide (free or bound in proteins), is a frequent component of various proteins. The contents of methionine sulfoxide in protein sources used for foods and feeds usually vary from 0 to 30% of the total methionine content (e.g. up to 11% methionine sulfoxide apparently occurs in milk powder, 13% in lean beef, 16–28% in wheat gluten and 50% in orange juice). It is fully available as a source of methionine as it can be reduced back to methionine by sulfoxide reductases, but the final oxidation product, methionine sulfone, is unavailable as a source of methionine (Figure 2.34). The oxidation of the methyl group to

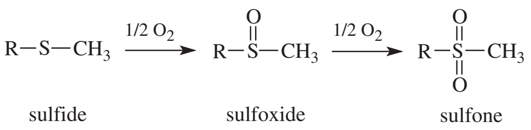

Figure 2.34 Oxidation of methionine, R = $CH_2CH_2CH(NH_2)COOH$.

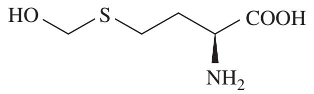
a hydroxymethyl group by hydroxyl radicals gives L-2-amino-4-(hydroxymethylthio)butanoic acid (**2-104**). The so-called hydroxymethionine, (*R*,*S*)-2-hydroxy-4-(methylthio)butanoic acid, and its salts are used in cosmetic preparations intended to prevent the signs of the cutaneous ageing, such as sagging of the cutaneous and subcutaneous tissue and loss of cutaneous elasticity.



2-104, L-2-amino-4-(hydroxymethylthio) butanoic acid

2.5.1.1.3 Phenylalanine and tyrosine

Phenylalanine residues in proteins and free phenylalanine are oxidised by various reactive oxygen species to 2- and 3-hydroxy derivatives, and possibly other products too.

The most important reaction is the direct post-translational enzymatic oxidation of tyrosine to 3,4-dihydroxyphenylalanine (DOPA) in animals *in vivo*, which is catalysed by tyrosine hydroxylase. Subsequent reactions then lead to melanins, an important group of pigments widely distributed in all living organisms (see Section 9.3.1.1). Tyrosine is also a substrate of oxidoreductases in the enzymatic browning reactions in foods (see Section 9.12).

Oxidation catalysed by peroxidases (Figure 2.35) converts the tyrosine residues in proteins into bityrosine and isobityrosine derivatives. Bityrosine has been found in animal proteins from resilin, a protein found in the cuticle of insects and arthropods, to elastin and collagen in vertebrates. Both bityrosine and isobityrosine, as well as some higher order structures, have been shown to be synthesised in human phagocytes by a myeloperoxidase–hydrogen peroxide system. Bityrosine, formed by oxidation of tyrosine residues with reactive oxygen species and oxidising agents (ascorbic acid, azodicarbonamide and potassium bromate) was also discovered in wheat flour, dough and bread. It has been suggested that it is a stabilising cross-link in the wheat gluten structure in addition to disulfide bonds. Singlet oxygen mediated oxidation of tyrosine residues in proteins suggests the initial formation of an unstable endoperoxide via 1,4-cycloaddition of singlet oxygen to the aromatic ring. The endoperoxide undergoes ring opening to produce a hydroperoxide that decomposes to the corresponding alcohol. The hydroperoxide derived from free tyrosine yields a hydroperoxide of an indole derivative by ring closure, which is transformed to the corresponding alcohol and other heterocyclic products (Figure 2.36).

2.5.1.1.4 Histidine

Oxidation of histidine by singlet oxygen results in a complex mixture of products. The initial 1,4-cycloaddition of singlet oxygen yielding one or more endoperoxides is followed by subsequent ring opening, which produces unstable hydroperoxides decomposing to a variety of products via free radicals. Some intermediates can form adducts with various nucleophilic reagents, dimers with another histidine molecules and a range of other products. The final reaction products are aspartic acid, asparagine and urea. The reaction

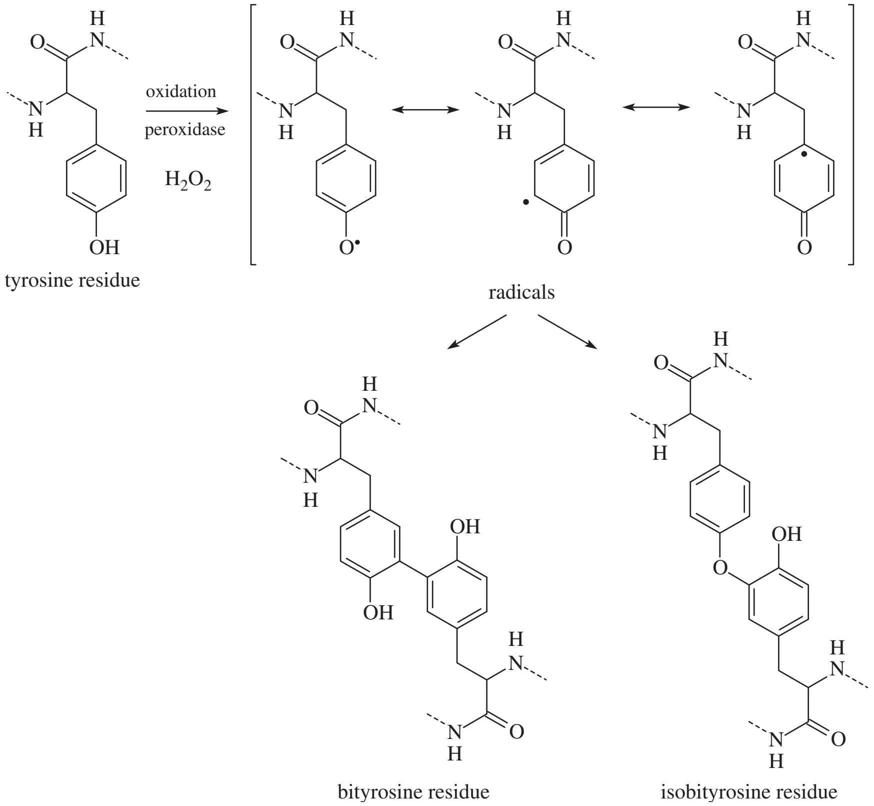


Figure 2.35 Oxidation of tyrosine by peroxidases.

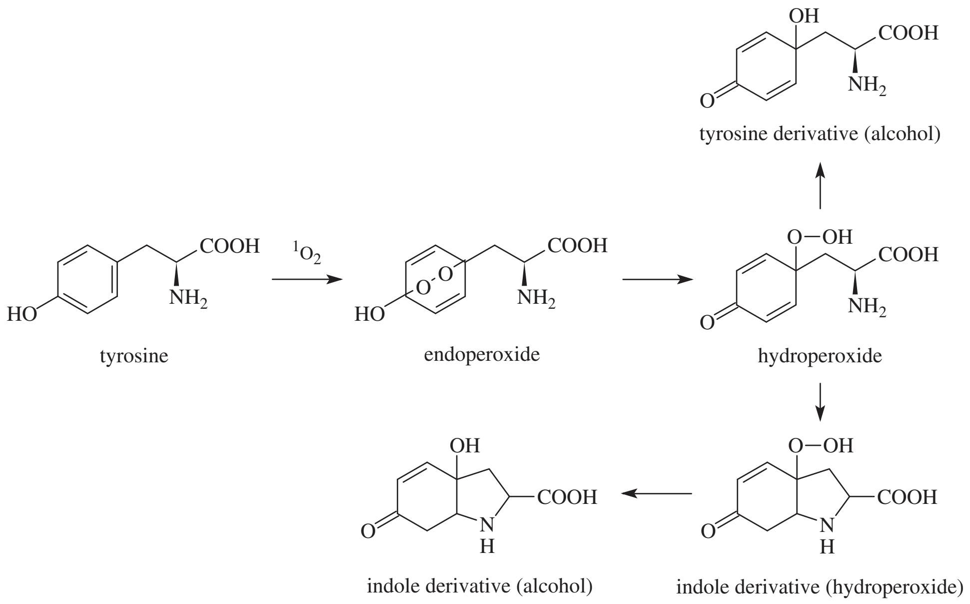

Figure 2.36 Oxidation of tyrosine by singlet oxygen. Wright, Bubb, Hawkins and Davies, 2002, Scheme 1. Reproduced by permission of John Wiley and Sons.

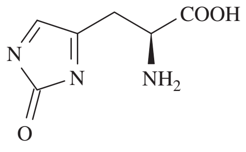
is schematically illustrated in Figure 2.37. Recent studies revealed the formation of 2-oxohistidine (**2-105**) in the histidine residues in proteins. The oxo group can be hydrated or undergo reaction with a lysine side chain amine group to form a protein cross-link.



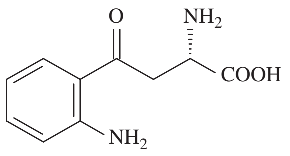
2-105, 2-oxohistidine

2.5.1.1.5 Tryptophan

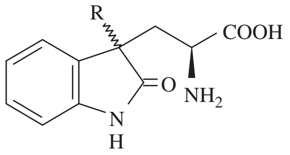
Tryptophan (free and bound in proteins) is a very oxylabile compound, especially in acid solutions. Free tryptophan and tryptophan residues in proteins are oxidised by reactive oxygen species, by hydrogen peroxide, fatty acid hydroperoxides, sulfoxides, peroxyacids and other oxidation agents and can also react via physical quenching, which results in energy transfer and de-excitation of singlet oxygen.

The main products of tryptophan oxidation with singlet oxygen are a dioxethane derivative, formed via 1,4-cycloaddition and a hydroperoxide at C-3. Subsequent decomposition of these intermediates yields *N*-formylkynurenine, whereas their ring closure leads to *cis*- and *trans*-isomers of 3α-hydroxypyrroloindoles, that is, 3a-hydroxy-1,2,3,3,8,8a-hexahydropyrrolo[2,3-*b*]indole-2-carboxylic acids and 3α,8α-dihydroxypyrroloindoles. The simplified reaction sequences are given in Figure 2.38.

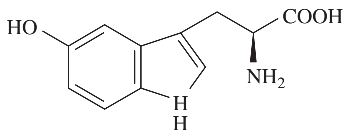
The oxidation of tryptophan with hydrogen peroxide yields a number of oxygen-containing products, via *cis*- and *trans*-isomers of hydroperoxides and free radicals. The main degradation products are the normal physiological metabolites *N*-formyl-L-kynurenine and L-kynurenine (3-anthraniloyl-L-alanine, **2-106**), totally unavailable as a source of tryptophan. Other reaction products include 3α-hydroxypyrroloindole derivative (Figure 2.38), 2,3-dihydro-2-oxotryptophan or 2-hydroxytryptophan (keto–enol tautomerism), also known as oxindolylalanine (**2-107**), dioxindolylalanine (**2-107**), that is, 2,3-dihydro-3-hydroxy-2-oxo-tryptophan and 5-hydroxytryptophan (**2-108**).



2-106, kynurenine, R = H



2-107, oxindolylalanine, R = H
dioxindolylalanine, R = OH



2-108, 5-hydroxytryptophan

The main intermediate in tryptophan degradation occurring in acid hydrolysates of proteins, where tryptophan is completely degraded, is oxindolylalanine (**2-107**), followed by simple indoles, such as 3-hydroxy-2-oxindole (**2-109**) and 2-oxindole (**2-109**). The reaction of tryptophan with cystine in acid solutions yields cysteine and α-amino-2-[(2-amino-2-carboxyethyl)thio]-1*H*-indole-3-propionic acid, known as tryptathionine (**2-110**). The tryptathionine cross-link formed between tryptophan and cysteine is characteristic of the toxic bicyclic peptides amatoxins and phallotoxins (see Section 10.3.2.9.2). 2-Aminoacetophenone (**2-111**) (together with its *N*-formyl derivative) is known as the character impact compound responsible for the atypical gluey and glutinous off-flavour of milk powders and sulfurated wines, which is a measure that is indispensable for white wine making. In non-fat

dry milk it is responsible for a strong flavour characterised as potato-like or cocoa-like. In wine, where it is formed by oxidative degradation of the phytohormone indole-3-acetic acid triggered by sulfuration, its flavour resembles naphthalene. Its odour threshold is 1 μg/l in wine. The products of microbial degradation of tryptophan, indole (**2-112**) and 3-methylindole known as skatole (**2-112**), are responsible for the off-flavour of some foods, such as stored eggs and boiled tripe (see Section 8.2.11.1.4).

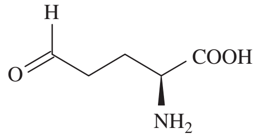
2.5.1.1.6 Other amino acids

In addition to the side chain of bound cysteine that is oxidised to bound cystine, other amino acid side chains in proteins can also react with reactive oxygen species (such as hydroxyl radicals) with catalysis by transition metal ions, which leads to generation of hydroxyl, oxo and formyl protein derivatives or peptide fragments. For example, the side chain of bound leucine is oxidised to 3-, 4- or 5-hydroxyleucine, the hydroxyl group of threonine is oxidised to an oxo group (yielding 2-amino-3-oxobutanoic acid on hydrolysis), the side chain of arginine yields a glutamic acid 5-semialdehyde residue (**2-113**), while the side chain of lysine produces 2-aminoadipic acid 6-semialdehyde residues (**2-114**).



2-113, glutamic acid 5-semialdehyde

2.5.1.2 Isomerisation

Conventional processing of food raw materials, as well as culinary methods used during food preparation, does not usually cause a significant isomerisation (racemisation) of L-amino acids (Table 2.25) (with the exception of aspartic acid). L-Aspartic acid and L-serine undergo racemisation relatively easily. L-Isoleucine (isomerises to D-*allo*-isoleucine), L-proline, L-threonine (isomerises to D-*allo*-threonine) and L-valine yield smaller amounts of D-isomers. Free amino acids are roughly ten times more stable than amino acids bound in proteins. An extensive racemisation of amino acids does however occur, even at relatively low temperatures, in alkaline media used to inactivate enzymes, microorganisms, microbial

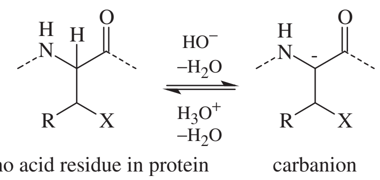

Figure 2.39 Racemisation of amino acids.

toxins, for extraction of nucleic acids, removal of residual meat from bones, production of protein isolates, peeling fruits and vegetables or during debittering of olives. In sterilised alkali-treated olives, significant amounts of D-Asx, D-Glx, D-Ser, D-His, D-Arg, D-Ala, D-Tyr, D-Val, D-Phe, D-Ile, and D-Leu were found. D-Lys was not detected. The most-abundant D-amino acids were D-Asx, D-Glx, D-Ser and D-Leu. The total content of D-amino acids in olives averaged 260 mg/kg in the edible portion, which is 4.2% of the total content of the amino acids (L- and D-enantiomers, 6170 mg/kg edible portion).

The racemisation of amino acids bound in proteins is accompanied by β-elimination of certain functional groups in side chains of amino acids, which yields **dehydroproteins** and subsequently cross-links in protein molecules (see Section 2.5.1.3.4). Racemisation begins with α-proton elimination of protein-bound amino acids, giving rise to an immediately isomerisable intermediate carbanion. This carbanion reacts with a proton (hydronium ion), which gives an equimolar mixture of the D-enantiomer and the original L-amino acid bound in protein. Proteolysis then releases the free D-amino acid (Figure 2.39).

The formation of D-amino acids reduces the nutritional value of the protein, because proteins containing D-amino acids have reduced digestibility by the organism and hence lower availability. The reason is the different methods of absorption, while L-amino acids are absorbed very efficiently in the digestive tract by active transport, D-amino acids are absorbed by passive diffusion, the effectiveness of which is limited. The toxicity of D-isomers is insignificant, with the exception of D-serine, which is reportedly nephrotoxic.

Racemisation of L-amino acids (elimination of an α-proton of protein bound amino acids) occurring *in vivo* during aging and some diseases (Alzeheimer's disease, cataracts and diabetes) is facilitated by reducing sugars. An example is the reaction of D-glucose shown in Figure 2.40. In essence, the Amadori product formed in the Maillard reaction (see Section 4.7.5) isomerises and is hydrolysed to a mixture of L-and D-amino acids under the formation of 3-deoxy-D-*erythro*-hexos-2-ulose or 1-deoxy-D-*erythro*-hexo-2,3-diulose.

2.5.1.3 Elimination and other reactions

2.5.1.3.1 Decarboxylation

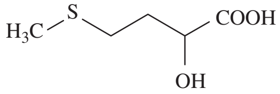
Amino acids eliminate carbon dioxide under the action of specific decarboxylases and, to a lesser extent, during heating to temperatures around their melting point (at around 200 °C). The products of decarboxylation of amino acids are the corresponding amines (Figure 2.41). Amines can also form by transamination of aldehydes catalysed by transaminases (see Section 8.2.10.1.2).

Aliphatic amines (e.g. methylamine formed from alanine and isobutylamine arising from valine) are very often flavour-active compounds of non-acidic foods, such as some cheeses. Amines derived from aromatic, heterocyclic and basic amino acids are biologically active compounds; therefore, they are collectively termed biogenic amines (see Section 10.3.2.8). An example of a biogenic amine is histamine, which is formed by decarboxylation of histidine. Histamine is involved, among other things, in immunological reactions of the organism. In meat and fish, biogenic amines are formed mostly as products of bacterial contamination. In foods obtained by fermentation processes (such as wine and sauerkraut), biogenic amines form by the activity of the microorganisms employed. A significant group of biogenic amines are the so-called polyamines, some of which (e.g. spermidine and spermine formed from putrescine or agmatine, the arginine decarboxylation product) play the roles of growth factors in both eukaryotic and prokaryotic cells. Phenylethylamine (the decarboxylation product of phenylalanine) is a precursor of catecholamines (dopamine, norepinephrine, or noradrenaline, and epinephrine, or adrenaline), a group of hormones secreted by the adrenal glands (see Section 10.3.2.8.1).

2.5.1.3.2 Transamination and oxidative deamination

Enzymatic reactions

Transamination catalysed by aminotransferases (formerly called transaminases) or oxidative deamination catalysed by oxidases transforms α-amino acids into the corresponding 2-oxoacids (Figure 2.42). Dehydrogenases transform 2-oxoacids into the corresponding secondary alcohols. For example, the product of glutamic acid oxidative deamination is 2-oxoglutaric acid, serine yields pyruvic acid and 2-oxobutanoic acid arises from threonine. Transamination of 2-oxobutanoic acid gives 2-aminobutyric acid. Certain bacteria, yeasts (including the yeast *Saccharomyces cerevisiae*) and fungi produce 2-hydroxy-4-(methylthio)butanoic acid (**2-115**) from methionine via reduction of the corresponding oxoacid. It is therefore a natural component of foods and feeds (in amounts of up to 60 mg/kg) produced by fermentation processes, such as fermented milk products, beer, bread and silage. In the form of its calcium salt, this methionine hydroxy analogue is used to fortify animal feeds. In the body, it is transformed into methionine.



2-115, 2-hydroxy-4-(methylthio)butanoic acid

Under the catalysis of ligases of the acid-thiol type, 2-oxoacids are transformed into acyl-CoA esters or by the action of decarboxylases (carboxylyases) into aldehydes having one carbon atom less than the original amino acid. For example, decarboxylation of pyruvic acid yields acetaldehyde and decarboxylation of 2-oxobutanoic acid gives propanal. The same aldehydes also form by Strecker

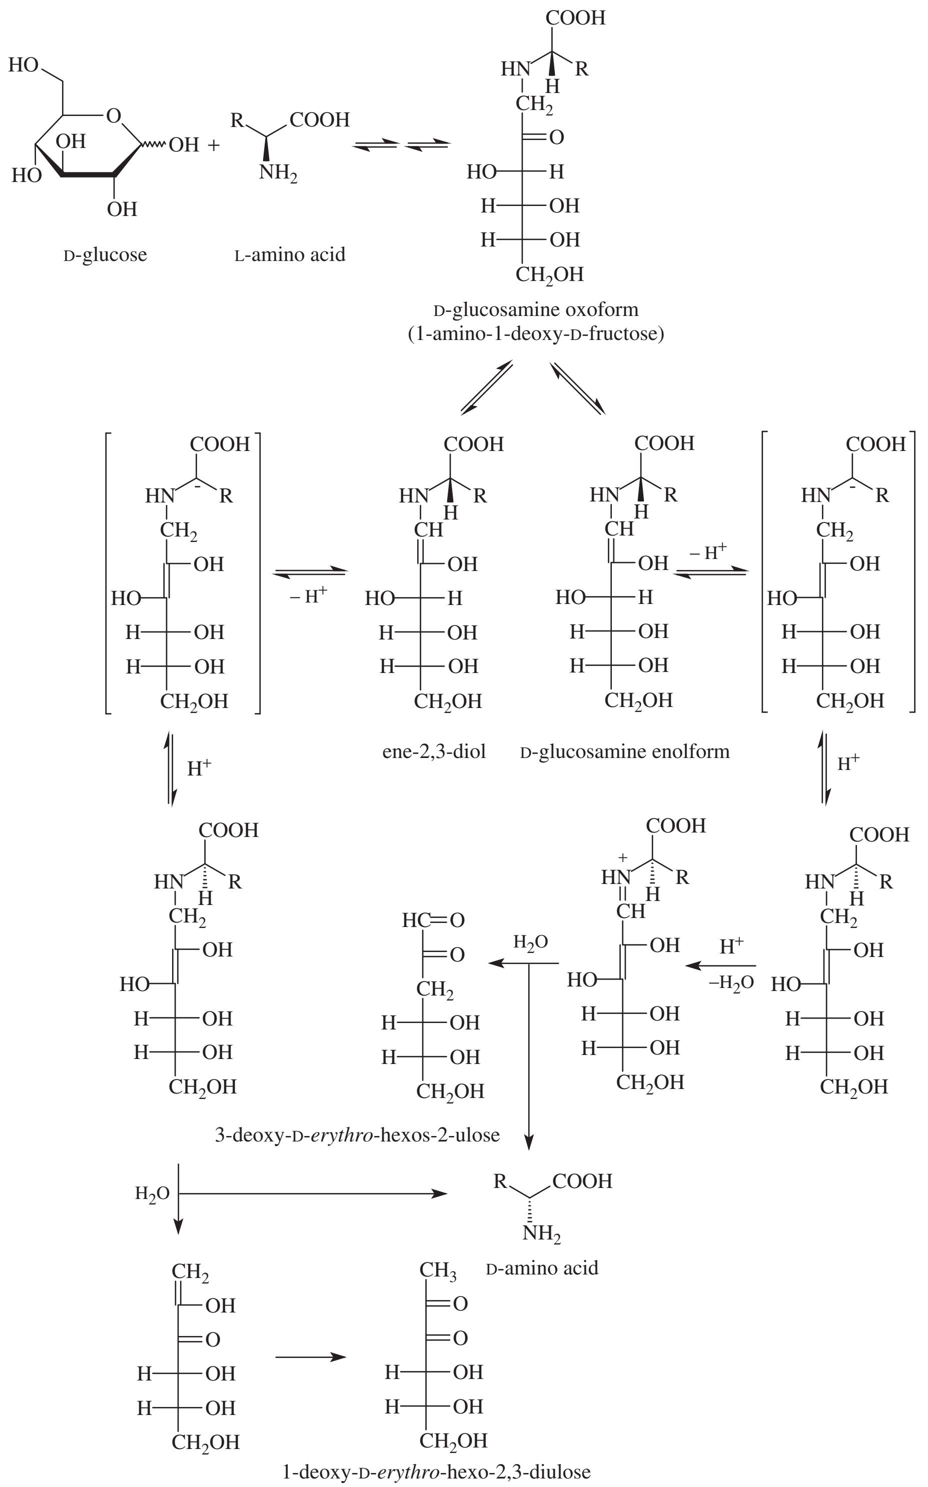


Figure 2.40 Isomerisation of L-amino acids catalysed by reducing sugars.

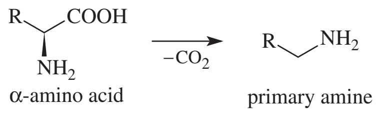

Figure 2.41 Decarboxylation of amino acids.

degradation of amino acids, which proceeds without catalysis by enzymes. Reduction of aldehydes by aldehyde dehydrogenases yields the corresponding primary alcohols. These can react with acyl-CoA esters (in the reaction catalysed by alcohol acyltransferases) to form carboxylic acids esters. Oxidation of aldehydes by aldehyde dehydrogenases provides carboxylic acid, and the

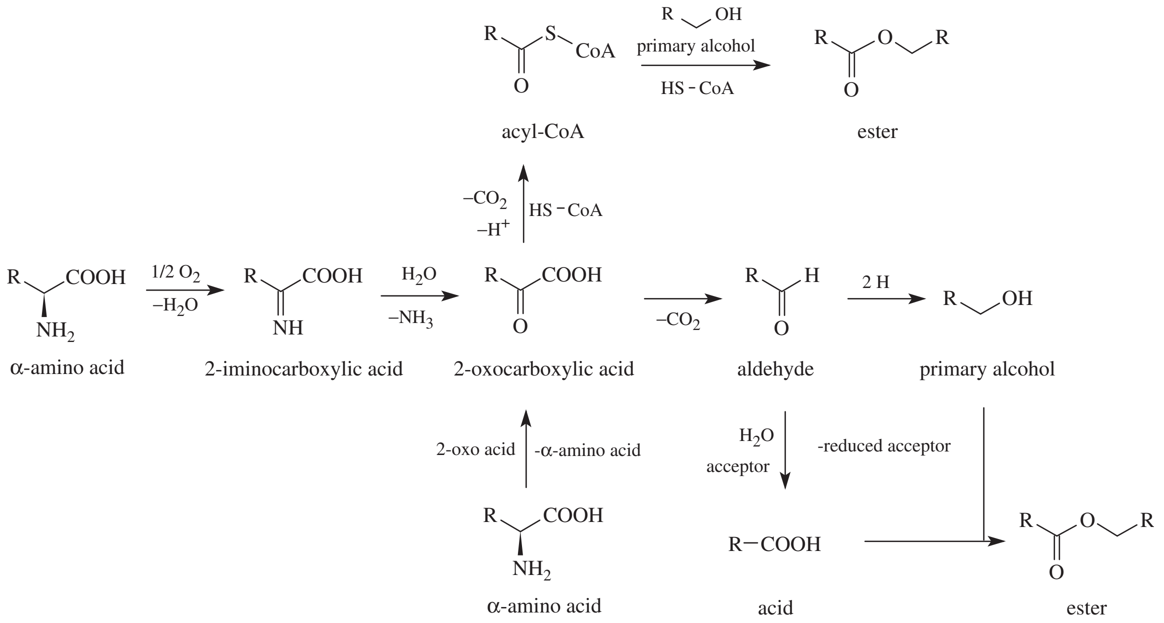

Figure 2.42 Formation of aldehydes, alcohols, carboxylic acids and their esters.

reaction with alcohols catalysed by carboxylesterases yields esters of carboxylic acids.

Aldehydes, alcohols, carboxylic acids, their esters and other transformation products of amino acid are important food volatiles. Aldehydes and fusel oil alcohols formed during alcoholic fermentation are important flavour-active compounds of alcoholic beverages. Esters of carboxylic acids are important flavour constituents of many foods, especially fruits, alcoholic beverages and dairy products. Aldehydes are also formed in the Maillard reaction during cooking, baking, frying and other thermal operations.

Strecker degradation

Oxidation of amino acids by oxidising agents, which generates carbon dioxide, ammonia and a carbonyl compound containing one less carbon atom than the starting amino acid, is called a **Strecker degradation** of amino acids (Table 2.26).

Monoaminomonocarboxylic α-amino acids with a primary amino group produce sensory active aldehydes called Strecker aldehydes. Strecker degradation of β-amino acids yields alkan-2-ones known as methylketones (see Section 8.2.4.1.2). By analogy, alkane-3-ones (ethylketones) are formed from γ-amino acids. The general reaction is schematically indicated in Figure 2.43. The reaction mechanism, however, varies considerably depending on the type of oxidant and amino acid. 2-Imino acids and 2-oxoacids can in some cases apparently form as intermediates, analogous to enzymatically catalysed transamination and oxidative deamination of amino acids (see Section 2.5.1.3.2). Some Strecker aldehydes readily decompose, such as methional, or yield cyclic products, such as 5-aminopentanal, which dehydrates to 2,3,4,5-tetrahydropyridine.

Inorganic oxidising agents, such as hypochlorites found in some sanitation and disinfection agents, may oxidise amino acids only in exceptional circumstances. Important oxidising agents are

Table 2.26 Strecker aldehydes produced from α-amino acids.

Amino acid	Degradation product	Amino acid	Degradation product
Glycine	Formaldehyde (methanal)	Cysteine	2-Mercaptoethanal
Alanine	Acetaldehyde (ethanal)	Methionine	3-Methylthiopropanal (methional)
Valine	2-Methylpropanal	Aspartic acid	3-Oxopropionic acid
Norvaline	Butanal	Glutamic acid	4-Oxobutyric acid
Leucine	3-Methylbutanal	Lysine	5-Aminopentanal
Norleucine	Pentanal	Ornithine	4-Aminobutanal
Isoleucine	2-Methylbutanal	Phenylalanine	2-Phenylethanal (phenylacetaldehyde)
Serine	Glycolaldehyde	Tyrosine	4-Hydroxyphenylacetaldehyde
Threonine	2-Hydroxypropanal	3,4-Dihydroxyphenylalanine	3,4-Dihydroxyphenylacetaldehyde

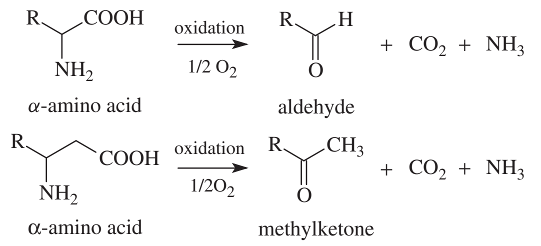

Figure 2.43 General scheme of Strecker degradation of amino acids.

mainly organic compounds, which contain electronegative functional groups in the molecule. The active substances in the Strecker degradation of amino acids in foods are therefore also fatty acid hydroperoxides, unsaturated aldehydes and ketones, derivatives of furan-2-carbaldehyde, α-hydroxyaldehydes and α-hydroxyketones and sugars (aldoses and ketoses). The active substance is also pyruvic acid, L-dehydroascorbic acid, quinones such as benzoquinones, naphthoquinones and anthraquinones and, therefore, also some compounds belonging to vitamins K or vitamins E (oxidised to tocopheryl quinones). The active substances are also some unsaturated lipid oxidation products, such as epoxyoxoene fatty acids.

Strecker degradation of amino acids is an extremely important reaction that occurs during storage and particularly during thermal processing of food. The main products of this reaction (Strecker aldehydes) are important volatiles in a variety of foods and many other aromatic and flavouring substances are formed by subsequent reactions of Strecker aldehydes and other Strecker degradation products, especially α-aminocarbonyl compounds, ammonia, amines and various sulfur compounds. Strecker degradation of amino acids also has its negative side, which is a loss of some essential amino acids (valine, leucine, isoleucine, threonine, methionine and phenylalanine).

2.5.1.3.3 *Elimination of ammonia, hydrogen sulfide and water*

α-Aminocarboxylic acids

When heated to higher temperatures (above their melting points) and in acidic solutions, α-amino acids condense through the formation of linear and cyclic dipeptides, cyclic six-membered amides known as 3,6-disubstituted 2,5-dioxopiperazines (see Section 2.3.3.2 and Figure 2.14).

β-Aminocarboxylic acids

Heating β-amino acids leads to the elimination of ammonia and to the formation of alk-2-enoic acids (α,β-unsaturated) acids (Figure 2.44). For example, aspartic acid behaves as a β-amino acid and produces (*E*)-but-2-enedioic acid, known under the trivial name fumaric acid. The reverse reaction, in which fumaric acid gives aspartic acid, occurs in living organisms and is catalysed by the enzyme aspartase. Analogously, elimination of ammonia from asparagine produces fumaric acid monoamide, known as

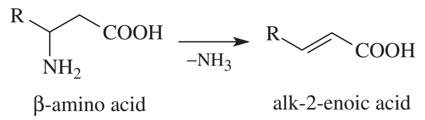

Figure 2.44 Formation of alk-2-enoic acids from β-amino acids.

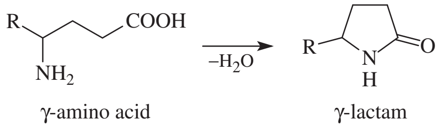

Figure 2.45 Formation of γ-lactams from γ-amino acids.

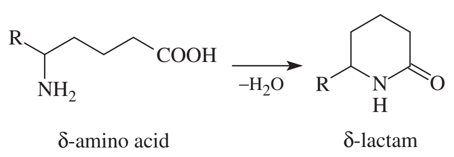

Figure 2.46 Formation of δ-lactams from δ-amino acids.

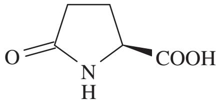
fumaramic acid. Its decarboxylation could theoretically produce toxic acrylamide. However, acrylamide is produced in reactions of asparagine with reducing sugars (known as the Maillard reaction) that enable its decarboxylation (see Section 12.2.2).

γ-Aminocarboxylic acids and δ-aminocarboxylic acids

The heating of γ- and δ-amino acids leads to intramolecular condensation and the formation of *N*-analogues of lactones, termed lactams. γ-Lactams (butane-4-lactams or pyrrolidine-2-ones) form from γ-amino acids (Figure 2.45), while δ-amino acids yield δ-lactams (pentane-5-lactams or piperidine-2-ones) (Figure 2.46).

Glutamic acid and glutamine behave as γ-amino acids, as they are easily transformed into L-5-oxopyrrolidin-2-carboxylic acid (also known as pyroglutamic acid, glutiminic acid or 5-oxoproline, 2-116) and its ammonium salt, respectively, during the thermal processing of foods. Pyroglutamic acid reportedly exhibits umami-like taste. The free acid occurs at levels of up to 300 mg/kg in fresh vegetables and fresh and preserved fruits, and in concentrations of 500–3000 mg/kg in canned vegetables, for example in pickled beets. The pyroglutamic acid content can serve as a qualitative index to estimate the proportion of tomatoes (refractometric dry matter introduced by the raw material) in tomato products, for example in the production of tomato paste (ketchup) by the hot-brake technology that includes preheating of tomatoes and straining of tomato seeds, as well as other operations conducted at elevated temperatures (such as thickening, puree



2-116, L-5-oxopyrrolidine-2-carboxylic acid

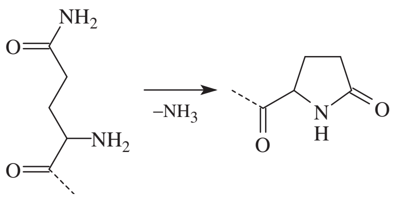


Figure 2.47 Transformation of *N*-terminal glutamine.

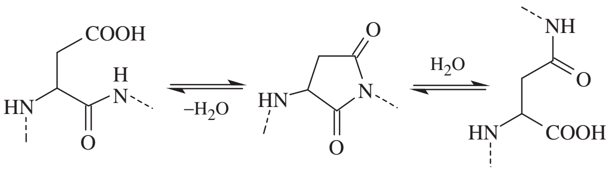

Figure 2.48 Interconversion of aspartic acid carboxylic groups.

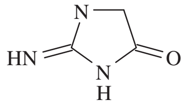
pasteurisation, stirring and ketchup pasteurisation). Fresh tomatoes typically contain less than 10 mg/kg pyroglutamic acid. During processing, its content increases by one to two orders, and the final concentration of pyroglutamic acid in tomato juice is 25–40 mg/kg, in ketchup 150–220 mg/kg and in puree 630–820 mg/kg, depending on the tomatoes content.

Transformation (spontaneous cyclisation) of the *N*-terminal glutamine into *N*-terminal pyroglutamate also occurs in proteins (e.g. in κ-casein and *para*-κ-casein) during thermal processing, and takes place especially easily in acidic solutions (Figure 2.47). Aspartic acid only undergoes interconversion of α- and β-carboxylic groups under the same conditions (Figure 2.48).

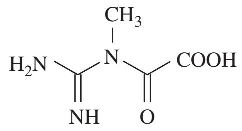
On heating the γ-amino acid creatine (**2-46**) yields an imidazolidine derivative known by the trivial name of creatinine (**2-117**). For example, fresh beef muscle contains creatine in amounts ranging from about 0.30 to 0.60% (according to the muscle type), while the creatinine content is only 0.020–0.040%. The creatine content of pork meat is lower than in beef, being 0.25–0.37%, while the creatinine content is only 0.003–0.009%. However, when the meat is cooked, the creatine content decreases whilst the creatinine content increases: the total content of these two substances might therefore be a useful indicator for quantifying the heat treatment applied in the processing of meat products. For example, cooked ham contains 0.29–0.32% of creatine and 0.032–0.073% of creatinine.



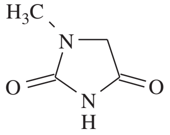
2-117, creatinine

The quality criteria for beef extract specify the minimum creatinine content as 8.5% (dry matter, added salt excluded) for use in the production of bouillon cubes. Creatine and creatinine levels may be therefore used as a measure during the detection of beef extracts in food products. Serum creatinine concentration is the most frequently used clinical estimate of renal function.

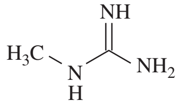
The product of creatine degradation via *N*-methylguanidinoglyoxylic acid (creatone, **2-118**) is oxalic acid and *N*-methylguanidine (**2-119**), which in fresh pork, beef, chicken and fish is found at levels of 1–10 mg/kg. *N*-Methylguanidine occurs in larger amounts (20–180 mg/kg) in some Japanese dishes prepared from smoked and dried fish. In the production of beef and whale meat extracts, which are used in soup seasoning preparations, creatinine produces small amounts of the amino acid sarcosine (*N*-methylglycine, **2-12**) and urea. Deamidation of creatinine by bacteria or in alkaline solutions can yield the toxic *N*-methylhydantoine (**2-120**). Creatinine is also a precursor of toxic aminoimidazoazaarenes found mainly in grilled meat and fish (see Section 12.2.1.1).



2-118, *N*-methylguanidinoglyoxylic acid



2-119, *N*-methylguanidine



2-120, *N*-methylhydantoine

Hydroxyamino acids

Under acidic conditions and especially during acid hydrolysis of proteins, serine and threonine isomerise to imino acids and β-elimination of water molecule yields the corresponding 2-oxoacids (Figure 2.49). Thus serine produces pyruvic acid (R = H) and threonine yields 2-oxobutanoic (2-oxobutyric) acid (R = CH_3). Decarboxylation of these oxocarboxylic acids at elevated temperatures yields acetaldehyde and propanal, respectively. Thermal degradation of serine, for example, has been reported to produce a wide range of products. The initial thermal degradation products include pyruvic acid, glycine and formaldehyde (formed by retro aldol condensation), 2-aminoethanol (formed by decarboxylation) and acetaldehyde (formed by elimination of ammonia from 2-aminoethanol). A number of products then arise in reactions of these initial products. Reaction of pyruvic

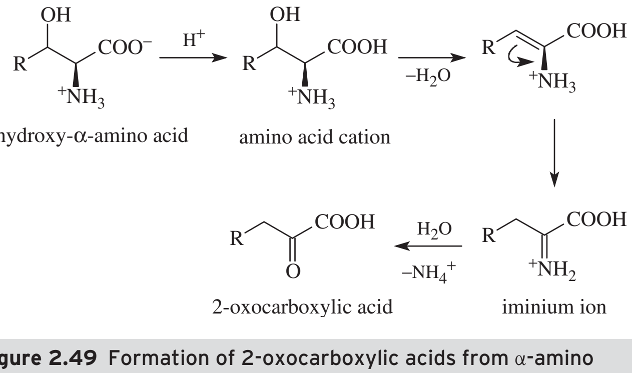


Figure 2.49 Formation of 2-oxocarboxylic acids from α-amino acids.

acid with 2-aminoethanol produces alanine and glycolaldehyde, reaction of acetaldehyde with 2-aminoethanol yields glycolaldehyde, ethylamine and 2-methyl-2-oxazoline, aldol condensation of formaldehyde to glycolaldehyde forms glyceraldehyde and reactive α-hydroxycarbonyl compounds are involved in the formation of heterocyclic compounds such as substituted pyrazines and pyrroles and some other heterocyclic compounds.

Amino acid amides

At temperatures of around 100 °C, asparagine and glutamine side chains react with the side chain of bound lysine (Figure 2.50) with the elimination of ammonia (the reaction is termed deamidation) and the peptide chains are connected by intermolecular and intramolecular transverse covalent bonds. These bonds, known as isopeptide bonds, consist of dipeptides ε-*N*-(β-aspartyl)-L-lysine and ε-*N*-(γ- glutamyl)-L-lysine, respectively. About 15% of lysyl residues can react in this way. The digestive proteases of some animals (e.g. chickens and rats) can split these bonds, but for humans the so-called bound lysine is not available. The result is the certain, but usually not very significant, reduction of the nutritional value of proteins. Reduction of the nutritional value can be important in cases where a diet is low in protein and the limiting amino acid of the protein is lysine. The Maillard reaction often leads to an extensive loss of lysine.

Sulfur amino acids

Free cystine is relatively stable at temperatures around 100 °C. The reaction that is observable during thermal processing of foods at temperatures of approximately 100 °C is partial elimination of hydrogen sulfide from bound cystine, which is often called protein desulfuration (Figure 2.51). This reaction splits the disulfide bridges in protein with the formation of cysteine and sulfenic acid residues. The unstable sulfenic acid intermediate is hydrolysed with the formation of hydrogen sulfide, yielding a reactive molecule containing a free carbonyl group. This compound reacts with the ε-amino group of lysine, which results in a clear loss of cystine (cysteine) and lysine. The collagen-bound lysine reacts similarly (see Section 2.4.5.1.3). At higher temperatures or in alkaline solutions, even under milder conditions, bound cysteine eliminates hydrogen sulfide yielding dehydroprotein as an intermediate (Figure 2.52). The resulting hydrogen sulfide is involved in the formation of many flavour-active compounds in thermally processed foods (see Section 8.2.9.1.1). Similarly to protein bound cysteine, some other protein bound amino acids can eliminate small molecules, yielding dehydroprotein. For example, protein bound methionine eliminates dimethyl sulfide.

If allowed by the structure of the protein bound amino acids, the heat treatment of protein or reaction in an alkaline solution produces carbanion as an intermediate in the pathway to D-amino acids (see Section 2.5.1.2) and dehydroprotein (Figure 2.52). The most frequently eliminated groups are the cysteine thiol group (X = SH), hydroxyl group of serine (X = OH) and phosphorylated hydroxyl group of phosphoserine (X = OPO_3H_2), which yield dehydroprotein containing bound 2-aminoacrylic acid, known as dehydroalanine (R = H). The reactive side chains of bound amino acids, such as side chains of lysine, ornithine and cysteine, can add to the double bond of the dehydroprotein, which leads to cross-linking of polypeptide chains in the protein (Figure 2.53).

Cross-linked proteins produce unusual amino acids by proteolysis. Bound lysine yields lysinoalanine (**2-121**), cysteine lanthionine (**2-122**) and ornithine ornithinoalanine (**2-123**). Bound ornithine forms in proteins (together with urea) by alkaline hydrolysis of arginine. In the same way, many other amino acids (arginine, histidine, threonine, serine, tyrosine and tryptophan) and also amines and ammonia react with dehydroprotein.

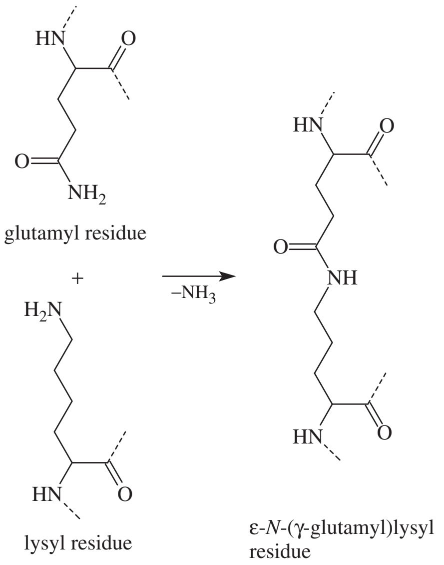

Figure 2.50 Deamidation of proteins.

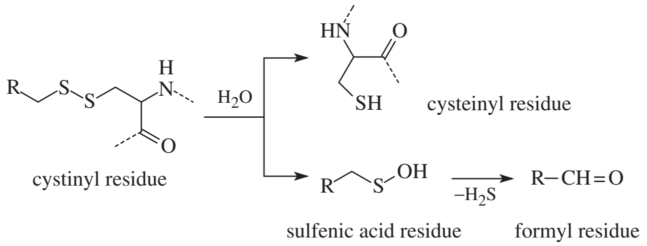

Figure 2.51 Desulfuration of proteins.

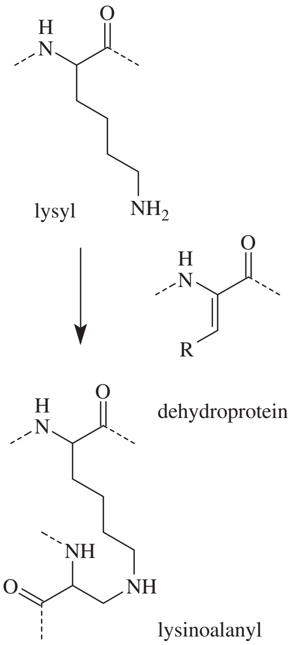

Figure 2.53 Formation of cross-links in proteins.

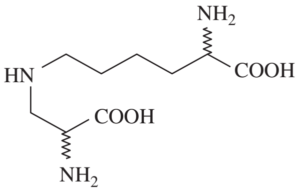
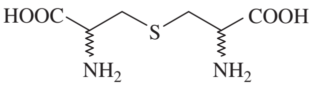
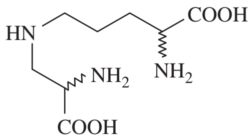


2-121, lysinoalanine



2-122, lanthionine



2-123, ornithinoalanine

These unusual amino acids are not bioavailable and therefore reduce the nutritional value of proteins. Some products are even toxic, especially lysinoalanine. In theory, the hydrolysis of protein containing bound L-lysine produces the same amount of free L,L- and L,D-lysinoalanine. Furthermore, the isomerisation of bound L-lysine produces bound D-lysine and protein hydrolysis then gives free D,L- and D,D-lysinoalanine. It is suggested that alkali treatment of protein might have important toxicological implications for man. Free lysinoalanine is partly excreted in the urine and partly catabolised in the kidney. Feeding lysinoalanine to rats induces changes in kidney cells characterised by enlargement of the cytoplasm and nucleus, designated as nephrocytomegaly (karyomegaly). The toxicity of the individual isomers differs. The least toxic is D,D-lysinoalanine, about three times more toxic is L,L-isomer, ten times more toxic is D,L-isomer and about 30 times more toxic is L,D-lysinoalanine. Lysinoalanine and related amino acids of protein cross-links are present in many foods, especially foods processed at high temperatures and in alkaline media (Table 2.27).

Table 2.27 Lysinoalanine content in some foods.

Food	Content (g/kg protein)	Food	Content (g/kg protein)
Soybean meal (defatted)	1.5	Sausage (boiler)	0.05
Soy protein (texturised)	0.3	Sausage (baked)	0.2
Soy protein (isolate)	0.4–11.6	Chicken (raw)	0.0
Milk evaporated	0.4–0.9	Chicken (baked)	0.1
Casein (acidic)	0.1–0.2	Egg white (original)	0.02
Sodium caseinate	0.3–6.9	Egg white (boiled)	0.1–0.4
Calcium caseinate	0.2–4.3	Egg white (baked)	0.4–1.1
Sausage (original)	0.0	Egg white (dried)	0.2–1.8

The peptide nisin, for example, contains *meso*-lanthionine (see Section 11.2.1.2.1).

More than 50 xenobiotic amino acids are known. Ammonia, which adds to dehydroprotein to form 2,3-diaminopropionic acid (β-aminoalanine, **2-41**), was used in the prevention of lysinoalanine and other cross-link amino acids formation.

2.5.2 Reactions with food components

2.5.2.1 Reactions with minerals

Polypeptide chains of proteins and peptides and free amino acids contain basic functional groups (typically amino or imino groups) and acidic functional groups (usually carboxyl groups or phosphoric acid residues in phosphoproteins), and therefore react with acids and bases. Salts of amino acids and proteins with acids and bases are stable only in a certain range of pH values. High molecular weight complexes can also be formed between basic and acidic proteins and between proteins and some polysaccharides. The most important reaction is the formation of salts and complexes with metal ions. Metal ions, however, often act as cofactors of enzymes and constitute a natural part of many complex proteins, such as milk caseins. Formation of salts and complexes of proteins with various metal cations (sodium, potassium, calcium) is employed in various food technologies, for example in production of caseinates and soybean curd (tofu). The formation of protein salts with various inorganic metal ions affects the solubility of proteins. Sodium, potassium and ammonium salts are predominantly soluble, while calcium salts are less soluble, and salts of heavy metals are mostly insoluble. Particularly strong complexes (their stability depends on pH and the conformation of polypeptide chains) are formed by cysteine, tyrosine and basic amino acids, lysine and histidine, therefore proteins, peptides and amino acids often act as natural antioxidants of lipids and other oxylabile substances because they react with ions of heavy metals, such as Fe^{3+} and Cu^{2+} that act as

active catalysts in the oxidation of lipids. A few simple examples of the structures of metal complexes are given in Section 6.2.2.1.

In some cases, however, the formation of salts and complexes is an unwanted phenomenon, as protein salts and complexes with polyphenols form hazes and sediments in preserved fruit, fruit juices and beer. Protein hazes can also form in white wines after bottling, where the main factor is inorganic sulfate ions. Protein complexes with transition metals are often coloured, and their formation in processed foods is generally undesirable. An example is the protein conalbumin occurring in egg white, which readily forms coloured complexes with metal ions (pink with Fe^{3+}, yellow with Cu^{2+} and Mn^{3+}) in media of pH $\geq$ 6 through tyrosine and histidine residues of the polypeptide chain. Complexes with iron ions often cause discoloration of egg products, but in media with pH < 4, these complexes dissociate to the original colourless compounds.

In addition to oxidation reactions (summarised in Section 2.5.1.1), the side chains of amino acids residues in proteins are readily oxidised through the catalysis of metal ions.

2.5.2.2 Reactions with oxidised lipids

Oxidised lipids react with each other and also with non-lipid food components under the conditions used in culinary and technological processing and even during storage and *in vivo*. Hydroperoxyl free radicals and epoxy and aldehyde functional groups of oxidised lipids are mainly involved in the reactions with proteins (also with peptides and free amino acids), reacting mainly with sulfhydryl, amino, guanidyl and imidazole functional groups of proteins and to a small extent with their peptide bonds. Reaction of proteins with oxidised lipids results in products of decreased solubility and digestibility, and often lead to unwanted discolourations, especially in fish.

Reaction products of reactive aldehydes derived from oxidised lipids, such as acrolein, (*E*)-4-hydroxynon-2-enal and malondialdehyde, with lysine, arginine and other amino acids are described as examples in Section 4.7.5.6. These products, ALE (advanced lipoxidation end products), formed *in vivo* are markers of oxidative stress in the organism. Reaction mechanisms are discussed in Section 3.8.1.12.1. As the final reaction products, proteins and oxidised lipids also form dark insoluble macromolecular products that contain variable proportions of lipid and protein fractions. In particular, such products include protein oligomers, proteins with oxidised sulfur amino acids, proteins containing imine bonds (C=N) formed by reaction with aldehydes or hydroperoxides (they mostly arise from the ε-amino group of bound lysine) and lipoproteins, in which lipids and proteins are bound by covalent bonds in contrast to native lipoproteins.

The amino groups of free amino acids and *N*-terminal amino groups of proteins also react with free fatty acids and triacylglycerols, yielding the corresponding fatty acid amides. These may be precursors of non-volatile nitroso compounds (nitrosamides) classified as food contaminants (see Section 12.2.7.1).

2.5.2.3 Reactions with aldehydes, ketones and sugars

2.5.2.3.1 Reactions with aldehydes

α-Amino groups of free amino acids, *N*-terminal α-amino groups of amino acids bound in peptides and proteins and ε-amino group of bound lysine react with carbonyl compounds (such as aldehydes, ketones and reducing sugars). The reaction starts with the addition of the amino group of the amino acid to the carbonyl group of the carbonyl compound to form imines, formerly known as Schiff bases (Figure 2.54). Subsequent reactions of the imines lead to a variety of reaction products. The reaction with reducing sugars, the Maillard reaction, is the most important reaction that takes place in foods during processing (see Section 4.7.5).

An important factor influencing the reactivity of amino acids and carbonyl compounds is pH. Reactivity of amino acids also depends greatly on basicity, or more precisely on the nucleophilicity, of the amino group, but also on other factors that are described in detail in Section 4.7.5.

Amino acids with reactive functional groups in the side chains, both aromatic and heterocyclic amino acids, react with aldehydes with the formation of a variety of heterocyclic products. Common food components that appear in foods during production are aldoses and various aliphatic, aromatic and heterocyclic aldehydes (such as formaldehyde, acetaldehyde, benzaldehyde and 2-furancarbaldehyde) and vanillin and anisaldehyde, which are added to foods as flavouring agents. With formaldehyde, cysteine gives thiazolidine-4-carboxylic acid, also known as thioproline. Higher aldehydes yield C-2 substituted (2*RS*,4*R*)-thiazolidine-4-carboxylic acids (Figure 2.55).

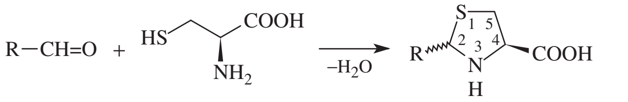


Figure 2.55 Reaction of cysteine with aldehydes.

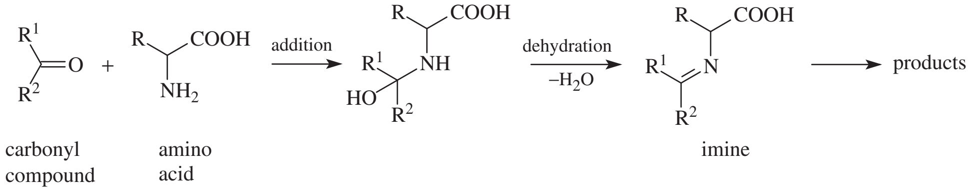

Figure 2.54 Reaction of amino acids with carbonyl compounds.

2-Methylthiazolidine-4-carboxylic acid, a condensation product of cysteine and acetaldehyde, occurs even in human blood as a consequence of ethanol consumption. Serine and threonine analogously produce C-2 substituted (2*RS*,4*S*)-oxazolidine-4-carboxylic acids (**2-124**). Heterocyclic products, C-2 substituted (2*RS*,4*S*)-pyrimidine-4-carboxylic acids, are also produced in the reaction of aldehydes with asparagine (**2-125**). Phenylalanine yields C-1 substituted (1*RS*,3*S*)-tetrahydroisoquinoline-3-carboxylic acids (**2-126**) and analogous products arise from tyrosine. Tryptophan reacts with aldehydes under the formation of 9*H*-pyrido[3,4-b]indole (also known as β-carboline or norharmane) derivatives, (1*RS*,3*S*)-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acids (**2-127**, R = H or alkyl or residues of other aldehydes and sugars), the reaction of tryptamine yields the corresponding (1*RS*)-1,2,3,4-tetrahydro-β-carbolines.

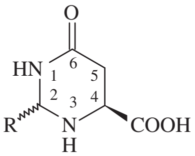
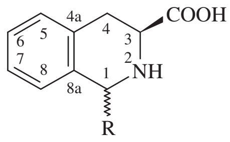
R^1 = CH_3, threonine derived products



2-125, pyrimidine-4-carboxylic acids



2-126, 1,2,3,4-tetrahydroisoquinoline-3-carboxylic acids

Of special importance are two types of these heterocyclic products, thiazolidine-4-carboxylic acids and β-carboline derivatives that may react with nitrogen oxides or nitrites with the formation of nitroso compounds, which can occur in foods as contaminants (see Section 12.2.7). Tryptophan-derived 1,2,3,4-tetrahydro-β-carboline and β-carboline alkaloids have been increasingly found in mammalian tissues and fluids, as well as in many foods of different origins, alcoholic and non-alcoholic drinks, fruit-derived products and tobacco smoke. Biochemical studies have revealed several actions of β-carbolines, including inhibition of monoamine oxidase, which catalyses the oxidative deamination of monoamines, competitive inhibition of monoamine neurotransmitter serotonine uptake, general inhibition of Na^+ dependent transports, binding to benzodiazepine (a psychoactive drug) and opiate receptors. They may act as neuromodulators and some may have an endocrinological function.

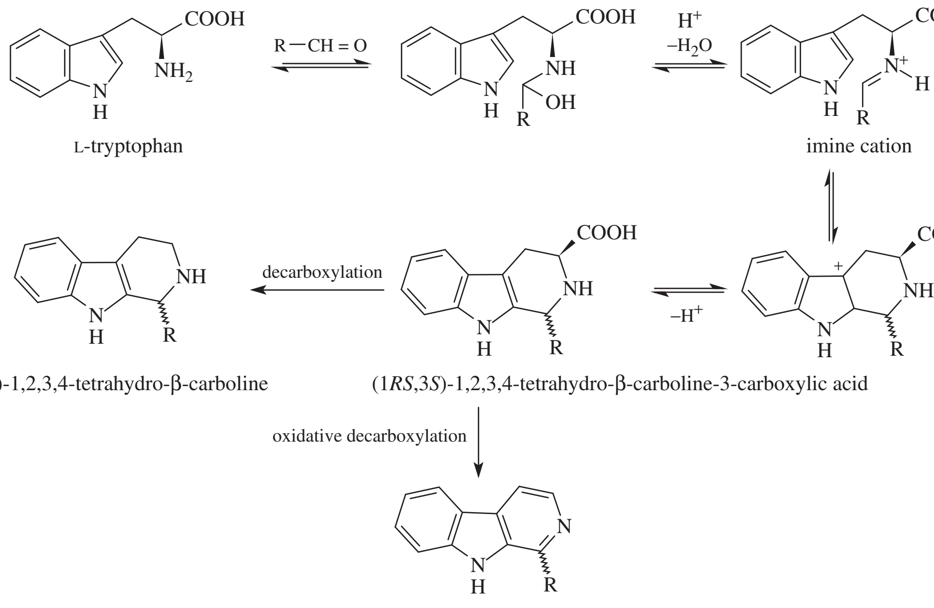

Figure 2.56 Reaction of tryptophan with aldehydes.

Tryptophan-derived 1,2,3,4-tetrahydro-β-carboline and β-carboline alkaloids result in foods through a Pictet–Spengler condensation (a special case of the Mannich reaction) of indoleamines, such as tryptophan and tryptamine, with aldehydes. The mechanism of the Pictet–Spengler reaction leading to 1,2,3,4-tetrahydro-β-carboline and β-carboline alkaloids is given in Figure 2.56.

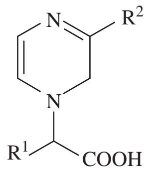
1,2,3,4-Tetrahydro-β-carboline-3-carboxylic acids derived from formaldehyde and acetaldehyde and their decarboxylation products, 1,2,3,4-tetrahydro-β-carboline (**2-127**, R = H) and 1,2,3,4-tetrahydro-1-methyl-β-carboline (**2-127**, R = CH_3) have been identified in various products, such as cashew nuts, walnuts, pineapple, banana, wine, vinegar, beer, soy sauce, fruit juices, syrups, purees and jams. For example, 1,2,3,4-tetahydro-β-carboline-3-carboxylic acid and 1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid, as two diastereoisomers (1*S*,3*S* and 1*R*,3*S*), have been found in commercially prepared fruit juices at levels of 0.01–1.45, 0.02–9.1 and 0.01–2.48 μg/g for 1,2,3,4-tetahydro-β-carboline-3-carboxylic acid, (1*S*,3*S*)-1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid and (1*R*,3*S*)-1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid, respectively. The content was higher in citrus juices (orange and grapefruit) than in other juices (grape, apple, pineapple, peach, banana, pear and tomato).

Decarboxylation and oxidation products of 1,2,3,4-tetrahydro-β-carboline-3-carboxylic acids derived from formaldehyde, 9*H*-pyrido[3,4-*b*]indole (norharmane, **2-127**), and acetaldehyde, 1-methyl-9*H*-pyrido[3,4-*b*]indole (harmane, **2-127**), were identified in a number of foods at levels up to 700 mg/kg, although more typically their concentrations in smoked, cooked and fermented foods range from a few mg/kg to 1–2 orders of magnitude less. Typical norharmane and harmane findings in pan-fried, minced meat, beef patties or ground beef prepared at temperatures of 175–230 °C and cooking times 2–10 min ranged from 0.8 to 11.3 μg/kg and from 1.4 to 10.3 μg/kg, respectively. In raisins norharmane concentrations ranged from 2 to 120 μg/kg and concentrations of harmane were 6–644 μg/kg. Dark-brown raisins (sun-dried) contained higher levels of these alkaloids than golden raisins. 1,2,3,4-Tetrahydro-β-carboline-3-carboxylic acids were identified in higher amounts, reaching up to 50 mg/kg. Arabica coffees contained norharmane and harmane at levels of about 136 and 51 μg/l, respectively. Commercial blends (usually with a maximum of 30% robusta) ranged from the cited arabica values to 345 μg/l of norharmane and to 145 μg/l of harmane. Higher levels were found in tobacco smoke, with 11.2 μg of norharmane and 3.6 μg of harmane per cigarette.

Reactions of tryptophan with aldohexoses (at temperatures above 50 °C and in acidic solutions) are a prerequisite for the formation of glycotetrahydro-β-carbolines that arise together with *N*-glycosides and *C*-glycosyl conjugates of tryptophan. Pictet–Spengler type condensation of tryptophan and glucose gives (1*R*,3*S*)- and (1*S*,3*S*)-diastereoisomers of 1-(D-*gluco*-1,2,3,4,5-pentahydroxypent-1-yl)-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid (**2-127**). These compounds were also found in fruit juices. Grape juices or mixed fruit juices containing grape juice exhibited the highest level of pentahydroxypentyl-tetrahydro-β-carboline-3-carboxylic acids (up to 3.8 mg/l). Relatively high concentrations of these β-carbolines were also found in tomato, pineapple, multifruit and tropical fruit juices. In contrast, it was not detected in apple juices or banana and peach nectars, whereas a low level was detected in orange juices. In the presence of atmospheric oxygen or mild oxidants, such as L-dehydroascorbic acid, 1-(D-*gluco*-1,2,3,4,5-pentahydroxypent-1-yl)-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid readily eliminates carbon dioxide and is oxidised to 1-(D-*gluco*-1,2,3,4,5-pentahydroxypent-1-yl)-β-carboline (**2-127**). Diastereoisomeric 1-(1,3,4,5-tetrahydroxypent-1-yl)-β-carbolines, 1-(1,4,5-trihydr-

oxypent-1-yl)-β-carbolines and *E*/*Z* isomers of 1-(1,5-dihydroxypent-3-en-1-yl)-β-carbolines, arising by oxidative decarboxylation and dehydration, isomerisation and reduction of the carbohydrate-derived side chain, were found in various food products. The highest concentrations of these β-carbolines were found in ketchups, soy and fish sauces. The main components were diastereoisomers of 1-(1,3,4,5-tetrahydroxypent-1-yl)-β-carbolines (1.4–3.5 mg/kg). β-Carbolines flazine and perlolyrine (**2-127**) derived from a degradation product of hexoses 5-hydroxymethylfuran-2-carbaldehyde were also found in soy sauce. Common concentrations of these alkaloids were 24 and 2.8 mg/kg, respectively.

Most of the reactions that occur in amino acids also take place in peptides and proteins. Heterocyclic products are formed when the *N*-terminal amino acid is involved in the ring formation. Products such as *N*-3 substituted 2-alkylpyrazin-2-ones form, for example, in reactions of peptides with glyoxal (**2-128**, R^1 and R^2 = peptide residues).



2-128, substituted pyrazin-2-one derivative

2.5.2.3.2 Reactions with sugars

The reaction with reducing sugars, the Maillard reaction, is the most important reaction that takes place in foods during processing. Reducing sugars are very reactive compounds. Their reactions with amino acids are described in detail in Section 4.7.5.1. For example, the reaction of amino acids with D-glucose yields imine as a primary product, which is transformed to the cyclic form D-glucosylamino acid and in a sequence of reactions splits off carbon dioxide, Strecker aldehyde and ammonia, while D-glucose is reduced to 2-deoxy-D-glucose. Another product of this reaction (in the absence of decarboxylation and cleavage of aldehydes) is the amino analogue of D-glucitol known as 1-amino-1-deoxy-D-glucitol (Figure 2.57). Strecker aldehydes can also be formed by oxidation of 1-amino-1-deoxyketoses (ketosamines) and by degradation of their oxidation products in the later stages of the Maillard reaction.

2.5.2.3.3 Reactions with dicarbonyl compounds

Particularly potent oxidants are α-dicarbonyl compounds, especially compounds produced by degradation of simple sugars and other food components (such as glyoxal and methylglyoxal) and their higher homologues, that is glycosuloses (aldoketoses and diketoses). The mechanism of oxidative decarboxylation of amino acids by α-dicarbonyl compounds is in fact more complex than that given in Figure 2.58. As in the reaction of other carbonyl compounds with amino acids, the first step is the addition of amino acid on the carbonyl group of an α-dicarbonyl compound with the formation of imine and elimination of water. The resulting imine then eliminates carbon dioxide and hydrolysis of the product yields Strecker aldehyde (preferably in a weakly acidic solution). Reduction of an α-dicarbonyl compound (transamination) produces a reactive aminocarbonyl compound. Other products include ammonia, amines, α-hydroxycarbonyl compounds, carboxylic acids and other compounds (Figure 2.58).

Carboxylic acids are formed in the presence of traces of transition metals, preferably in weakly alkaline solutions, and by oxidation with α-dicarbonyl fragments that are stronger oxidation agents than glycosuloses. The formation of carboxylic acids by autoxidation of

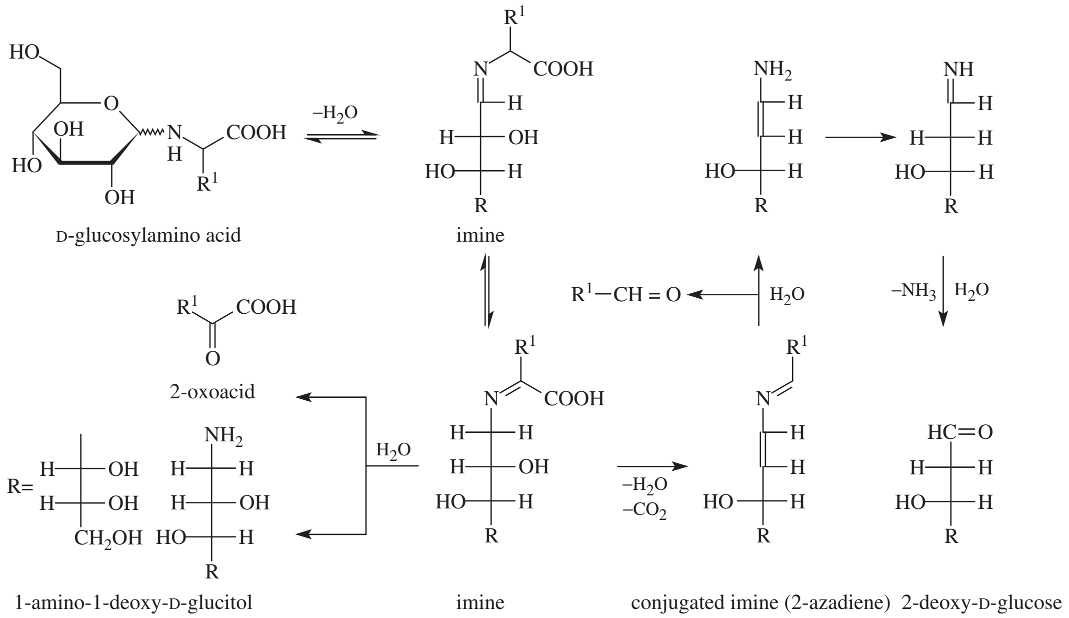


Figure 2.57 Strecker degradation of amino acids by aldoses.

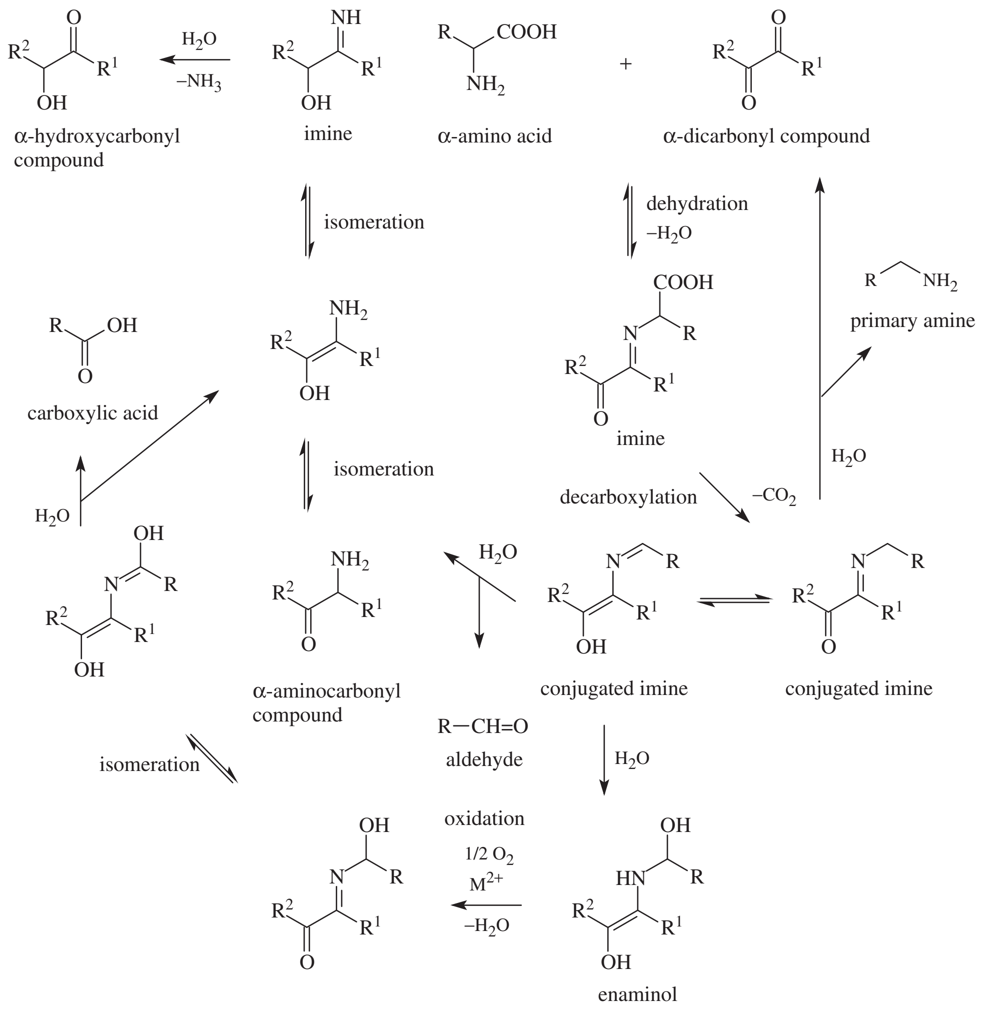

Figure 2.58 Strecker degradation of α-amino acids by α-dicarbonyl compounds.

Strecker aldehydes is not very significant, but some Strecker acids are important aroma components of cooked foods. The levels of amines formed by Strecker degradation, such as during roasting of cocoa beans, exceeds by several orders the amount of identical amines that are formed during fermentation and is comparable to the level of Strecker aldehydes generated.

The Strecker degradation of ornithine proceeds analogously, but the intermediate 4-aminobutanal forms by cyclisation the final product, 1-pyrroline (Figure 2.59). This reaction is important for the development of the characteristic aroma of bread crust (see Section 8.2.12.4.1), the aroma of other cereal products, certain fragrant rice varieties (such as Basmati rice) and in the biosynthesis of pyrrolidine alkaloids in plants (see Section 10.3.2.1.1). It was proposed that pyrrolidine and 1-pyrroline also result upon Strecker-type reaction of proline by α-dicarbonyl compounds.

In some cases, Strecker aldehydes are unstable and decompose to other products. For example, aspartic acid produces 3-oxopropionic acid (**2-129**), which provides acetaldehyde by decarboxylation. Other products are pyruvic acid and fumaric acid. Glutamic acid produces 4-oxobutyric acid (4-oxobutanoic acid, **2-130**), which eliminates carbon dioxide and yields propionaldehyde and other products, such as 2-oxobutyric acid and 5-oxopyrrolidine-2-carboxylic acid (**2-116**).

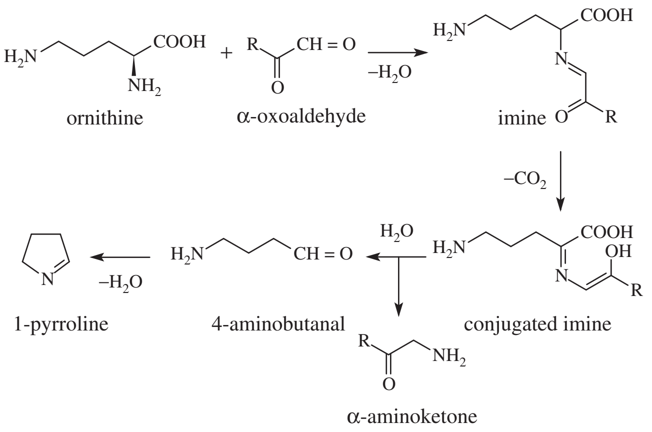

Figure 2.59 Strecker degradation of ornithine by α-dicarbonyl compounds.

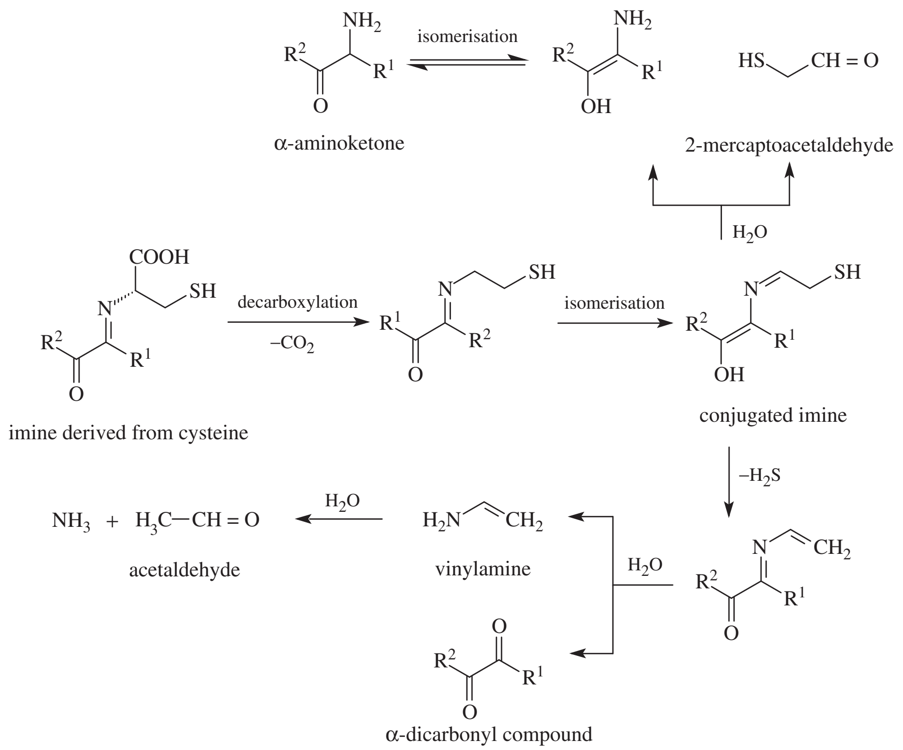

Figure 2.60 Strecker degradation of cysteine.

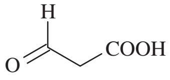
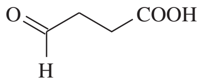
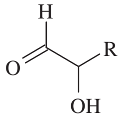


2-129, 3-oxopropionic acid



2-130, 4-oxobutanoic acid

More complicated is the Strecker degradation of hydroxyamino acids (serine and threonine) and of sulfur amino acids (cysteine and methionine). The Strecker degradation product of serine is glycolaldehyde (**2-131**), while threonine produces 2-hydroxypropanal (lactic acid aldehyde, **2-131**). Both aldehydes are highly reactive compounds that enter into a number of other reactions. Degradation of the imine of cysteine yields 2-mercaptoacetaldehyde and also vinylamine as a minor degradation product (Figure 2.60). Methionine (the corresponding imine) yields an unstable volatile aldehyde methional (3-methylthiopropanal), which is a characteristic odorous product of boiled potatoes. Methional further decomposes to acrolein and methanethiol (methylmercaptan), which spontaneously oxidises to dimethyldisulfide in the presence of oxygen (Figure 2.61). Oxidation of methional yields the corresponding sulfoxide, which decomposes via methanesulfenic acid to acrolein. Methanesulfenic acid reacts with methanethiol or other thiols producing dimethyldisulfide or mixed disulfides, respectively.



2-131, glycolaldehyde (R = H)
2-hydroxypropanal (R = CH_3)

Oxidising agents often cause degradation of amino acids and of the reaction intermediates by homolytic cleavage (homolytic fission) of their covalent bonds under the formation of free radicals, whose recombination creates a number of other compounds. For example, the main reaction product of the Strecker degradation of phenylalanine is phenylacetaldehyde, but also its lower homologue benzaldehyde and the higher homologue 3-phenylpropanal arise as minor products. Some other minor Strecker degradation products of phenylalanine include bibenzyl and *trans*-stilbene.

2.5.2.4 Reaction with isothiocyanates

Isothiocyanates are formed by the degradation of glucosinolates present in cruciferous vegetables (see Section 10.3.2.4.2). Free and bound peptides and proteins react with isothiocyanates via amino groups, mercapto groups or other nucleophilic functional groups (hydroxyl groups). Their reactivity depends, as well as the addition on the carbonyl group, on their nucleophility, pK_a and pH values.

Reactions of α-amino groups of amino acids with isothiocyanates in a weakly alkaline medium produce *N*,*N*′-disubstituted thioureas (*N*-thiocarbamoyl derivatives of amino acids) as primary products, which cyclise under acidic conditions, or on heating, to 2-thiohydantoines (Figure 2.62) that are considered to be responsible for some of the biological effects of isothiocyanates. In neutral and alkaline media, 2-thiohydantoines yield symmetric dehydrodimers as a result of cleavage of the acidic hydrogen atom in position C-5. 2-Thiohydantoines with the methylene group at C-5 ($R^1 = H$, Figure 2.63), derived from glycine, yield yellow to

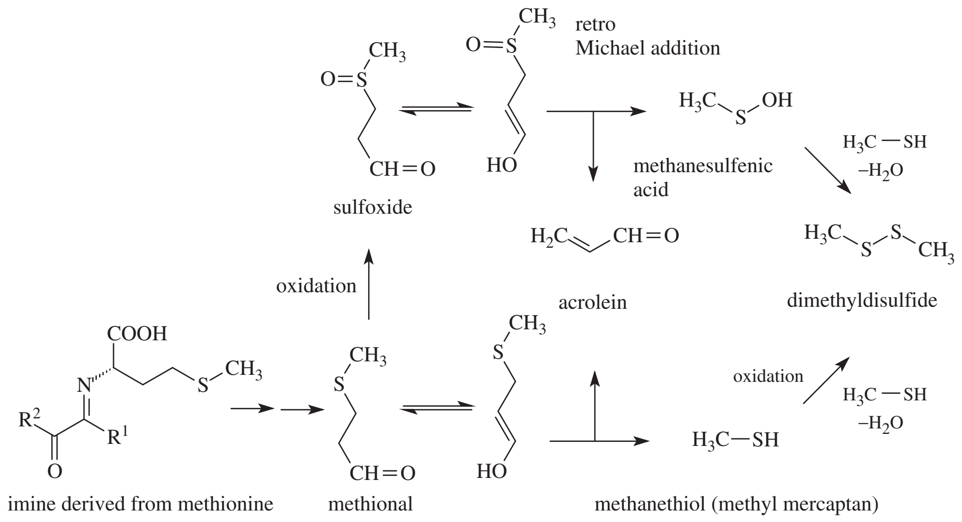


Figure 2.61 Strecker degradation of methionine.

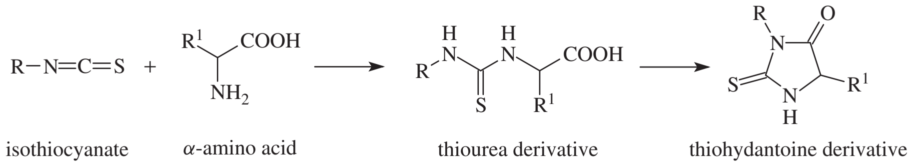

Figure 2.62 Reaction of α-aminokyselin with isothiocyanates.

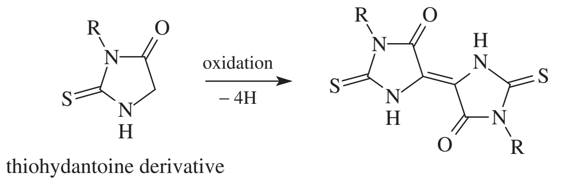

Figure 2.63 Formation of coloured 2-thiohydantoine dehydrodimers.

red diastereoisomeric 3,3′-dialk(en)yl- or 3,3′-diaryl-2,2′-dithioxo-[5,5′]-bisimidazolidinylidene-4, 4′-diones. Sarcosine actually yields blue products in alkaline solutions.

The reaction of isothiocyanates with cysteine gives (depending on pH) two types of primary products. In weakly acidic solutions (pH 5–6), isothiocyanate reacts exclusively with the thiol group of cysteine, producing *N*-substituted esters of dithiocarbamic acids and heterocyclic products. The same products are formed from cystine as from cysteine. Detoxification of isothiocyanates in the body is based on their reaction with reduced glutathione (G-SH) mercapto group. The resulting mercapturate is excreted in the urine.

In a weakly alkaline solution, isothiocyanate reacts with the α-amino group of cysteine (Figure 2.64). The reaction of isothiocyanates with cystine leads to the cleavage of disulfide bond (–S–S–) with the formation of cysteine sulfenic acid and a dithiocarbamic acid ester. Dehydration of this ester yields 5-amino-1,3-thiazine-4-one-3-thione derivative and elimination of hydrogen sulfide produces a cyclic 2-thiazoline-4-carboxylic acid derivative (Figure 2.65). Reaction of cystine with thiocyanates (R–S–C≡N), formed by spontaneous isomerisation of isothiocyanates, produces disulfide Cys–S–S–R and β-thiocyanoalanine, which cyclises to 2-thiazoline derivative (Figure 2.66).

Isothiocyanates also react with the hydroxyl group of tyrosine and other hydroxyamino acids. The addition of a hydroxy compound usually yields *N*-substituted thiocarbamates, which are esters of *N*-substituted thiocarbamoic acids (Figure 2.67).

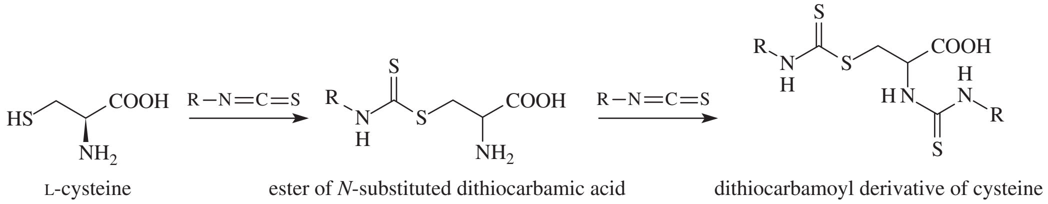

Figure 2.64 Reaction of isothiocyanates with cysteine.

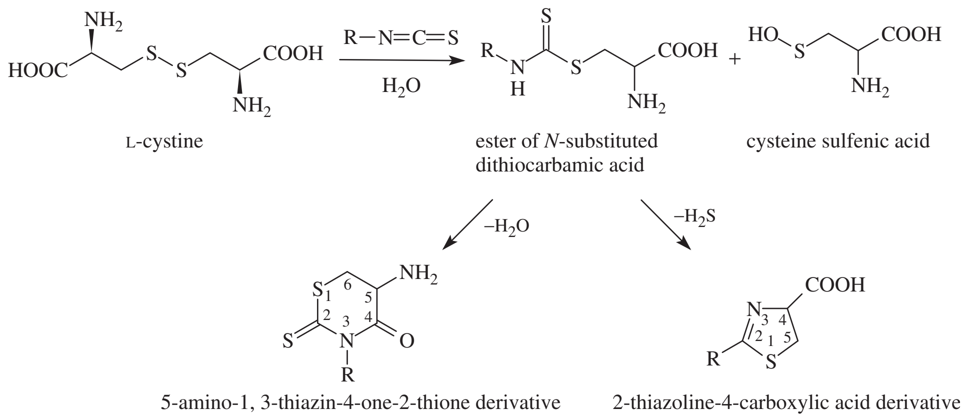

Figure 2.65 Reaction of isothiocyanates with cystine.

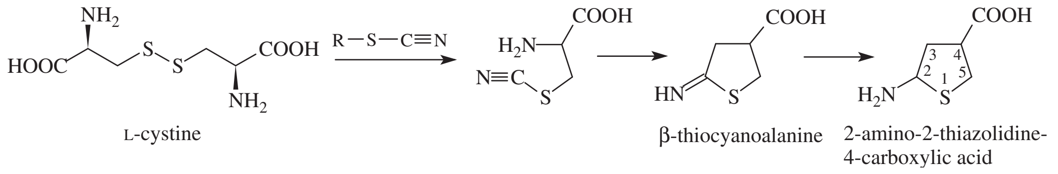

Figure 2.66 Reaction of thiocyanates with cystine.

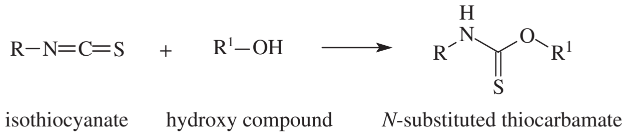

Figure 2.67 Reaction of isothiocyanates with hydroxy compounds.

Isothiocyanates react with *N*-terminal amino groups of peptides[13] to form thiourea, which spontaneously cyclises to imidazolidine derivatives under acidic conditions and the reaction product is the original peptide without *N*-terminal amino acids (Figure 2.68). Reactions of isothiocyanates with the *N*-terminal amino groups of proteins and other nucleophilic centres containing thiol, disulfide, ε-amino and hydroxyl groups can cause changes in protein conformations. These proteins are poorly hydrolysable in the protein conformation, which is related to the antimicrobial and antithyroid activity of isothiocyanates.

[13]Reaction with phenyl isothiocyanate (Edman degradation) has been of great significance in determining the primary structure of peptides.

2.5.2.5 Reaction with plant phenols

Phenolic compounds known as polyphenols (such as phenolic acids and flavonoids) are easily oxidised by atmospheric oxygen in reactions catalysed by oxidoreductases (*o*-diphenol:O_2 oxidoreductases). These reactions are known as enzymatic browning reactions (see Section 9.12). Autoxidation of plant phenols catalysed by heavy metal ions (mainly cupric and ferric ions) and oxidation by lipid hydroperoxides lead to similar products. The products of oxidation of the so-called *o*-diphenols (1,2-dihydroxybenzenes) are *o*-quinones (1,2-benzoquinones), highly reactive compounds that react with proteins (amino acids) and other food components with the formation of dark-coloured polymeric products resistant to proteolysis.

The reaction of *o*-quinone with amino or thiol groups of proteins (*N*-terminal group or ε-amino group of lysine) leads to adducts that are transformed into *o*-diphenols. They are very oxylabile and readily oxidise to the disubstituted *o*-quinones (Figure 2.69), which can react with other quinone or protein molecules to form oligomeric products. The reaction with thiol groups of proteins occurs in weakly acidic and neutral solutions. The reactions with amino groups of proteins in neutral solutions also lead to disubstituted *o*-quinones. In alkaline solutions, amino group adds to the

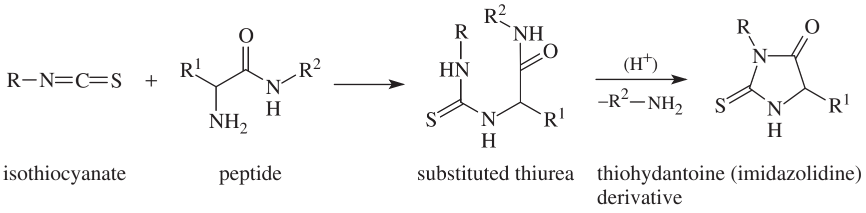

Figure 2.68 Reaction of isothiocyanates with peptides.

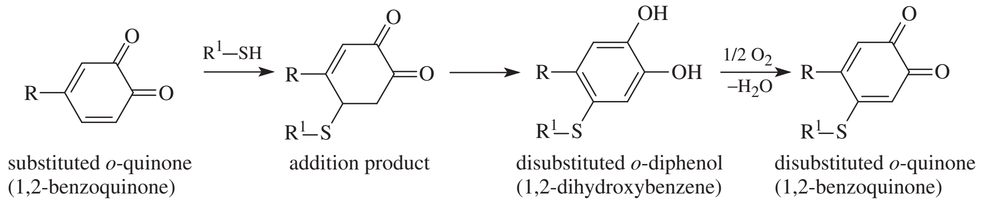

Figure 2.69 Reaction of 1,2-benzoquinones with protein thiol group.

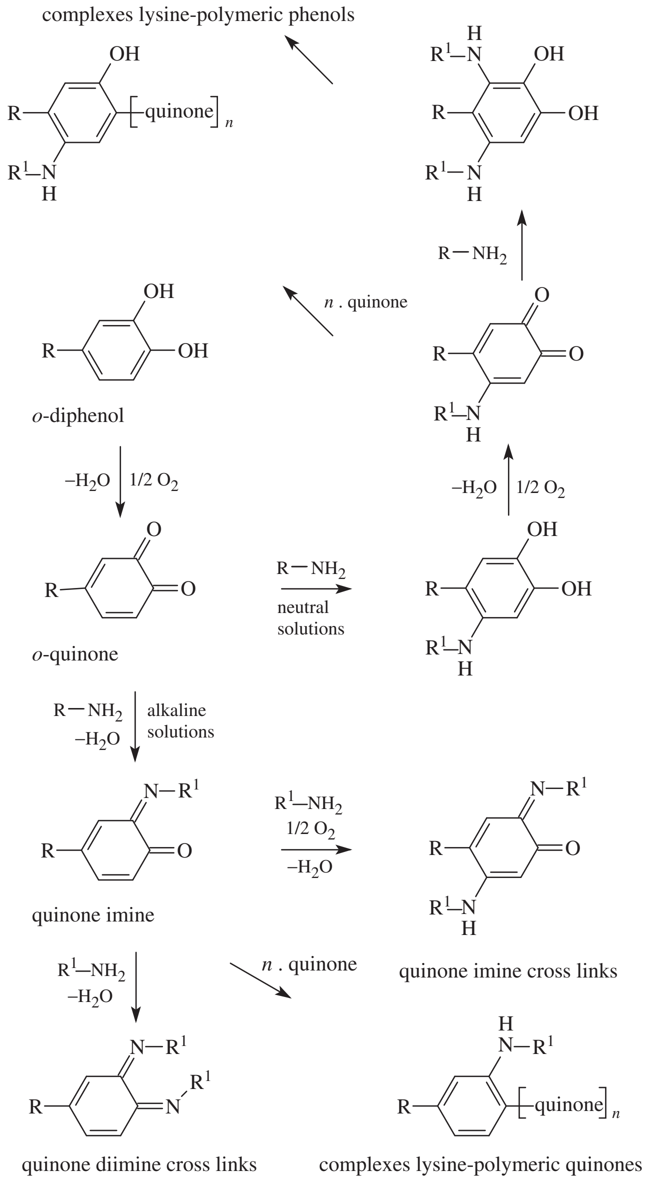

Figure 2.70 Reaction of lysine with o-quinones (R^1-NH_2 = ε-amino group of lysine). Stephen 1995, fig 10. Reproduced by permission of Taylor & Francis – Marcel Dekker.

carbonyl group of quinones, which results in replacement of one or both quinone oxygen atoms (=O) by an =N–R group and formation of quinonimines (quinone imines) (Figure 2.70). Strecker degradation of amino acids also takes place as a side reaction. The reaction of proteins with plant phenols during the extractions of oil meals (e.g. in sunflower meal, which contains a considerable amount of polyphenols) when extracting proteins from alkaline solutions and in the production of protein isolates, therefore, leads to a range of discolourations of the products and also reduces the protein nutritional value due to the loss of essential amino acids lysine (bound in the non-available products), methionine (by oxidation) and a lower availability of tryptophan, which is due to lower protein digestibility.

2.5.2.6 Hydrolysis and protein hydrolysates

Proteolytic enzymes are usually present in all raw food materials. Spontaneous hydrolysis of proteins therefore occurs during storage in a number of foods (e.g. in meat during ripening). Proteases also play a significant role in various plant materials. For example, they act during dough maturation, which affects the functional properties of gluten, in the production of malt and in other processes. Autolysis of fish meat, oysters and other marine animals, for example, is employed for the production of special Oriental sauces. Autolysates of waste brewery yeast are used as food additives. Various food technologies also employ proteolytic preparations from various microorganisms, for example chymosin is used in the production of some cheeses (see Section 2.4.5.2.3). Partial microbial protein hydrolysis is used for the production of soy sauces. Mineral acids are utilised to achieve almost complete hydrolysis of proteins to amino acids in the production of hydrolysed vegetable proteins for use as seasonings.

Soy sauce, or soya sauce, is the best-known representative of the **enzymatic protein hydrolysates**. It is made from soybeans (soya beans), roasted wheat, water and salt. The process of manufacture for naturally fermented soy sauce can be divided into four stages: preparation of koji, brine fermentation, filtration/pasteurisation and maturation. Koji is produced by cooking soya beans (defatted soya bean meal) and then mixing the resultant material with milled roasted wheat. The mixture is inoculated with a mould, either *Aspergillus oryzae* or *Aspergillus sojae*, cultured for 2–3 days at 25–30 °C, and then mixed with saltwater brine and yeast to give moromi. The moromi is fermented (2 days) and the resulting material is pressed to obtain the raw soy sauce, which is pasteurised, filtered and stored for a period of months in order to mature. Finally, the product is filtered, bottled and distributed.

Chemical protein hydrolysates, also called hydrolysed plant proteins or hydrolysed vegetable proteins, are typically produced by hydrochloric acid (HCl) hydrolysis of various proteinaceous vegetable raw materials (defatted oilseed meals, wheat gluten,

maize and rice protein and occasionally some animal proteins such as casein and keratin). The hydrolysis is usually carried out with 20% (6 M) HCl at temperatures exceeding 100 °C for up to about 8 hours. After cooling, the hydrolysate is neutralised by sodium hydroxide or sodium carbonate, generally to a pH ranging from 4.5 to 7. A product of this neutralisation is sodium chloride; its content in the hydrolysate is about 20%. The raw hydrolysate is filtered, it can be bleached and fortified with flavour-active compounds, and is then ripened for several weeks. The ripe product is then available as a liquid seasoning, alternatively it can be concentrated to a paste or dried to powder.

During production of the hydrolysate, amino acids react with sugars and other components of the original material, forming brown pigments called melanoidins or humins and a range of flavour-active compounds. Acid hydrolysis, however, leads to complete degradation of oxylabile tryptophan and glutamine and asparagine are hydrolysed to aspartic acid and glutamic acid, respectively. Approximately 5–10% of the hydroxyamino acids serine and threonine are degraded with the formation of 2-oxoacids and the cysteine is desulfurated to a large extent.

2.5.2.7 Other reactions

Food processing at higher temperatures during baking, frying, grilling and roasting leads to degradation of amino acids and production of many different products that significantly affect the smell, taste and colour of the product. Reactions are usually complex. There are several types of reactions taking place concurrently, and reaction products enter the mutual reactions and react with other food components.

Pyrolysates of amino acids and various foods processed at high temperatures (around 200 °C and above) contain some mutagenic and carcinogenic products, such as the technological contaminants acrylamide (the decomposition product of asparagine; see Section 12.2.2) and furan (formed from alanine, serine and other precursors; see Section 12.2.3) and aminoimidazoazaarenes (see Section 12.2.1.1), that are a result of creatinine and some Maillard reaction products. Other aromatic amines are generated by pyrolysis of amino acids such as tryptophan, glutamic acid, lysine, ornithine and phenylalanine. Structurally related heterocyclic products (derivatives of imidazopyrazines) were also found in the pyrolysates of aliphatic amino acids. Pyrolysis of amino acids and proteins at very high temperatures in burnt foods, but also by the burning of tobacco (around 800 °C) and other plant materials, generates a number of different products such as polycyclic aromatic hydrocarbons.

Amino acids also react with some food additives (such as sulfur dioxide), which results in the loss of cysteine and formation of non-available products. Toxic (carcinogenic) nitroso compounds are formed during the reaction of nitrites, nitrous acid or nitrogen oxides with amino acids containing a secondary amino group (*N*-alkylamino acids or imino acids). Toxic products are also formed in the reaction of methionine with some oxidising agents (nitrogen trichloride NCl_3) formerly used as food additives and in the reaction of cysteine with chlorinated solvent residues.

3
Fats, Oils and Other Lipids

3.1 Introduction

Lipids are one of the major components in foods and their role in human nutrition is one of the most important areas of concern in the field of nutritional science. Interestingly, however, lipids are such a diverse range of compounds that no single agreed definition exists; the main criterion for inclusion in this group of compounds is their hydrophobicity and not their chemical properties.

Lipids are usually defined as natural compounds containing bound fatty acids that contain more than three carbon atoms in the molecule. This definition is used by most biologically oriented workers, mainly physicians. However, ethyl esters of fatty acids with 4–12 carbon atoms, which are commonly found as odorous food components, are not classified as lipids. Some difficulty is caused by the inclusion of free fatty acids because they do not contain a bound alcohol residue. However, they are generally regarded as lipids and form a separate group together with their salts, which are known as soaps. Foods also frequently contain derivatives of fatty acids arising from industrial or other human activities (such as sugar esters and esters of sugar alcohols with higher fatty acids) that are not natural substances, but are still usually classified as lipids. Today, lipids are often defined as fatty acids and their derivatives, which are derived biochemically and related by their solubility in nonpolar solvents and general insolubility in water.

In practice, the non-volatile lipophilic compounds that accompany true lipids in both natural and manufactured products are also classified as lipids. They are termed **compounds accompanying lipids** (formerly called lipoids) in food chemistry, and 'unsaponifiable lipophilic substances' in food analysis. Their chemical structure is different and often these compounds do not even contain bound fatty acids. This group includes a large number of lipophilic compounds, for example some **terpenoids**,[1] especially steroids (see Section 3.7.4) and carotenoids (see Section 9.9). Compounds accompanying lipids also include lipophilic vitamins (see Chapter 5), some pigments (see Chapter 9), natural antioxidants (see Section 11.2.2) and other lipophilic compounds.

The following sections describe the individual classes of lipids and lipid accompanying substances, their structure, occurrence, isolation from natural sources and importance in nutrition and metabolism. Technological procedures used for production of lipid derivatives on an industrial scale are included. A large part of the chapter is devoted to the interactions of lipids with other food components and reactions that positively or negatively affect the nutritional value and organoleptic properties of foods. Attention is also paid to reactions of lipids under normal physiological conditions, such as during aging of living organisms and reactions linked with pathogenesis of certain diseases.

[1]Monoterpenoids, sesquiterpenoids and diterpenoids, despite their structural similarity with higher terpenoids, are not classified as lipids, although they are lipophilic. These compounds are described in detail in relation to food flavour (see Chapter 6).

3.2 Classification

According to their chemical composition, lipids are classified into three major groups[2]:

- **homolipids**
- **heterolipids**
- **complex lipids**.

[2]Recent classification systems define lipids as hydrophobic or amphipathic compounds biosynthesised solely or partially by condensation of thioesters (fatty acids and polyketides) or isoprenoid units (prenols, sterols and other compounds). Lipids are divided into two large groups, simple and complex lipids. Simple lipids provide at least two types of hydrolysis products (such as fatty acids and sterols or fatty acids and acylglycerols). The complex lipids (such as glycerophospholipids and glyceroglycolipids) provide three or more types of products through hydrolysis. According to the structure, lipids are divided into eight basic categories: fatty acids, glycerolipids, glycerophospholipids, sphingolipids, steroid lipids, prenoid lipids, saccharolipids and polyketides.

The Chemistry of Food, First Edition. Jan Velíšek.
© 2014 John Wiley & Sons, Ltd. Published 2014 by John Wiley & Sons, Ltd. Companion Website: www.wiley.com/go/velisek/foodchemistry.

Homolipids are compounds that contain fatty acids and alcohols. They are divided further according to the structure of the bound alcohol. Heterolipids are lipids that also contain, in addition to the fatty acids and alcohols, other covalently bound compounds, such as phosphoric acid in phospholipids or D-galactose in some glycolipids. Complex lipids contain homolipids and heterolipids, and, along with covalent bonds, some components are bound by various physical bonds, such as hydrogen bonds or hydrophobic interactions.

This classification is fairly logical in basic chemical or biochemical research of lipids, but in practice, however, this system is not often used. More frequently we come across a totally illogical designation such as 'neutral lipids' and 'polar lipids'. The neutral lipids include esters with glycerol, steroids and their esters, but also free fatty acids, although they are not neutral. Polar lipids include phospholipids, as well as many other heterolipids that often do not contain phosphorus or even fatty acids. This classification system of lipids is usually seen in biologically-oriented areas, and is based mainly on the behaviour of compounds during chromatographic separation. In food technology and oleochemistry, the name 'lipids' is not commonly used. Instead, only fats, oils, fatty acids, waxes and lecithin are recognised, since only these components have any industrial relevance.

3.3 Fatty acids

Fatty acids are the building blocks of lipids and nutritionally the most important lipid components. According to the terminology used in organic chemistry, the term fatty acids means carboxylic acids with an aliphatic hydrocarbon chain, but this definition does not correspond completely with the fatty acids present in lipids. Some fatty acids, according to the definition used by organic chemists (e.g. acetic acid), are not present in natural lipids, although they can occur in manufactured fat products. Fatty acids bound in lipids can, however, be alicyclic or even aromatic compounds.

3.3.1 Structure and nomenclature

In nature, and therefore also in foods, lipids contain the following groups of fatty acids:

- saturated fatty acids
- unsaturated fatty acids with one double bond (monoenoic)
- unsaturated fatty acids with several double bonds (polyenoic)
- fatty acids with triple bonds and with various substituents (alkynoic, branched chain and cyclic acids, acids with oxygen-, nitrogen- or sulfur-containing functional groups).

3.3.1.1 Saturated fatty acids

Saturated fatty acids are common constituents of natural lipids. They normally contain from four to 38 carbon atoms, but there are also higher fatty acids with about 60 carbon atoms, which are mostly linear (with unbranched chains) and usually have an even number of carbon atoms. In most natural lipids, saturated fatty acids constitute between 10 and 40% of the total fatty acids. Depending on the number of carbon atoms (chain length), saturated (as well as unsaturated) fatty acids can be divided into short chain fatty acids (C_4 and C_6), medium chain fatty acids (C_8–C_{12}), long chain fatty acids (C_{14}–C_{18}), very long chain fatty acids (C_{20}–$C2_6$) and ultra-long chain fatty acids (C_{28}–C_{38}).

An overview of important fatty acids with an even number of carbon atoms in the molecule is given in Table 3.1. Besides the systematic names derived from the corresponding hydrocarbons, trivial names are also given, and these are used predominately in routine practice, especially in the nomenclature of common fatty acids. In the literature, for brevity, various short designations predominate, such as an N:M ratio, where N is the number of carbon atoms in the molecule and M the number of double bonds. The most abundant saturated fatty acids in animal and plant tissues

Table 3.1 Saturated fatty acids occurring in lipids.

Fatty acid	Number of carbon atoms	Trivial name	Fatty acid	Number of carbon atoms	Trivial name
Butanoic	4	Butyric	Eicosanoic	20	Arachidic
Hexanoic	6	Caproic	Docosanoic	22	Behenic
Octanoic	8	Caprylic	Tetracosanoic	24	Lignoceric (carnaubic)
Decanoic	10	Capric (caprinic)	Hexacosanoic	26	Cerotic
Dodecanoic	12	Lauric	Octacosanoic	28	Montanic
Tetradecanoic	14	Myristic	Triacontanoic	30	Melissic
Hexadecanoic	16	Palmitic	Dotriacontanoic	32	Lacceric
Octadecanoic	18	Stearic	Tetratriacontanoic	34	Gheddic (geddic)

3-1, myristic acid

3-2, palmitic acid

3-3, stearic acid

are myristic (tetradecanoic, 14:0; **3-1**) acid, palmitic (hexadecanoic, 16:0; **3-2**) acid and stearic (octadecanoic, 18:0; **3-3**) acid.

Fatty acids with an even number of carbon atoms are accompanied by a small amount of fatty acids with an odd number of carbon atoms (most often they are fatty acids 13:0 to 19:0). The particularly common acids are pentadecanoic (15:0) and heptadecanoic (margaric, 17:0) acids, with pentanoic (valeric, 5:0), heptanoic (enanthic, 7:0), nonanoic (pelargonic, 9:0) acids and many others being present at low levels. These acids are found as esters in microbial lipids and in trace amounts in most animal tissues, at a concentration of 5% or more in tissues of ruminants.

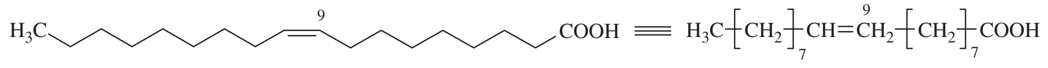
3.3.1.2 Unsaturated fatty acids with one double bond

Unsaturated fatty acids with one double bond, with the trivial name of monoenoic fatty acids, differ from each other by the number of carbon atoms, the double bond position in the hydrocarbon chain and the spatial organisation of molecules (*cis*–*trans* isomerism also known as *E*/*Z* isomerism or geometric isomerism). The most important of these are listed in Table 3.2. Many monoenoic fatty acids have trivial names, which are commonly used. A tpical example is *cis*- or (*Z*)-octadec-9-enoic acid, also known as oleic acid (**3-4**).

Many less common monoenoic fatty acids are only found in large amounts in inconsequential sources of lipids, but in foods they are usually present only in traces. For example, *cis*-hexadec-6-enoic acid (known as sapienic acid) is the most abundant fatty acid in human sebum, as among hair-bearing animals it is restricted to humans. Systematic names are often used for monoenoic fatty acids, especially when it is necessary to describe precisely the location and spatial configuration of the double bond in the molecule. For example, the major *cis*-octadec-9-enoic (oleic) acid is accompanied by a small amount of *cis*-octadec-11-enoic acid known as *cis*-vaccenic acid or asclepic acid, and *cis*-octadec-12-enoic acid appears to exist in hardened oils as a result of hydrogenation of linoleic acid so that only the double at the C-9 position is hydrogenated, whereas the double bond in the C-12 position remains unchanged. The short designation, 18:1, for all of these acids says nothing about the position of the double bonds. If we wish to indicate the position of the double bond, for example in oleic acid, the short designation

Table 3.2 Major monoenoic fatty acids accurring in lipids.

Fatty acid	Number of carbon atoms	Double bond position	Isomer	Trivial name
Decenoic	10	4	*cis*	Obtusilic
Decenoic	10	9	*cis*	Caproleic
Dodecenoic	12	4	*cis*	Linderic
Dodecenoic	12	9	*cis*	Lauroleic
Tetradecenoic	14	4	*cis*	Tsuzuic
Tetradecenoic	14	5	*cis*	Physeteric
Tetradecenoic	14	9	*cis*	Myristoleic
Hexadecenoic	16	6	*cis*	Sapienic
Hexadecenoic	16	9	*cis*	Palmitoleic
Hexadecenoic	16	9	*trans*	Palmitelaidic
Octadecenoic	18	6	*cis*	Petroselinic
Octadecenoic	18	6	*trans*	Petroselaidic
Octadecenoic	18	9	*cis*	Oleic
Octadecenoic	18	9	*trans*	Elaidic
Octadecenoic	18	11	*cis*	Asclepic (*cis*-vaccenic)
Octadecenoic	18	11	*trans*	*Trans*-vaccenic
Eicosenoic	20	9	*cis*	Gadoleic
Eicosenoic	20	11	*cis*	Gondoic
Docosenoic	22	11	*cis*	Cetoleic
Docosenoic	22	11	*trans*	Cetelaidic
Docosenoic	22	13	*cis*	Erucic
Docosenoic	22	13	*trans*	Brassidic
Tetracosenoic	24	15	*cis*	Nervonic (selacholeic)
Hexacosenoic	26	17	*cis*	Ximenic
Triacontenoic	30	21	*cis*	Lumequeic



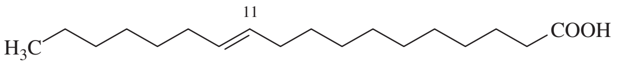
3-4, oleic acid

9-18:1 or 18:1Δ9 can be used, where the number 9 indicates that the double bond is at the ninth carbon atom from the carboxyl. The spatial configuration of natural fatty acids is usually *cis* (*Z*) or more rarely *trans* (*E*). Systematic names now increasingly use the newer designations of *Z* and *E*, but far more common (and still correct) is the designation *cis* and *trans*. Oleic acid is then *cis*-octadec-9-enoic acid or (*Z*)-octadec-9-enoic acid, also abbreviated as *c*-octadec-9-enoic acid, 9*c*-18:1 or 18:1 *cis*-9.

If the trivial name is used instead of the systematic name, it should be noted that this generally refers only to an isomer with a specific location of the double bond and steric configuration. Trivial names should therefore not be used when the individual isomers are not known, for example in the data on fat composition. In other words, the group of octadecenoic acids cannot be generally referred to as oleic acid, and it is not possible to speak of about 11-oleic acid, which does not exist. The designation isooleic acids has been applied to all isomers of octadecenoic acids, which have the double bond of the eighteenth carbon chain at some other place in the chain, instead of at C-9.

The prominent *trans*-unsaturated fatty acids are mainly (*E*)-octadec-9-enoic (elaidic) acid (**3-5**) and (*E*)-octadec-11-enoic (*trans*-vaccenic) acid (**3-6**).

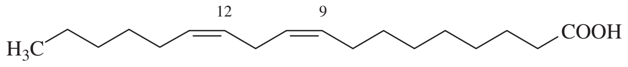
3-5, elaidic acid



3-6, *trans*-vaccenic acid

3.3.1.3 Unsaturated fatty acids with two or more double bonds

Fatty acids with two isolated double bonds separated by one methylene group (methylene interrupted double bonds) are very important in nutrition. Theoretically, there should be far more of these acids than of monoenoic fatty acids in natural lipids, but only a few are found in significant amounts (Table 3.3). The most important dienoic acid is linoleic acid (**3-7**). Again, positional as well as geometric isomers of polyenoic fatty acids exist. For example, linoleic acid is a 9*cis*, 12*cis*-isomer, that is, a 9-*cis*, 12-*cis*-isomer or (9*Z*,12*Z*)-octadeca-9,12-dienoic acid, abbreviated 9*c*12*c*-18:2 or 18:2 *cis*-9, *cis*-12.



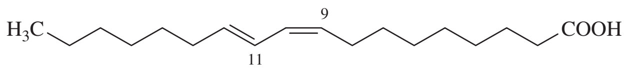
3-7, linoleic acid

In addition, categorising polyunsaturated fatty acids according to the position of the double bond away from the terminal methyl group is common in biological documents. The nomenclature *n*-*x* (or *ω*-*x*) means that the first double bond is located on carbon number *x* counting from the terminal methyl group. The omega notation is common in popular nutritional literature. Linoleic acid is an example of a polyunsaturated fatty acid of the *n*-6 series (**3-8**). A short notation for linoleic acid is 18:2*n*-6 (or 18:2ω-6). Similarly, we come across fatty acids of *n*-3 (or ω-3) series (**3-9**).

3-8, polyenoic fatty acids of *n*-6 series (ω=2–6, *n*=2–5)

3-9, polyenoic fatty acids of *n*-3 series (ω=2–6, *n*=2–6)

Of particular importance are fatty acids with conjugated double bonds, which differ significantly from fatty acids with isolated double bonds in their reactivity and have distinct physiological effects (see Section 3.3.3.2). An example is (9*Z*,11*E*)-octadeca-9,11-dienoic acid (formerly known as conjugated linoleic acid or bovinic acid; the recommended trivial name is rumenic acid, **3-10**).



3-10, (9*Z*,11*E*)-octadeca-9,11-dienoic acid

The number of naturally occurring fatty acids with three *cis*-double bonds is considerably smaller than would be expected from the possibilities of isomerism (Table 3.3). The most important representative of these fatty acids is linolenic acid with three isolated double bonds (**3-11**). For example, linolenic acid is the 9*cis*,12*cis*,15*cis*-isomer, that is, (9*Z*,12*Z*,15*Z*)-octadeca-9,12,15-trienoic acid, abbreviated to 9*c*12*c*15*c*-18:3 or 18:3 *cis*-9, *cis*-12, *cis*-15. In biological texts, it is often referred to as α-linolenic acid, which is a member of the *n*-3 series, unlike the isomeric *γ*-linolenic acid (octadeca-6,9,12-trienoic acid), a member of the *n*-6 series (**3-12**), which has different physiological effects. An example of conjugated fatty acids with three double bonds are (8*E*,10*E*,12*Z*)-9,11,13-octadecatrienoic (α-calendic) acid

3-11, α-linolenic acid

Table 3.3 Dienoic, trienoic and other polyenoic fatty acids occurring in lipids.

(**3-13**) and (9*Z*,11*E*,13*Z*)-octadeca-9,11,13-trienoic (punicic or trichosanic) acid (**3-14**).

Highly unsaturated fatty acids with four to six *cis*-double bonds in the molecule (Table 3.3 and Figure 3.1) occur relatively rarely in nature. They belong to the *n*-3 and *n*-6 series. The most important of these fatty acids are those with four or five double bonds. The acid with four all-*cis* double bonds (*n*-6 series) is arachidonic (5,8,11,14-eicosatetraenoic) acid (**3-15**), all-*cis* acids with five double bonds are represented by clupadonic (7,10,13,16,19-docosapentaenoic) acid (**3-16**) of the *n*-3 series.

Figure 3.1 Biosynthesis of higher essential fatty acids.

3.3.1.4 Alkynoic, branched-chain and cyclic fatty acids

Compared with the above types of fatty acids, these fatty acids are substantially less important in the food industry and in human nutrition.

3.3.1.4.1 Alkynoic acids

Fatty acids with one or more triple bonds (alkynoic, ethynoic or acetylenic acids), or fatty acids containing both double and triple bonds, occur rarely in nature. Examples are stearolic (octadec-9-ynoic) acid (**3-17**) and isanic (octadec-17-en-9,11-diynoic) acid, also known as bolecic acid (**3-18**), in short 9*a*-18:1 (or 18:1, 9*a*) and 17,9*a*,1*a*-18:3 (18:3, 17*E*,9*a*,11*a*). The positional isomer of stearolic acid is tariric (octadec-6-ynoic) acid.

3-17, stearolic acid

3-18, isanic acid

3.3.1.4.2 Branched acids

There is a large number of fatty acids (usually saturated) that have a side chain consisting of one carbon, which are therefore methyl derivatives of fatty acids. The methyl group is usually bound to the penultimate carbon atom (*n*–1). These acids are generally referred to as **isoacids** (**3-19**). If the methyl group is bound to the third carbon atom from the end (*n*–2), these fatty acids are called **anteisoacids** (**3-20**). Rare **neoacids** have two methyl groups on the penultimate carbon atom; therefore their terminal group is a tertiary butyl group (**3-21**). An example is 13,13-dimethyltetradecanoic acid (**3-22**). More rarely methyl groups are bound in the middle of the hydrocarbon chain and some fatty acids may have a higher number of methyl group. Typical examples are (4*S*)-4-methyloctanoic (4-methylcaprylic or hircinoic) and (3*RS*,7*R*,11*R*,15)-3,7,11,15-tetramethylhexadecanoic (phytanic) acids (**3-23**). Further examples are presented in Table 3.4.

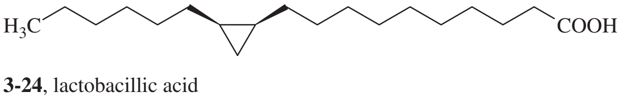
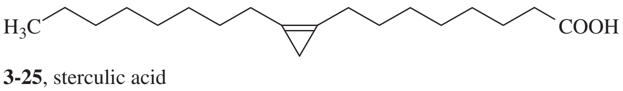
3,12,19-Trimethyltricosanoic	26	Phthioic
2,4,6-Trimethyloctacosanoic	31	Mycoceranic

3.3.1.4.3 Cyclic acids

Another group consists of cyclic fatty acids with saturated or unsaturated three-membered, five-membered and six-membered rings. The naturally occurring acids usually have the cyclopropane (**3-24**) or cyclopropene (**3-25**) ring in the middle of the hydrocarbon chain. The cyclopentene ring (**3-26**), as is the case of chaulmoogric

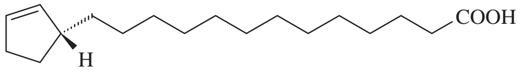


3-24, lactobacillic acid

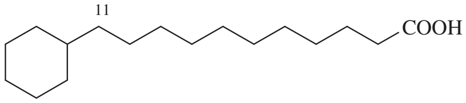


3-25, sterculic acid

acid, is usually at the end of the chain (Table 3.5). An example of fatty acids with the cyclohexane ring at the end of the hydrocarbon chain is 11-cyclohexylundecanoic acid (**3-27**).



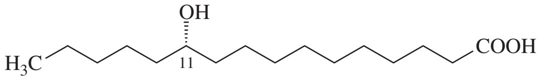
3-26, chaulmoogric acid



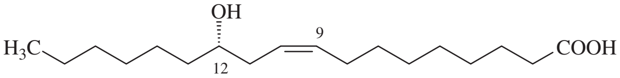
3-27, 11-cyclohexylundecanoic acid

3.3.1.5 Fatty acids with additional oxygen functional group

Hydroxy acids are found naturally in relatively large numbers, but mostly as minor fatty acids. An example of a saturated hydroxy acid is (+)-(*S*)-11-hydroxyhexadeconoic acid, known as jalapinolic acid (**3-28**). The unsaturated hydroxy acid (9*Z*,12*S*)-12-hydroxyoctadec-9-enoic acid, or ricinoleic acid (**3-29**), is the best known representative of the series of (+)-D-acids. It is accompanied by 9,10-dihydroxy- and 9,10,12-trihydroxystearic acids, which can also be found in some edible fats as secondary oxidation products.



3-28, jalapinolic acid



3-29, ricinoleic acid

Important polyhydroxy acids are 9,10,12,13-tetrahydroxyoctadecanoic acids, known as sativic acids (several steric isomers exist), which are derived from linoleic acid. Oxidation of linolenic acid analogously produces 9,10,12,13,15,16-hexahydroxyoctadecanoic (linusic) acids. An overview of common hydroxy fatty acids is given in Table 3.6.

An oxo group (keto group) occurs, for example, in (9*Z*,11*E*,13*E*)-4-oxooctadeca-9,11,13-trienoic acid (**3-30**), which is known under the trivial name α-licanic (couepinic) acid. An example of an epoxy fatty acid derived from ethylene oxide (oxirane) is (*Z*)-11-(3-pentyloxiranyl)undec-9-enoic acid, also known as (*Z*)-12,13-epoxyoctadec-9-enoic acid or 12,13-epoxyoleic acid, by the trivial name vernolic acid (**3-31**).

In addition, furan fatty acids can be found in natural products, and are known as F-acids. Their general structure is given in formulae **3-32**. The basic member of the homologous series of non-olefinic furan fatty acids is (10*Z*,12*Z*)-10,13-epoxy-11,12-dimethyloctadecanoic acid (abbreviated as F1-acid; $\omega = 8$, $n = 4$,

Table 3.5 Fatty acids with cyclic residue in chain.

Systematic name	Number of carbon atoms	Number of double bonds	Trivial name
(5*R*)-5-(Cyclopent-2-en-1-yl)pentanoic	10	1	Aleprestic

$R = CH_3$). The most common compound is (12*Z*,14*Z*)-12,15-epoxy-13,14-dimethyleikosa-12,14-dienoic acid (abbreviated as F1-acid, $\omega = 7$, $n = 3$, $R = CH_3$). Common F-acids are also olefinic fatty acids with one unsaturation on the side chains conjugated with the furan ring. The most common compound is (12*Z*,14*Z*)-12,15-epoxy-13,14-dimethyleicosa-12,14-dienoic acid (abbreviated as F6-acid, $\omega = 7$, $n = 3$, $R = CH_3$).

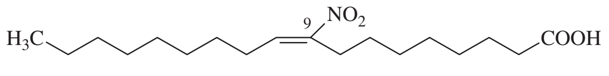
3.3.1.6 Other fatty acids

In addition to the above mentioned fatty acids, fatty acids containing nitrogen, sulfur and chlorine in their molecules also exist in nature. An example of a fatty acid containing a nitro group is 9-nitrooleic acid (**3-33**). An example of a fatty acid containing sulfur in the molecule is 5-(1,2-dithiolan-3-yl)pentanoic acid, which is better known as (*R*)-lipoic or α-lipoic acid (see Section 5.15). A representative of fatty acids with thiophene, tetrahydrothiophene and tetrahydrothiopyran rings in the hydrocarbon chain is 8-(5-hexyltetrahydrothiophen-2-yl)octanoic acid (**3-34**, R = H). Fatty acids with one or more chlorine atoms in the molecule are found in foods as contaminants (see Section 11.4.2.2.2).

3.3.2 Biochemistry, physiology and nutrition

3.3.2.1 Biosynthesis of fatty acids

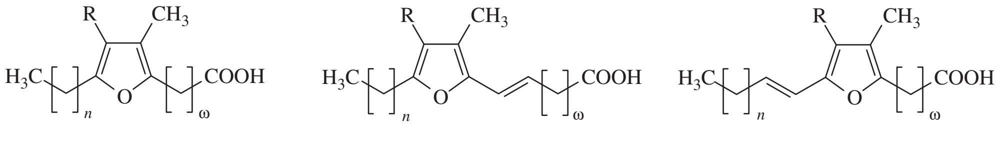
Fatty acid biosynthesis *de novo* is characteristic of all living organisms. The biosynthetic process involves the breakdown of excess dietary carbohydrates into acetate units. Saturated fatty acids are built primarily from acetyl coenzyme A (acetyl-CoA) units in the so-called acetate pathway, with chain assembly being achieved by a Claisen condensation. Acetyl-CoA (connecting glycolysis with the citric acid cycle) is formed from coenzyme A (HS-CoA) and the glycolytic product pyruvic acid. During each cycle, the fatty acid chain is extended by two carbon atoms and the resulting poly-β-oxo



3-33, 9-nitrooleic acid

chain, $-[CH_2-C(=O)]_n-$, is reduced before connecting another molecule of acetyl-CoA. Stabilisation of the chain by cyclisation and partial reduction leads to aromatic polyketides. Therefore, the fatty acids with an even number of carbon atoms are present in lipids far more often than fatty acids with an odd number of carbon atoms. Biosynthesis stops at 16–18 carbon atoms,[3] but in plants producing wax, fatty acid biosynthesis proceeds further. Fatty acids with an odd number of carbon atoms are formed by incorporation of propionyl-CoA instead of acetyl-CoA or by the loss of one carbon atom through α-oxidation. In the sebaceous glands of mammals and birds, malonyl-CoA can be replaced with

[3]In animal cells and yeasts, multienzyme complexes localised in cytosol, referred to as type I fatty acid synthase (FAS I), carry out the bulk of the *de novo* fatty acid synthesis. In animals, it occurs primarily in the liver, adipose tissue, central nervous system and lactating mammary gland. FAS I contains seven distinct catalytic centres and is arranged around a central acyl carrier protein (ACP) containing bound pantothenic acid (see Section 5.9.1). In prokaryotes and plants, distinct soluble enzymes localised in mitochondria and plastids, referred to as type II fatty acid synthase (FAS II), carry out the reactions.
In the first reaction, acetyl-CoA is converted into acetyl-ACP and partly carboxylated to malonyl-CoA that is transformed into malonyl-ACP by reaction with acetyl-ACP. Condensation of acetyl-ACP with malonyl-ACP followed by decarboxylation gives acetoacetyl-ACP, its reduction yields β-hydroxybutyryl-ACP, dehydration gives (*E*)-but-2-en-1-yl-ACP and on further reduction butyryl-ACP. Butyryl-ACP (with four carbon atoms) reacts with another molecule of malonyl-ACP and each turn of the cycle extends the chain length of the acyl group by two carbons. The acyl group length gradually increases up to 16 carbons giving rise to palmitoyl-ACP. Palmitoyl-ACP can react with malonyl-ACP yielding stearoyl-ACP. Both acyl-ACPs can release the bound fatty acids (palmitic and stearic) or may be transformed (by reaction with HS-CoA) into acyl-CoAs employed in the biosynthesis of lipids (reaction of acyl-CoA with glycerol phosphate).
Palmitoyl-ACP and stearoyl-ACP are precursors for the biosynthesis of unsaturated fatty acids palmitoleic and oleic catalysed by Δ^9-desaturase. Under the action of Δ^4-desaturase, palmitic acid is transformed into (*Z*)-hexadec-4-enoic acid, which gives rise to petroselinic acid by chain elongation. Chain elongation of palmitoleic acid gives asclepic (*cis*-vaccenic) acid. Oleic acid is a precursor of gondic acid (through the action of elongase), which yields erucic acid (elongase) and other fatty acids. The action of Δ^6-desaturase converts oleic acid into (6*Z*,9*Z*)-octadeca-6,9-dienoic acid in mammals, which gives (5*Z*,8*Z*,11*Z*)-eicosa-5,8,11-trienoic acid (Mead's acid) by elongation and dehydrogenation catalysed by Δ^5-desaturase. Mammals cannot synthesise linoleic and linolenic acids, which are only biosynthesised in plants and fungi. Plants and fungi produce linoleic acid from oleic acid by the action of Δ^{12}-desaturase, while Δ^{15}-desaturase catalyses the biosynthesis of linolenic acid. Desaturation of oleic acid on C-9 provides octadec-9-ynoic (stearolic) acid.



non-olefinic furan fatty acids

3-34, 8-(5-hexyltetrahydrothiophen-2-yl)octanoic acid, R = H

methylmalonyl-CoA, which leads to the biosynthesis of methyl derivatives of fatty acids. Thus, 2,4,6,8-tetramethyldecanoic acid is produced from an acetyl-CoA precursor and four methylmalonyl-CoA chain extender units. It occurs, for example, in the sebaceous glands of the goose, producing an oily and waxy secretion, called sebum, to lubricate and waterproof the feathers.

3.3.2.2 Metabolism of essential fatty acids

In addition to fatty acids obtained in the diet, the human organism is able to synthesise some saturated and unsaturated fatty acid in the same way as other animals and plants do. Unlike plants, however, polyene fatty acids of *n*-6 (linoleic acid) and *n*-3 series (linolenic acid) cannot be synthesised although they are strictly necessary. Therefore, these so-called essential fatty acids must be obtained through food in sufficient quantities. In the body, linoleic acid is extended by two carbon atoms and α-linolenic acids by six carbon atoms in elongation reactions catalysed by elongases. New double bonds are created by so-called desaturation, which is catalysed by desaturases. These reactions lead to fatty acids with 20–24 carbon atoms and from three to six double bonds. The oxygenated derivatives of C_{20} are pivotal signaling molecules in animals. In the bodies of animals, these essential fatty acids have an indispensable role as precursors of biologically active compounds called **eicosanoids**.[4] In animal systems, eicosanoids regulate cell differentiation, immune responses and homeostasis. In human metabolism, the most important substance is arachidonic acid (Figure 3.1), which is stored in biological membranes as the C-2 ester of phosphatidylinositol and other phospholipids (see Section 3.5.1). In terrestrial plants, the biological role of eicosanoids is played by other biologically active substances, derivatives of C_{18} and C_{16} fatty acids, known as **octadecanoids** and **hexadecanoids** that act as developmental or defense hormones. The oxygenated derivatives of fatty acids are collectively known as **oxylipins**.

[4]In addition to erythrocytes, **eicosanoids** are produced by all mammalian cells. Eicosanoids include **prostaglandins**, **leucotrienes**, **prostacyclins**, **thromboxanes** and **lipoxins**. These compounds act, for example, as vasoconstrictor and vasodilatory substances in regulating blood pressure, in blood clotting as platelet (thrombocytes) aggregation substances, in regulating leukocyte function, in sleep and waking cycles and other processes. Arachidonic acid yields prostaglandins, prostacyclins and thromboxanes of the series 2 (such as prostaglandin E_2 and thromboxane A_2) *via* cyclic endoperoxides formed by the action of cyclooxygenases (prostaglandin-endoperoxide cyclases) and other enzymes. Leucotrienes are created by 5-, 12- or 15-lipoxygenases. For example, 5-lipoxygenases synthesise Leucotrienes with index 4 and 12/15-lipoxygenases synthesise lipoxins with index 4 from arachidonic acid. Analogously, prostaglandins, prostacyclins and thromboxanes with index 3 and Leucotrienes with index 5 are formed from EPA. Dihomo-γ-linolenic acid is a precursor of prostaglandins with index 1 and of Leucotrienes with index 3.

Enzymes catalysing the desaturation and elongation of *n*-6 and *n*-3 fatty acids are the same, but elongation and desaturation takes place more easily in *n*-3 fatty acids. Some people have less active Δ^6-desaturase, so these transformations are more difficult. The main factors that negatively affect the activity of Δ^6-desaturase are age (in the elderly the enzyme activity is lower), nutrition (ethanol has an inhibitory effect, and there are negative impacts resulting from deficiencies of vitamin B_6, biotin, Zn, Mg and Ca, a higher intake of *trans*-unsaturated fatty acids and positional isomers of unsaturated acids), stress and viral infections. Today, various products containing γ-linolenic acid, dihomo-γ-linolenic acid, eicosapentaenoic acid (EPA) and other substances are available as dietary supplements.

3.3.2.3 Nutrition

The human diet contains only small amounts of free fatty acids. Dietary fat is mostly composed of neutral triacylglycerols accompanied by polar phospholipids and other fatty acid esters, which cannot be absorbed by the intestine. Digestion and absorption of fat requires that the complex fat molecules are broken down enzymatically into smaller, more manageable molecules (see Section 3.4.3.2). Dietary fat should constitute 30–35% of a person's total energy intake, and should contain saturated, monoenoic and polyenoic fatty acids in a ratio of $<1:1.4:>0.6$. Saturated acids should contribute <10%, polyenoic acids of the *n*-6 series 4–8% (on average about 5%) and acids of the *n*-3 series about 1% of energy provided by food. It is often stated that the ratio *n*-6 : *n*-3 should be no greater than 5 : 1. At least 0.5% of the energy intake should come from EPA, DHA and other higher polyunsaturated acids of the *n*-3 series (Figure 3.1).

3.3.2.4 Oxidation in organism

Fatty acids yield energy through a multi step process called β-oxidation, which takes place in the mitochondria of most body tissues. Less common is α-oxidation, which splits the carboxyl group and the chain is shortened by one carbon atom, while generating a fatty acid with an odd number of carbon atoms. ω-Oxidation (oxidation of the methyl group at the end of a chain) can also occur, leading to the formation of dicarboxylic acid.

Fatty acids oxidised during the process of β-oxidation have to be activated by coenzyme A with the formation a fatty acyl-CoA thioester (short and medium length fatty acids undergo this reaction in the mitochondria, while long chain fatty acids form acyl-CoAs at the outer mitochondrial membrane and are carried across the inner mitochondrial membrane by carnitine). The saturated fatty acid molecule with no double bond is then degraded to acetyl-CoA, its chain is shortened by two carbon atoms[5] and the shortened fatty

[5]The fatty acid bound to coenzyme A is first transformed into *trans*-unsaturated (alk-2-enoic) acid, then into 3-hydroxycarboxylic acid and finally into 3-oxocarboxylic acid. This acid breaks down, which results in the production of one acetyl-CoA and a fatty acid shortened by two carbons from each cycle of fatty acid β-oxidation. This acetyl-CoA then enters the mitochondrial citric acid cycle.

acid goes through another β-oxidation cycle. The final reaction product of saturated fatty acids with an even number of carbon atoms is acetyl-CoA. The end product of fatty acids with an odd number of carbon atoms is propionyl-CoA, which has to eliminate carbon dioxide with the formation of D-methylmalonyl-CoA. This is then is isomerised to L-methylmalonyl-CoA, which is rearranged to succinyl-CoA ready to enter the citric acid cycle.

β-Oxidation of unsaturated fatty acids with one *cis*-double bond takes place via similar reactions, but requires two additional enzymes. The β-oxidation cycles proceed as many times as they can before coming to the double bond. Then enoyl-CoA isomerase transforms the *cis*-double bond into a *trans*-double bond and moves it over one carbon so that the product can then continue through the β-oxidation. β-Oxidation of polyunsaturated fatty acids proceeds analogously, but it only goes through one more round using 2,4-dienoyl-CoA reductase to produce a *trans*-3-enoyl product, which is converted by enoyl-CoA isomerase into *trans*-2-enoyl-CoA. Fatty acids with *trans*-double bonds and hydroxy acids are difficult to break down and are a burden for the organism if they are present in large quantities in the diet. *Trans*-unsaturated fatty acids also adversely affect the ratio of low and high density lipoproteins (LDL/HDL) in serum (see Section 3.6.2) and incorporate instead of saturated fatty acids into the *sn*-1 position of the membrane and nervous tissue phospholipids. *Trans*-isomers of fatty acids deteriorate the insulin resistance and thus increase the risk of the metabolic disorder *diabetes mellitus* type 2. Certain pro-inflammatory and adverse effects on fetal development have also been described. Recommendations of the WHO/FAO therefore limit the intake of *trans*-unsaturated fatty acids to 1% of energy intake.

3.3.3 Occurrence

Free fatty acids formed by hydrolysis of lipids under the catalytic action of hydrolases are only found in plant and animal organisms in small quantities. Most of them are bound as esters or amides in homolipids and heterolipids. Some fatty acids, such as palmitic or oleic acids, are common constituents of lipids of all natural materials. Other fatty acids are specific only to microorganisms, plants or animals, some only to certain genera, families or orders, and therefore have particular importance in the taxonomy. For simplicity, the occurrence of free fatty acids and fatty acids bound in lipids is described collectively.

3.3.3.1 Saturated acids

An overview of the occurrence of saturated fatty acids in fats and oils is given in Table 3.7. Generally, the most common fatty acid is palmitic acid, which occurs in virtually all animal and plant lipids, bound in triacylglycerols and phospholipids.

Saturated short chain fatty acids, such as butyric and caproic acids, and the group of medium chain fatty acids acids with 8 and 10 carbons in the molecule typically occur in milk fat (Table 3.8). Butyric acid constitutes 4–8% (being found exclusively at the *sn*-3 position of triacylglycerols), and caproic acid 1–3% (also found mostly at the *sn*-3 position of triacylglycerols) of the weight of all fatty acids in cows' milk fat. These fatty acids are also present in milk fat triacylglycerols of other ruminants, such as sheep and goats, but they are not found in the fats of ruminants other than in the milk fats. Caproic acid is also a minor component of some seed fats (e.g. of palm seeds), which mainly contain fatty acids with medium chain length.

Medium chain fatty acids (C_8–C_{12}) are present, usually as minor components, in milk fat triacylglycerols (Table 3.8). They are not found in the majority of vegetable oils, with a few exceptions. A high content of these fatty acids, especially of lauric acid, which is accompanied by other acids, is found in palm seed oils (of the palm family, Arecaceae), such as coconut and palm kernel oil (Table 3.9) and seed oils of the Laurel family of plants (Lauraceae). Coconut

[a] From the kernel of coconut palm seed (*Cocos nucifera*, Arecaceae).
[b] From the fleshy mesocarp of the fruit of the oil palm (*Elaeis guineensis*).
[c] Derived from the kernel of the fruit of several varieties of the palm *Attalea* spp.; in Brazil from Babassu palm kernels (*Attalea speciosa*). In Mexico and Honduras, related cohune oil is pressed from the endosperm of cohune palm seeds (*A. cohune*).
[d] From the pulp (mesokarp) of oil palm fruits.

oil is derived from the seeds (kernels) of coconuts. Fat extracted from the pulp (mesocarp) of the oil palm is palm oil, which has a completely different composition from palm kernel oil, the fat derived from the kernel (endosperm). Its fractions (palmolein and palmstearin) are commercially available, and are often added to food products.

Myristic acid (**3-1**) is a common lipid component of most living organisms. It usually represents about 1–2% of total fatty acids and is present at higher levels in milk fat (10%) and coconut and palm kernel oils (14–21%). The fat of farm animals, especially of pigs and ruminants, contains long chain saturated fatty acids, palmitic and stearic acids. The content of these fatty acids is lower in the depot fat of commercially reared birds (Table 3.10).

Palmitic acid (**3-2**) is the most common saturated fatty acid. Its content in cow's milk ranges from 26 to 41% and in breast milk from 6.1 to 12.1%. Most animal tissue lipids contain 20–30% palmitic acid; its content in vegetable oils from seeds is 5–30%, while in palm oil it reaches 40% or more. Stearic acid (**3-3**) is found in the highest amount in ruminant fats (milk fat in Table 3.8, and tallow in Table 3.10). In vegetable fats, its highest levels are found in cocoa butter and shea butter (Table 3.11) and then in shortenings. In gangliosides, stearic acid may constitute up to 80% of the total fatty acids. Arachidic acid and other very long chain fatty acids (behenic and lignoceric) are usually present in traces in animal fats; only in some oils do they occur in relatively high concentrations. For example, peanut oil contains 5–7% of C_{20}–C_{24} acids, of which arachidic acid represents about a third. Around 2% of behenic acids are found in canola oil. These and higher fatty acids are found in larger quantities in waxes.

Saturated fatty acids with an odd number of carbon atoms (C_{13}–C_{25}) are relatively rare, and occur only as trace components in triacylglycerols, for example in the milk of mammals. These acids (mainly pentadecanoic acid and heptadecanoic acid, also known as margaric or daturic acid) are present at higher concentrations in the lipids of some microorganisms, in skin lipids and in depot fat and the milk of ruminants (5% or more) from which they enter into the human depot fat.

Arachidic	0.2-1.0	1.2	0.2

3.3.3.2 Unsaturated acids

Animal fats and vegetable oils mostly contain unsaturated straight chain fatty acids with 10–36 carbon atoms. The most common fatty acids are monoenoic and polyenoic fatty acids with 16–18 carbon atoms. The unsaturated fatty acids content of fats and oils ranges widely, from more than 90% of total fatty acids in rapeseed oil to less than 10% in coconut oil. Unsaturated fatty acids in animal fats occur in a much smaller concentration range, usually between 50 and 70% (Table 3.7). The only exception is fish oil, because it contains fatty acids with 20–22 carbon atoms and 4–6 double bonds (Table 3.12). The fat of freshwater fish differs in composition from the fatty acids in the fat of marine fish. Fish do not synthesise

Table 3.10 Composition of major fatty acids in the fat of farm animals and birds (% of total fatty acids).

Fatty acid	Beef tallow	Sheep tallow	Pork lard	Rabbit lard	Chicken lard	Goose lard	Emu lard[a]

these fats themselves, but acquire them through their food (they are present in plankton, such as crustaceans and algae). Therefore, aquatic mammals (such as whales) that feed on small crustaceans have a similar fatty acids composition to that of fish. There is far greater diversity in the composition of unsaturated fatty acids in plants than in animals.

Vegetable fats and oils are divided into groups according to their related fatty acid composition. Information about the fat content of major vegetable oil raw materials is listed in Tables 3.9, 3.13, 3.14 and 3.15. The following groups are recognised:

- Oils from palm seeds, which generally contain a small amount of oleic acid and only traces of acids with more double bonds (Table 3.9); typical examples are coconut oil and palm kernel oil.

- Plant butters,[6] where the content of unsaturated fatty acids is similar to that in animal fats and consists mainly of oleic acid (Table 3.11 and Table 3.14); a typical example is cocoa butter (today there are objections to the term plant butter as it might be confused with cows' butter).

- Oils with predominantly oleic acid and small amounts of polyunsaturated fatty acids; the most common representative

[6]The name plant butter is derived from the fact that in countries of origin these fats have a consistency like cow's butter, in our climate they are hard fats, but melt in the mouth. A typical example is cocoa butter from cacao beans (*Theobroma cacao*, Sterculiaceae). This is obtained by pressing and is used unrefined in the chocolate and pharmaceutical industries. Because it is expensive, it is often replaced by other plant butters. The most common is shea butter from the African plant commonly known as shea tree or karité (*Butyrospermum parkii*, Sapotaceae, syn. *B. paradoxa*), butter illipe of an Indian plant (*Madhuca longifolia*, syn. *Bassia longifolia* from the same family of plants), butter mowrah from a similar plant (*Madhuca latifolia*), Borneo tallow from the East Asian plant *Shorea stenoptera* (Dipterocarpaceae), Chinese vegetable tallow from the plant *Stillingia sebifera* (Euphorbiaceae), for its rigid consistency often regarded as a wax, and nutmeg (*Myristica fragrans*, Myristicaceae) fat and fat from plants related to nutmeg. Plant butters have a specific composition of triacylglycerols with palmitic, stearic and oleic acid as the main components, which causes a narrow range of melting points of these fats. Sometimes, plant butters are replaced with artificial fat prepared by fractionation of palm oils.

is olive oil; today, a number of plants containing seeds with oils high in linoleic acid have been bred so that the fatty acid composition resembles the composition of olive oil; examples include sunflower, safflower and peanut oils (Tables 3.13 and 3.14); palm oil can also be included as it contains about 10% linoleic acid and has a high content of palmitic acid (Table 3.9).

- Oils with a medium content of linoleic acid, but not containing linolenic acid; these oils include the traditional peanut oil (also known as arachis oil or groundnut oil) (Table 3.14).

- Oils high in linoleic acid, but not containing linolenic acid, such as traditional sunflower, cottonseed, safflower, poppy seed, germ or sesame oils (Table 3.14).

[a]Traditional rapeseed oil (turnip rape oil, colza oil, ravison oil, sarson oil or toria oil) is produced from seeds of *Brassica napus*, *Brassica campestris*, *Brassica juncea* and *Brassica tournefortii*. Low erucic acid rapeseed oil (low erucic acid turnip rape oil; low erucic acid colza oil; canola oil) is produced from low erucic acid *Brassica napus*, *Brassica campestris* and *Brassica juncea* seeds.

[b]The maximum permissible concentration of erucic acid in vegetable oils, fats and foods containing more than 5% fat is 5% of total fatty acid content.

- Oils with a medium content of linolenic acid, such as soybean oil and rapeseed 00 oil (Table 3.15); this group also includes oils from seeds of Brassica plants, which originally contained erucic acid[7]; linseed oil is the traditional oil that is rich in linolenic acid.

- Oils containing some specific fatty acids such as γ-linolenic acid (Table 3.16), which occurs in oil from the seeds of evening primrose (*Oenothera biennis*, Oenotheraceae), borage (*Borago officinalis*, Boraginaceae) and seed oil from currants and gooseberries (*Ribes* spp.; Grossulariaceae); erucic acid is found in seed oils of cruciferous plants (Brassicaceae) and plants belonging to the family Tropaeolaceae; petroselinic acid is found in oils of carrot parsley and celery seeds, plants of the Apiaceae family and also in plants of the Araliaceae family.

The most widespread unsaturated fatty acid is oleic acid (**3-4**), which occurs, at least in a small amount, in virtually all animal and plant lipids. Oleic acid constitutes 30–40% of the total fatty acids in adipose tissue of animals and 20–80% of the total fatty acids in vegetable fats and oils. For example, olive oil contains up to 78% oleic acid.

Linoleic acid (**3-7**) is the most common polyenoic fatty acid. It is present, at least in traces, in all fats. For example, sunflower and soybean oils usually contain 50-60% of linoleic acid; safflower oil contains 75% linoleic acid. In the fat of animals, where this essential fatty acid gets from plant food, its content is typically 15-25%, but may be higher (cardiolipin of heart muscle contains 75% linoleic acid). Linolenic acid (**3-11**) is the main component of leaves, especially in the photosynthesising apparatus of algae and higher plants. Linolenic acid is present in linseed oil in amounts of up to 65%. Soybean and rapeseed oils only contain up to 10% linolenic acid. In animal tissues, it is usually a minor component (up to 1%), although the adipose tissue of horses contains up to 10% of this essential fatty acid.

[7]Rapeseed oil traditionally contained a high level of erucic acid (C22:1), which is toxic to humans in large doses. Traditional uses were for lamp oils, soap making, high-temperature lubricating oils and plastics manufacturing. Since 1991, virtually all rapeseed production in the European Union has shifted to rapeseed 00 (double zero oil), with a low content of both erucic acid and glucosinolates, which is a highly appreciated edible oil. The European rapeseed production is conventional (non-GMO). Rapeseed oil has also become the primary feedstock for biodiesel in Europe. Canadian plant breeders produced a premium quality rapeseed oil called canola. The name was derived from '**Can**adian **o**il, **l**ow **a**cid' in 1978. This improvement in the oil resulted from a reduction in erucic acid to levels below 2%.

Table 3.17 Content of *trans*-unsaturated fatty acids in some animal fats (% of total *trans*-unsaturated fatty acids).

Double bond position	Milk fat[a]	Butter[a]	Depot fat (beef tallow)[a]
8	1-3	1-2	1-2
9	7-15	5-16	8-14
10	4-13	4-7	5-7
11	28-55	51-68	64-69
12	4-9	3-6	2-3
13	4-9	3-6	2-3
14	4-10	4-7	3-4
15	4-8	3-5	2-3
16	5-10	4-7	3-4

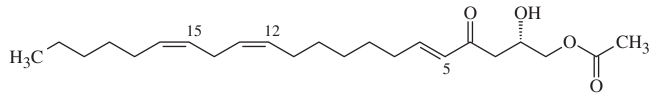
[a]Total amount of *trans*-unsaturated fatty acids in milk fat and butter is 2-8% and in beef tallow it is 2-3% of the total fatty acids.

Milk fat contains some other monoenoic fatty acids, such as caproleic, palmitoleic (about 4%) and asclepic (*cis*-vaccenic, 1–5%; commonly present in vegetable oils, where, as a minor acid, it accompanies oleic acid), and also their *trans*-isomers, especially vaccenic acid (Table 3.17). Larger quantities of myristoleic, palmitoleic (approximately 12–14%) and selacholeic acids are found in fish and whale fats. Palmitoleic acid is present at high levels in the fruits of sea buckthorn (*Hippophae rhamnoides*, Elaeagnaceae) and the oil of macadamia nuts (*Macadamia integrifolia*, Proteaceae). Petroselinic acid, in quantities up to 50% and higher, occurs in the seeds of plants of the Apiaceae family, to which carrots (*Daucus carota*), parsley (*Petroselinum crispum*) and coriander (*Coriandrum sativum*) belong. Ximenic acid is present in the seeds of tropical trees and shrubs of the genus *Ximenia* (Olaceae), from which technical as well as cooking oils are obtained.

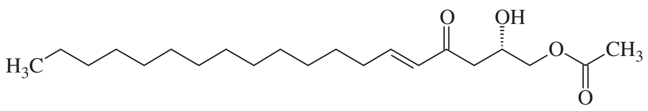
Isomers of linoleic acid with conjugated double bonds occur in milk fat and in lower amounts (2.9–11.3 g/kg) in dairy products and in the meat of ruminants. The main fatty acids are (9*Z*,11*E*)-octadeca-9,11-dienoic (rumenic) acid (**3-10**) and (10*E*,12*Z*)-octadeca-10,12-dienoic acid.

Some conjugated polyenoic fatty acids are also natural components of vegetable oils. α-Calendic acid (**3-13**) is the major fatty acid (50–60%) of oil from the seeds of marigold (*Calendula officinalis*, Asteraceae), and punicic acid (**3-14**) occurs at a level of about 60% in oil from the seeds of pomegranate fruit (*Punica granatum*, Lythraceae). α-Eleostearic acid (with three conjugated double bonds) and β-eleostearic acid are found in significant quantities in tung oil (Chinese wood oil) and abrasin oil, formerly used for lighting and now used for biodiesel production. Tung oil is obtained by pressing the nut of the tung tree (*Vernicia fordii*, Euphorbiaceae), which is native to southern China, Burma and northern Vietnam, but is now grown in subtropical regions around the world. Abrasin oil, used in technological applications similarly to tung oil, is obtained from the *V. montana* tree, and is prized for use in wood finishing. α-Parinaric acid with four conjugated double bonds is present in the seeds of the plant *Atuna racemosa* (syn. *Parinarium laurinum*, Chrysobalanaceae), originally from the island of Fiji and other Pacific islands, where it is present at about 46% (34% of the fatty acids of the oil consists of α-eleostearic acid). α-Parinaric acid is present at about 29% in the seed oil of *Impatiens balsamina* (Balsaminaceae), native to southern Asia and India. Polyenoic acids with isolated double bonds, such as hiragonic (hexadecatrienoic), stearidonic (octacosatetraenoic), clupanodonic (eicosapentaenoic), clupadonic (docosapentaenoic, commonly known as DPA) and nisinic (tetracosahexaenoic) acid, are found primarily in fats of marine fish (Table 3.3). Acetates of unsaturated fatty acids occur as natural substances in avocado fruit (*Persea americana*, Lauraceae). Examples of these fatty acid esters are (2*R*,12*Z*,15*Z*)-2-hydroxy-4-oxoheneicosa-12,15-dien-1-yl acetate, (2*R*,5*E*,12*Z*,15*Z*)-2-hydroxy-4-oxoheneicosa-5,12,15-trien-1-yl acetate, known as persenone A (**3-35**) and (2*R*,5*E*)-2-hydroxy-4-oxononacosa-5-en-1-yl acetate (persenone B, **3-36**), which act as antioxidants, preferentially suppressing radical generation.

Natural fatty acids are mostly of a *cis* (*Z*) configuration. Acids with *trans* (*E*) configuration occur mainly in the depot fat of ruminants



3-35, persenone A



3-36, persenone B

(Table 3.17), resulting from conversion of the digested vegetable fats through biohydrogenation by microorganisms in the rumen, the first and the largest stomach of ruminants. Key products of biohydrogenation are (*E*)-octadec-11-enoic (*trans*-vaccenic) acid (**3-6**), which arises from linoleic or α-linolenic acid and (9*Z*,11*E*)-octadeca-9,11-dienoic (rumenic) acid (**3-10**), which is produced from α-linolenic acid (see Section 3.3.3.1). The ratio of these two fatty acids is about 3 : 1. In the mammary gland, rumenic acid forms via desaturation of *trans*-vaccenic acid.

An increased content of *trans*-unsaturated fatty acids is also found in some other mammals (such as kangaroos) where herbage is pre-digested by microorganisms in their digestive tract. *Trans*-unsaturated fatty acids partly pass into the milk (the predominant acid is vaccenic acid, but also present are elaidic acid, **3-5**, and some other fatty acids). These fatty acids are ingested by humans as a part of their food and therefore occur in human depot fat and in breast milk.

Trans-fatty acids are also formed during industrial catalytic hydrogenation (see Section 3.8.1.7) of plant or fish oils. This hydrogenation improves the thermal stability and prevents oxidation of unsaturated oils. These *trans*-fatty acids therefore occur in fat products based on hydrogenated oils. Unsaturated fatty acids with a *trans*-configuration also form during heating of polyenoic fatty acids (at temperatures over 240 °C); for example, they form during deodorisation of oils (see Section 3.4.3.7). Some invertebrates, but also plants and microorganisms (membrane lipids of bacteria *Pseudomonas putida*), contain traces or even a substantial amount of *trans*-acids.

3.3.3.3 Other acids

3.3.3.3.1 Alkynoic acids

Alkynoic acids are distributed mainly in the lipids of mosses and also in the lipids of some tropical plants. Their occurrence is largely limited to species of plants of the family Santalaceae, where the seeds of some plants of the genera *Exocarpus*, *Santalum* and *Ximenia* contain stearolic acid (**3-17**), plants of the Simaroubaceae family contain tariric acid, and plants of the Olaceae family contain isanic acid (**3-18**). Boleka oil, containing tariric acid, and isano oil, containing isanic acid, are used in technological applications.

Alkynoic fatty acids are toxic. It is assumed that they interfere with the metabolism of lipids and fatty acids and inhibit lipoxygenases and cycloxygenases.

3.3.3.3.2 Branched acids

The basic member of the homologous series of branched chain carboxylic acids is 3-methylbutanoic (isovaleric) acid, which is ranked among the hemiterpenoids (see Section 8.2). Triacylglycerols containing isovaleric acid are important components of fat in European sturgeon, known as beluga (*Huso huso*), a species of anadromous fish in the sturgeon family (Acipenseridae). Isovaleric acid occurs in larger amounts in valerian root (*Valeriana officinalis*, Valerianaceae), in the form of esters of various monoterpenoids (such as borneol, also known as bornan-2-ol) and some less common sesquiterpenoids.

Higher isoacids and anteisoacids are predominantly found in the depot fat and milk of ruminants (Table 3.18) at levels of 1–2%. The dietary branch chain fatty acids come from milk, dairy products and meat of ruminants. They also constitute the lipid part of cell walls in some colon bacteria. Several mechanisms appear to be involved in their formation. Some branched chain fatty acids arise from acetyl-CoA elongation of 2-oxoacids acting as the precursors of amino acids (such as valine and isoleucine), without the involvement of fatty acid synthase mediated reactions, suggesting integration of amino acid and fatty acid metabolism. Methyl side chains can also be introduced when methylmalonyl-CoA replaces malonyl-CoA as the chain-extending unit in fatty acid biosynthesis (see Section 3.3.2.1).

Common branched chain fatty acids are anteisoheptadecanoic acid (14Me 16:0), anteisononadecanoic acid (16Me 18:0), anteisopentadecanoic acid (12Me 14:0) and anteisotridecanoic (10Me 12:0) acid. These acids occur in higher levels in the lipids of mammal hairs. Lanolin (wool fat) for example, contains isoacids and anteisoacids C_{10} to C_{34}. One of these, the anteisoacid 18-methyleicosanoic acid, represents up to 60% of fatty acids bound by thioester bonds in sheep wool. Fish oils contain 1–2% C_{14}–C_{18} isoacids and anteisoacids. 4-Methyloctanoic (4-methylcaprylic or hircinoic) and 4-methylnonanoic acids have been implicated as primary contributors to the so-called 'soo' odor of mutton, which is an unpleasant fatty-goaty type note. The odour recognition threshold of (*S*)-hircinoic acid is 13 μg/l in air.

Microbial degradation of isoprenoids in the rumen of ruminants, for example of the chlorophyll side chain formed by (2*E*,3,7*R*,11*R*,15)-3,7,11,15-tetramethylhexadec-2-en-1-ol (phytol), yields some more branched acids, such as (2*RS*,6*R*,10*R*)-tetramethylpentadecanoic (pristanic) or (3*RS*,7R,11R,15)-3,7,11,

Table 3.18 Content of branched chain fatty acids in animal fats (% of total fatty acids).

17	0.42	<0.5	1.6	traces
18	traces	traces	0.2	0

15-tetramethylhexadecanoic (phytanic) acid (**3-23**). Phytanic acid is therefore found in dairy products such as butter, and in the fat of ruminants,[8] as a mixture of (3*RS*)-epimers. Branched fatty acids obtained by oxidation of paraffins are used for technical purposes, for example in cosmetics. Branched fatty acids are less utilisable.

Plant isoacids and anteisoacids are the main component of the surface waxes. For example, pine seeds (*Pinus* sp., Pinaceae) contain 14-methylhexadecanoic acid at a level of 0.5–1%. A higher number of branched acids is a typical characteristic of lipids in the cell walls of certain bacteria (including pathogens). An example is (*R*)-tuberculostearic acids of *Mycobacterium tuberculosis* and related species. Neoacids occur in some microorganisms, algae, higher plants and marine animals. For example, 13,13-dimethyltetradecanoic acid (**3-16**) is a minor component of conifer resins.

3.3.3.3.3 Alicyclic acids

Alicyclic saturated fatty acids with a cyclopropane ring and alicyclic unsaturated fatty acids with a cyclopropene ring are relatively rare in natural fats and oils. These fatty acids are found at trace levels in the lipids of bacteria and lipids of other lower organisms and plants. An example is *cis*-11,12-methyleneoctadecanoic acid, known as lactobacillic or phytomonic acid (**3-24**). It was first isolated as a constituent of triacylglycerols from the bacteria *Lactobacillus arabinosus*, and was later found in many other bacteria. This acid is accompanied by *cis*-9,10-methylenehexadecanoic acid and C_{18}–C_{20} homologues. Some microorganisms contain *cis*-9,10-methylenoctadecanoic (dehydrosterculic) acid.

Sterculic acid (**3-25**) occurs at low concentrations (1.0–2.3 g/kg) in cottonseed (*Gossypium* spp., Malvaceae) oil accompanied by malvalic acid (2.4–3.4 g/kg) and dihydrosterculic acid (1.0–1.8 g/kg). In unroasted cottonseed meal, concentrations of these acids are about ten times lower. This fatty acid is found in a significantly higher amounts in seed oils of the genus *Sterculia* plants in the mallow family (Malvaceae), originating in tropical South America, where it is also accompanied by lower homologues, malvalic and dihydrosterculic acids. Fruits known as tropical chestnuts have a flavour reminiscent of pistachios. The sterculic acid and malvalic acid contents in oils from *S. foetida* are about 49 and 6%, respectively, and in *S. monosperma* about 19 and 0.6%. These oils have special properties because they polymerise at normal temperatures and at elevated temperatures (around 250 °C) they form gels. Gum karaya is extracted from *Sterculia* species and is used as a thickener and emulsifier in foods. Dihydrosterculic acid is found at a level of 35–48% in the oil from the seeds of Chinese lychee (*Litchi chinensis*) and longan fruits (*Dimocarpus longan*) of the Sapindaceae family.

Cyclic unsaturated fatty acids with a cyclopentene ring at the end of the chain, such as chaulmoogric acid (**3-26**) and hydnocarpic acid, are present in the seeds of evergreen trees known as chaulmoogra (*Hydnocarpus*, syn. *Taraktogenos*) of the Achariaceae (formerly Flacourtiaceae) family, which grow in the rain forests of Southeast Asia. Poisonous fruits of *H. wightiana* contain about 35% of oil with a specific odour that was used in folk medicine for the treatment of leprosy and skin diseases.[9] The oil of related species *H. anthelminticus* contains about 68% chaulmoogric, 9% hydnocarpic and 1% gorlic acids. The content of these acids in the oil of *H. kurzii* is about 35, 23 and 23%, respectively.

Fatty acids with a cyclohexane ring at the end of the hydrocarbon chain, such as 11-cyclohexylundecanoic (**3-27**) and 13-cyclohexyltridecanoic acids are minor constituents of milk, butter, sheep's tallow and rumen bacteria. The amount of 11-cyclohexylundecanoic acid in cow and goat milk is 1–2 g/kg. It was found that this acid has inhibitory effects on the bacteria *Bacillus cereus*, *Escherichia coli* and fungi *Fusarium culmorum*. Cyclic fatty acids are also found in the ordinary oils, where their formation is induced by heating (see Section 3.8.1.5).

3.3.3.3.4 Epoxy acids

Epoxy fatty acids occur either as 1,2-epoxy compounds derived from ethylene oxide or 1,4-epoxides derived from furan (furan acids).

Natural 1,2-epoxides are saturated and unsaturated compounds with 18 carbon atoms, which are found mainly in small amounts as components of cutin and oils from plant seeds. Vernolic acid (**3-31**) occurs in the seeds of trees of the genus *Vernonia* of the Asteraceae family, originating from tropical Asia and America. For example, seeds of *V. anthelmintica* and of *V. galamensis* contain 62–78% of vernolic acid. Coronaric acid is found at levels of 8–18% in the seeds of garland, also known as chrysanthemum greens or edible chrysanthemum (*Chrysanthemum coronarium*) from the same plant family. The leaves of these plants are often eaten as a salad. Small amounts of 9,10-epoxystearic (about 2.5% of total fatty acids), vernolic and coronaric acids occur in germ peanut oil (*Arachis hypogaea*, Fabaceae).

Furan fatty acids (**3-32**) are present in plants, fishes, amphibians, reptiles and mammals, including man. In some fish, F-acids can typically represent 1–6% of the fatty acids in the liver lipids. In some freshwater fish, however, furan fatty acids may represent up to 25% of the total fatty acids. They also occur in butter, meat, vegetable oils, shrimps and mushrooms in small amounts. For example, virgin olive oils contain non-olefinic 10,13-epoxy-11,12-dimethyloctadeca-10,12-dienoic acid ($\omega = 8$, $n = 4$, $R = CH_3$) and 12,15-epoxy-13,14-dimethyleicosa-12,14-dienoic acid ($\omega = 10$, $n = 4$, $R = CH_3$) and two olefinic derivatives: 12,15-epoxy-13,14-dimethyleicosa-12,14,16-eicosatrienoic acid ($\omega = 10$, $n = 2$, $R = CH_3$) and 12,15-epoxy-13,14-dimethyleicosa-10,12,14-eicosatrienoic acid ($\omega = 8$, $n = 4$, $R = CH_3$). Furan fatty acids also arise as products of lipid oxidation. Autoxidation or photoxidation of furan fatty acids yields α,β-unsaturated γ-lactones known as bovolides (see Figure 8.54).

[8] Phytanic acid is normally present in small amounts in human tissues. Many defects in the α-oxidation pathway, including Refsum's disease, result in an accumulation of phytanic acid leading to neurological distress, deterioration of vision, deafness, loss of coordination and eventually death.

[9] Compounds responsible for this specific odour, in addition to other components, are the degradation products of cyanogenic glycoside gynocardin with a cyclopentene ring (see Section 10.3.2.3.1).

3.3.3.3.5 Hydroxy acids

2-Hydroxy fatty acids with 16–26 carbon atoms are important components of animal sphingolipids (see Section 3.5) and plant waxes occurring on the surface of leaf vegetables. In addition, 2-hydroxy fatty acids and 3-hydroxy fatty acids are characteristic compounds of the lipid component of the lipopolysaccharides, which are located in the outer membrane of Gram-negative bacteria. For example, even-numbered 2- and 3-hydroxy fatty acids (with chain lengths of from 8 to 16 carbons) were identified in bovine milk fat. 2-Hydroxyoctanoic acid (45 mg/kg) was present in the highest amount, followed by 3-hydroxyhexadecanoic (42 mg/kg), 3-hydroxydodecanoic (34 mg/kg), 3-hydroxydecanoic (32 mg/kg) and 3-hydroxytetradecanoic (25 mg/kg) acids. Other 2- and 3- hydroxy fatty acids were present in lower amounts. In food samples, both (*R*)-enantiomers (D-hydroxy fatty acids) and (*S*)-enantiomers (L-hydroxy fatty acids) of 2- and 3-hydroxy acids were detected, with the (*R*)-enantiomer being the enantiopure or predominant. In particular, 2- and 3-hydroxyhexadecanoic acids were found to contain relevant proportions of the (*S*)-enantiomer.

4-Hydroxycarboxylic acids and 5-hydroxycarboxylic acids occur in the form of corresponding γ- and δ-lactones in many fruits, especially apricots and peaches. Many other hydroxy fatty acids are also found in seed oils of plants. For example, (*S*)-jalapinolic acid (**3-28**) occurs in lipophilic ester-type dimers of acylated pentasaccharides derived from L-rhamnose in sweet potato (*Ipomoea batatas*, Convolvulaceae), which are known as batatins. (9*Z*,12*S*)-12-Hydroxyoctadec-9-enoic (ricinoleic) acid (**3-29**) occurs in castor oil, where it represents about 90% of the total fatty acids. So-called castor oil is extracted from the seeds of the castor oil plant (*Ricinus communis*) of the Euphorbiaceae family, and is used only for technical purposes as it has purgative properties.

3.3.3.3.6 Oxoacids

Oxoacids (ketoacids) are less common than hydroxy acids. Saturated oxoacids with 10–24 carbon atoms and unsaturated oxoacids with 14–18 carbon atoms and the carbonyl group at C-5 to C-13 represent about 1% of fatty acids in milk fat. The so-called oiticica oil is extracted from the seeds of subtropical and tropical South American plants of the genus *Licania* (Chrysobalanaceae), which includes shrubs and trees, such *L. rigida* and *L. arborea*. This oil typically contains licanic acid (**3-30**). Parinaric acid occurs in some plant oils of the rose family (Rosaceae) and the balsam family (Balsaminaceae).

3.3.3.3.7 Other acids

Nitro fatty acids are one of the forms used to link the signaling pathways of the two major groups of cell function regulators: eicosanoids and reactive forms of nitrogen, derived from nitric oxide (NO). Their interaction with the oxidised fatty acids can be crucial in the regulation of pro-oxidative and antioxidative processes in the immune responses and development of inflammatory processes. The most abundant nitro fatty acids are 9- (**3-33**) and 10-nitrooleic and 10- and 12-nitrolinoleic acids. Nitro derivatives of linolenic and icosapentaenoic acids have also been described.

Sulfur-containing fatty acids are rarely encountered. The lower homologue of (*R*)-5-(1,2-dithiolan-3-yl)pentanoic acid, known as (*R*)-lipoic or α-lipoic acid (see Section 5.15), is 1,2-dithiolane-3-carboxylic acid, known as tetranorlipoic or tetranorthiooctic acid. It was recently isolated from garlic (*Allium sativum*, Amaryllidaceae), together with sulfur substituted C_{18} fatty acids with thiophene, tetrahydrothiophene (**3-33**) and tetrahydrothiopyran rings. An example of these fatty acids is 8-(5-hexyltetrahydrothiophen-2-yl)octanoic acid (**3-34**, R = H). A derivative of this fatty acid, with the tetrahydrothiophene ring substituted with a methyl group in the β-position (**3-34**, R = CH_3), and other two position isomers (the corresponding C_{18} hexanoic and heptanoic acids) were found as minor sulfur-bearing components of unprocessed canola oil.

Chlorine-containing fatty acids arise as contaminants in reactions of unsaturated fatty acids with chlorine or chlorine dioxide (see Section 11.4.2.2.2).

3.3.4 Properties of fatty acids

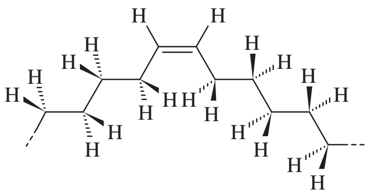
Fatty acids are colourless liquids or solids. Lower saturated fatty acids are liquid, while caprinic (capric) acid and higher fatty acids are solid at room temperature. Their melting points depend on the number of carbon atoms, but when this number is higher than 20, the melting point does not change significantly (Table 3.19).

Fatty acids with an odd number of carbon atoms have a slightly lower melting point than fatty acids with an even number with one less carbon atom. Unsaturated fatty acids with a double bond in the middle of the chain have significantly lower melting points than saturated fatty acids. Considerable influence on the melting point (the conformation of the molecule) comes from the *cis*-double

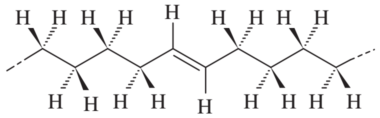
Table 3.19 Melting points of important fatty acids.

Fatty acid	Melting point (°C)	Fatty acid	Melting point (°C)
Saturated		***Unsaturated***	
Butyric	−7.9	Petroselic	33.0
Caproic	−3.4	Oleic	16.0
Caprylic	16.7	Elaidic	45.0
Caprinic	31.6	Asclepic	15.0
Lauric	44.2	Vaccenic	43.8
Myristic	54.1	Linoleic	−5.0
Palmitic	62.7	Linolelaidic	28.5
Stearic	69.6	Linolenic	−10.6
Arachidic	75.4	Erucic	33.5
Behenic	79.9	Brassidic	61.5
Lignoceric	84.2	Arachidonic	−49.5

bond, which causes bending of the straight chain by about 42°; therefore, *cis*-derivatives (**3-37**) have melting points a few tens of degrees lower than the corresponding *trans*-derivatives (**3-38**). The shift of the double bond toward the carboxyl in *cis*-monoenoic acids leads to an increase in the melting point. A higher number of double bonds in the all-*cis* configuration results in lowering of melting points (Table 3.19).

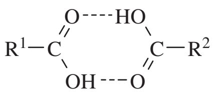


3-37, chain conformation of *cis*-monoenoic acid



3-38, chain conformation of *trans*-monoenoic acid

The majority of common unsaturated fatty acids are viscous thixotropic liquids (see Section 7.8.3.2.2). Thixotropy is the property of certain gels or fluids that are thick (viscous) under normal conditions, but flow (less viscous) over time when agitated or otherwise stressed. As with liquid saturated fatty acids, they are associated by hydrogen bonds of the carboxyl groups and form dimers (**3-39**).



3-39, association of fatty acids by carboxyl groups

Melting point also depends on the crystalline modification of the fatty acid.[10] On cooling, fatty acids pass from the liquid phase first to a solid unstable phase, which is gradually transformed into more stable modifications. Modifications are labelled A, B and C in acids with an even number of carbon atoms, and A′, B′ and C′ in acids with an odd number of carbons in the molecule (Figure 3.2).

Forms A and A′ are triclinic crystals (one of the seven crystal systems described by three basis vectors), other forms are orthorhombic crystals. Fatty acids can generally be present in any form (considering the conditions of crystallisation). Saturated fatty acids usually form the stable modification rather quickly; unsaturated fatty acids are converted more slowly (because e.g. oleic acid has two modifications melting at different temperatures, 14 and 16 °C). The crystals of fatty acids form layers, in which carboxyl groups are oriented to one side and the methyl groups of the chain end to the other side. The chains are parallel to each other (Figure 3.3). This arrangement of fatty acid molecules leads to soft crystals. Single crystal modifications differ by the slope of fatty acids to the plains of individual layers. Even above the melting point, the fatty acids preserve the partially oriented structure, which causes the already mentioned thixotropy of these compounds.

Lower fatty acids are volatile at atmospheric pressure, while higher fatty acids are non-volatile. Their boiling point increases with the increasing number of carbon atoms, but double bonds have little influence. Fatty acids with short carbon chains are miscible with water, while others are basically soluble in water, but solubility decreases rapidly with an increasing number of carbon atoms in the molecule (Table 3.20) and a two-phase system is created. It is also necessary to consider the water solubility in fatty acids, which also rapidly decreases with an increasing number of carbon atoms. Higher fatty acids dissolve in water only slightly, but can form monomolecular films (a closely packed layer of molecules) in which fatty acid molecules are oriented towards each other, with carboxyl groups to the aqueous phase and the methyl groups to the gaseous phase. When reducing the surface area, the monomolecular films collapse, creating a multimolecular layer (see Section 7.6.2.3).

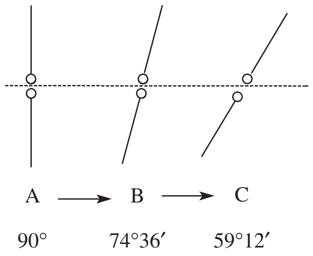


Figure 3.2 Slope of saturated fatty acid chain in different crystal modifications: —— = hydrocarbon chain, o = carboxyl, ------ = crystal plane.

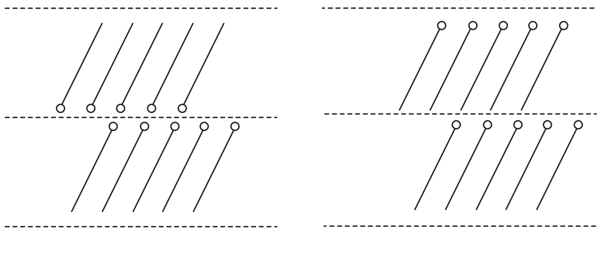

Figure 3.3 Simplified packing patterns of fatty acids in crystals (solid phase).

[10]Solid substances with the same chemical composition and different crystal structure are called polymorphic forms or modifications. Each polymorphic form has characteristic properties (such as specific volume and melting point). The formation of a given polymorphic form depends on many factors (such as temperature, cooling rate of the liquid phase and type of solvent). In the solid crystal state, one polymorphic form is transformed into the other polymorphic forms without previous melting of the crystals. If one of the forms and another form is stable, these two polymorphic forms are called monotropic. The transformation occurs only in one direction, the stable form arises from the metastabile form. All natural fats are monotropic.

Table 3.20 Solubility of some fatty acids at 20 °C.

Fatty acid	Solubility (g/l)		Fatty acid	Solubility (g/l)	
	Water	Ethanol (95%)		Water	Ethanol (95%)
Butyric	Miscible	Miscible	Lauric	0.055	912
Caproic	9.70	Miscible	Palmitic	0.0072	49.3
Caprylic	0.68	Miscible	Stearic	0.0029	11.3

Fatty acids are a group of weak acids. In solutions, they are found almost exclusively in non-dissociated form. Formic and acetic acids are much stronger acids than higher homologues of this series.

3.4 Homolipids

Homolipids, which consist of fatty acids linked to various alcohols, are now categorised exclusively by the structure of the bound alcohol. The most common alcohol in natural lipids is glycerol. Rarely occurring alcohols are glycols, higher monohydric aliphatic alcohols, aliphatic and alicyclic terpenoid hydroxy compounds, such as xanthophylls (see Section 9.9.1.2), and various steroid compounds (see Section 3.7.4).

3.4.1 Esters of monohydric alcohols

Esters of fatty acids with monohydric alcohols are known by the trivial name of a **wax**. The most important natural compounds are fatty acids esters with various:

- aliphatic alcohols, which were previously called **cerides**
- alicyclic alcohols, formerly known as **sterides**.

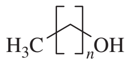
The term wax, however, is used for pure compounds and also for a variety of natural products of animal and vegetable origin, components of which are fatty acid esters with monohydric alcohols, but also other lipophilic compounds, such as higher hydrocarbons, free alcohols, ketones and fatty acid. These compounds, with the exception of fatty acids, are classified as lipid accompanying substances (see Section 3.7). Esters of fatty acids with monohydric alcohols may even be minority constituents in these natural mixtures. It may therefore be more appropriate to use the term wax just for natural products rather than for pure compounds that are often called **wax esters**.

The waxy material on the surface of the above-ground parts of plants, such as the skins of fruit and leaves of vegetables, seeds and pollen grains, is called surface or **epicuticular wax**. The next hydrophobic layer of the cuticle is **cutin**, which is a polymeric material built from hydroxy fatty acids. Wax and cutin together constitute the **epicuticular lipids**. In most plants, wax is not associated with cutin at all. On the surface of the underground parts of plants, wax does not occur. Polymeric lipid material on the surface of the underground parts of plants and on any injured tissues is called **suberin**. However, cutin and suberin are not classified as lipids.[11]

3.4.1.1 Structure and nomenclature

Esterified fatty acids bound in waxes are usually saturated acids with a higher number of carbon atoms (fatty acids with long and ultra long chains having 20–34 carbon atoms). Fatty acids with hydroxyl group often occur, for example, in position C-4. These then easily form δ-lactones, which are then always present in industrial waxes in small amounts.

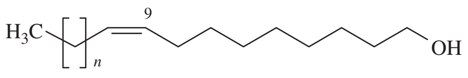
Policosanol is the common name for a mixture of high molecular weight (12–36 carbon atoms) saturated aliphatic primary alcohols, which are constituents of plant epicuticular waxes, such as the common alcohols cetyl alcohol (C_{16}), ceryl alcohol (C_{26}) and myricyl alcohol (C_{30}) (**3-40**). The cuticular wax of wheat, for example, contains lignoceryl alcohol (C_{24}), ceryl alcohol (C_{26})



3-40, lauryl alcohol, n = 11
myristyl alcohol, n = 13
cetyl alcohol, n =15
stearyl alcohol, n = 17
arachinyl alcohol, n = 19
docosyl alcohol, n = 21
lignoceryl (carnaubyl) alcohol, n = 23
ceryl alcohol, n = 25
tetraenanthyl alcohol, n = 27
myricyl (melissyl) alcohol, n = 29
lacceryl alcohol, n = 31
tritriacontan-1-ol, n = 33

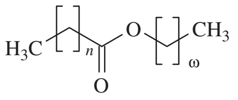
[11]The building units of cutin are called cutin acids, which include mono-, di- and trihydroxycarboxylic fatty acids and also higher dicarboxylic, dihydroxydicarboxylic and also other acids. The characteristic monomers are 18-hydroxyoctadeca-9,12-dienoic, 10,16-dihydroxyhexadecanoic and *threo*-9,10,18-trihydroxyoctadecanoic acids.
Suberin has a qualitatively similar composition, but the amounts of the individual compounds differs. The prevailing acids are C_{16}–C_{22} dicarboxylic acids (such as octadec-9-ene-1,18-dioic acid), C_{20}–C_{26} fatty acids and alcohols, which constitute about one third of the suberin weight. The remainder is composed of phenolic compounds.

and myricyl alcohol (C_{28}) as the major polycosanol components. Myristoleyl alcohol and oleyl alcohol are derived from unsaturated fatty acids (**3-41**). Less frequently, secondary aliphatic alcohols can be found.



3-41, myristoleyl alcohol, *n* = 5
oleyl alcohol, *n* = 7

Alcohols are usually esterified with fatty acids of similar structure. The characteristic structure is expressed by formula **3-42**. The compound name is formed by the radical names of the alcohol and the bound acid. For example, ceryl cerotate is the ester of cerotic acid with ceryl alcohol. The main wax ester on the surface of sunflower seeds is ceryl cerotate. The main surface wax esters of apples and cabbage leaves are ceryl palmitate and ceryl stearate. The constituents of the epicuticular wax of apple fruits are also C_{16}–C_{26} fatty acid esters of (*E*)- and (*Z*)-*p*-coumaryl alcohol. The fatty acid esterification occurs at the γ-hydroxyl group rather than at the 4-hydroxyl on the phenyl ring.



3-42, general structure of aliphatic waxes
cetyl palmitate, *n* = 14, ω =15
ceryl cerotate, *n* = 24, ω = 25
lacceryl laccerate, *n* = 30, ω = 31

Fatty acids can also be bound to various secondary aliphatic alcohols, such as nonacosane-15-ol, to carotenoids containing hydroxyl groups (known trivially as xanthophylls, see Section 9.9.1.2), as well as to flavonoids and some terpenoids (steroids) (see Section 3.7.4). Other wax constituents, in particular the epicuticular wax components, include alkanes, aldehydes, ketones and free fatty acids.

3.4.1.2 Biochemistry, physiology and nutrition

The main significance of waxes is that they form a hydrophobic layer on the surface of organisms. In animals these occur in the skin, hair, fur or feathers, while in plants they are found in the surface layers of leaves, fruits and other aerial (above ground) parts. They act mainly to control transpiration, preventing water loss by evaporation, and protecting the organisms against environmental influences, insects and parasites.

Waxes are synthesised by reduction of fatty acids to primary alcohols via aldehydes. Primary alcohols react with acyl-CoAs to form esters, aldehydes eliminate carbon monoxide (by decarbonylation) giving rise to hydrocarbons (alkanes). Oxidation of alkanes yields secondary alcohols, and oxidation of secondary alcohols gives rise to ketones.

Waxes do not decompose easily in the body, but when they do, the mechanism is similar to that of fatty acids in fats and oils with similar chain lengths. In human nutrition, waxes have virtually no significance.

3.4.1.3 Occurrence

Waxes are widely distributed in nature in both the animal and plant kingdoms, but are usually only seen in foods at low levels.

3.4.1.3.1 Animal waxes

The wax found in the cranial cavity of the marine mammal the sperm whale (*Physeter macrocephalus*, syn. *P. catodon*) and two related species (pygmy sperm whale and dwarf sperm whale) from the sperm whale superfamily has industrial importance. The milky-white waxy substance, or spermaceti, is composed mainly of cetyl palmitate (**3-42**). The proportion of spermaceti with a lower melting point, containing predominantly unsaturated fatty alcohols, is called sperm oil.

Another animal wax is beeswax, which is used by honey bees to build honeycomb cells in which their larvae are raised and honey and pollen are stored. Its major component is ceryl cerotate (**3-42**), but a diverse mix of its homologues is also present. The basic composition of animal waxes is shown in Table. 3.21.

The industrially important animal waxes include the wax on the surface of wool, which is obtained as a by-product of wool scouring, and after bleaching and purifiying this wax is termed lanolin. The alcohol components are mainly triterpenic (alicyclic) alcohols, such as lanosterol (see **3-92**), cholesterol (see **3-114**) and related steroids. Lanolin is used in the manufacture of cosmetics and pharmaceuticals.

3.4.1.3.2 Plant waxes

An example of the composition of cuticular waxes is the cuticular wax of thale cress (also known as mouse-ear cress or Arabidopsis

Table 3.21 Main wax acids and alcohols.

Wax	Fatty acid	Fatty alcohol
Animal		
Beewax	Palmitic, cerotic	Ceryl alcohol
Spermaceti	Palmitic	Cetyl alcohol
Sperm oil	Lauric, myristic	Oleyl alcohol, myristoleyl alcohol
Plant		
Chinese	Cerotic, montanic	Ceryl alcohol
Carnauba (Brasil, palm)	Cerotic	Ceryl alcohol, myricyl alcohol
Jojoba	Eicosenoic, docosenoic	Eicosanol, docosanol
Shellack	Cerotic, lacceric	Ceryl alcohol, lacceryl alcohol

(*Arabidopsis thaliana*, Brassicaceae), which is a plant used as a model organism in molecular biology and genetics. The major components of this wax are alkanes (38%), followed in quantity by ketones (30%), primary alcohols (12%), secondary alcohols (10%), aldehydes (6%), free fatty acids (3%) and their esters (1%). The main alkane is nonacosane (C_{29}), the main ketone is ditetradecylketone (C_{29}), myricyl alcohol (melissyl alcohol, C_{29}) and ceryl alcohol (C_{26}) are the main primary alcohols, the main secondary alcohols are C_{29}, C_{31} and C_{27} compounds, and the major fatty acids are mellisic acid (C_{30}) and montanic acid (C_{28}). The epicuticular wax of wheat and related species contains alkanes (5–10%), esters (10–30%), aldehydes ($\leq$5%), alcohols (15–55%) and acids ($\leq$5%).

The plant waxes that are of industrial importance include a hard, white wax known as Chinese wax, which is secreted by Indian Wax Scale insects (*Ceroplastes ceriferus*, syn. *Coccus ceriferus*) on injury of Chinese ash (*Fraxinus chinensis*, Oleaceae) and laid on tree branches. Japan wax is actually not the true wax, but a pale-yellow fat obtained from the fruits of the sumac wax tree (*Rhus succedanea*, Anacardiaceae) that grows in China and Japan. The seeds of jojoba shrubs (*Simmondsia californica*, Buxaceae), native to the desert of Sonora and adjacent areas of the United States and Mexico, contain a liquid wax (with melting point of 7 °C), which is called jojoba oil (wax). Candelilla wax is a yellowish-brown, hard wax located on the leaves and shoots of the small Candelilla shrub (*Euphorbia antisyphilitica*, Euphorbiaceae) growing in northern Mexico and the southwestern United States. Carnauba wax (also known as Brazil wax or palm wax) is a hard yellow–brown wax secreted on the surface of leaves of *Copernicia cerifera* (Arecaceae) palms from tropical South America. Palm wax similar to the previous one is also obtained from Andean palm *Ceroxylon andicola* and related palm species. Myrica wax comes from the California Wax Myrtle growing in North America (*Myrica cerifera*, Myricaceae). It is used to manufacture candles and perfumes. Similar waxes are produced by other species of the genus *Myrica*. Shellac is a product obtained after removal of dyes from lacks, resinous materials arising from various fig trees (*Ficus* spp., Moraceae), flowering plants of the genus *Butea* (Fabaceae) and other plants after injury caused by the Lac insect (*Coccus lacca*). An overview of fatty acids and alcohols bound in important plant waxes is shown in Table 3.21.

Esters of fatty acids with monohydric alcohols can also be produced by industry or in the laboratory. In this case, however, esters with lower alcohols, namely methanol, ethanol, propan-2-ol or butan-1-ol are produced. Esters of fatty acids with methanol are components of so-called biodiesel; esters of fatty acids with ethanol and fusel oil alcohols are common components of alcoholic beverages.

3.4.1.3.3 Mineral waxes

Some waxes are of mineral origin. They come from the breakdown products of natural plant waxes. These include montan wax (also known as lignite wax) and the refined product ozokerite. Their alcoholic component and bound fatty acids have longer hydrocarbon chains than plant waxes.

3.4.1.4 Properties

Waxes are usually hard materials with melting points between 60 and 110 °C. They are insoluble in water and poorly soluble in organic solvents. Some waxes are liquid and also hydrophobic, but they dissolve well in organic solvents, can leave greasy stains and easily forming emulsions. Esters of lower alcohols produced by industry also have some of the properties of liquid waxes, but due to their lower molecular weights they have a lower viscosity and better solubility in alcohols.

3.4.1.5 Use

In the food industry, waxes are used as agents to repel water (hydrophobicity) on the surface of fruits and other food products, and to improve their appearance (fruits and some sweets). The waxes that are allowed for use in foods are legally limited to white and yellow beeswax, candelilla wax, carnauba wax and shellac.

Spermaceti was historically used primarily for the manufacture of cosmetic products such as ointments, cosmetic creams and pomades. Later it was used for the manufacture of fine wax candles, in textile finishing and as an industrial lubricant. Natural or bleached beeswax is used in the cosmetics and pharmaceutical industries, and a practical uses include the making of candles (today only for luxury and church candles), and various dressings and polishes. Lanolin is an important raw material in the cosmetics and pharmaceutical industries.

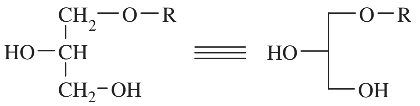
Chinese wax is used in perfumery and skin polishing. Japan wax is used for the manufacture of polishing creams for floors, footwear and furniture and for the manufacture of candles and matches and in the cosmetics industry. Jojoba oil is a liquid; it is therefore used for the production of fat emulsions and moisturisers in the cosmetics and pharmaceutical industries, as a carrier for speciality fragrances and as a lubricant for delicate mechanisms. It has also been considered as a low-energy replacement for edible fats. The wax prepared from the oil is used as a polishing wax, in the manufacture of carbon paper and linoleum. It also has a potential use as a biodiesel fuel.

Candelilla wax and carnauba wax are mainly used for the production of candles. Carnauba wax can produce a glossy finish and as such is used in automobile waxes, shoe polishes and waxing skin. Carnauba wax is also used for the preparation of polishing waxes, carbon paper and many other purposes. Palm wax is the raw material for the production of wax candles and matches. Myrica wax and related waxes have found application in the pharmaceutical and food industries. Shellac is used to make paints, varnishes, sealing waxes, adhesives and in insulating materials.

As waxes are a relatively expensive raw material, in the production of cosmetics and candles they have been replaced by mineral hydrocarbon fractions (paraffin), solid triglycerides (tristearin, also known as stearin) or by various synthetic materials (polyethylene and polypropylene). Mineral waxes are used almost exclusively for non-food purposes. The so-called montanic acid esters and oxidised polyethylene wax can also be used to modify the surfaces of fresh citrus fruits. Montanic acid esters are used pharmaceutically to improve the retardation of drug release from tablets.

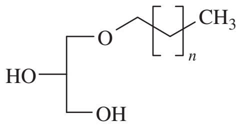
3.4.2 Glyceryl ethers

Monoalk(en)ylethers of glycerol or 1-*O*-alky(en)yl-*sn*-glycerols or 1-alkoxy-*sn*-glycerols (**3-43**) are compounds that have bound fatty alcohol in the *sn*-1 position of the glycerol. They are related to plasmalogenes (see Section 3.5.1.1.2), which are glycerylethers of phospholipids and classified as heterolipids.



3-43, glyceryl ether (glyceryl 1-*O*-alkylether)

The main monoalkylethers of glycerol are 1-*O*-hexadecyl-*sn*-glycerol (chimyl alcohol, **3-44**), 1-*O*-octadecyl-*sn*-glycerol (batyl alcohol, **3-44**) and (*Z*)-1-*O*-octadec-9-en-1-ylglycerol (selachyl alcohol, **3-45**). Trivial names are derived from the names of the animals from which the fats were first isolated. Glyceryl ethers are not hydrolysed by lipases. In nature, glyceryl ethers are mostly found as esters of higher fatty acids. For example, 2-*O*-arachidonoylglyceryl ether derived from arachidonic acid, trivial name noladin ether, occurs in the brain of pigs. The most common compounds are diesters of glyceryl ethers, 1-*O*-alk(en)yl-2,3-diacyl-*sn*-glycerols.



3-44, chimyl alcohol, $n = 14$
batyl alcohol, $n = 16$

Glyceryl ethers are present in animal and plant lipids in amounts that normally do not exceed 1%. They are found at higher levels in microbial lipids and lipids of some marine animals (cartilaginous fish, starfish, urchins and clams), especially in lipids of cartilaginous fishes of the class *Chondrychthyes*, subclass Elasmobranchii, which includes sharks (Selachii) and rays (Batoidea). Shark liver oils commonly contain about 53% triacylglycerols, 45% diesterified glyceryl ethers, 1.5% cholesteryl esters and 0.5% squalene. In the liver oils of some species of these animals, depending on the season, glyceryl ethers can constitute about 10% (in spiny dogfish, *Squalus acanthias*), but also up to 50–80% of the unsaponifiable fraction (in squaliform sharks of the genus *Centrophorus* and in kitefin sharks of the genus *Scymnorhinus*).

3.4.3 Glyceryl esters

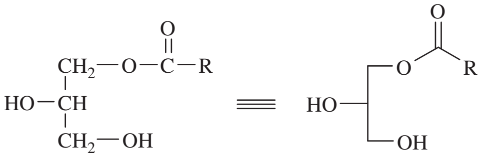
Glyceryl esters are the most important food lipids. They are generally known by the names of their physical state as **fats** or **oils**, even if the name fats should be only be used for natural products containing triacylglycerols that are usually solid at ambient temperature, rather than for individual compounds. If fats are liquid at ambient temperature, they are called oils. In the past vegetable oils were categorised according to the behaviour of a thin film of the oil when exposed to the air. The categories that could be distinguished were:

- **non-drying oils** (such as olive, peanut, coconut, palm, palm kernel and castor oils) that do not harden when exposed to air
- **semi-drying oils** (soybean, sunflower, poppyseed, sesame and cottonseed oils)
- **drying oils** (linseed, safflower and perlila oils; see Section 8.2.1.1.1) that harden after exposure to air.

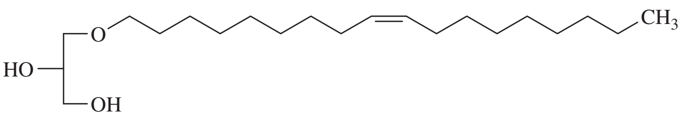
However, these groups do not have precise boundaries. Today, the division of triacylglycerols into fats and oils has only historical significance, and the term 'fat' commonly refers to the entire group, regardless of consistency.

3.4.3.1 Structure and nomenclature

The glycerol molecule can be bound to one, two or three fatty acids. The resulting monoesters are then either 1-**monoacylglycerols** (**3-46**) or 2-monoacylglycerols (**3-47**). These esters were formerly called monoglycerides and this name is often still used, especially among experts from industry. The ratio of both isomers in natural materials depends on the stereospecifity of lipase synthesising monoacylglycerols, and the major compounds in food lipids are the more stable 1-monoacylglycerols (Table 3.22). Two fatty acids bound on the glycerol molecule yield 1,2-**diacylglycerols** (**3-48**) or 1,3-diacylglycerols (**3-49**), which predominate in natural fats. Diacylglycerols were previously called diglycerides. Monoacylglycerols and diacylglycerols are collectively referred to as **partial esters of glycerol**. In nature, the most frequently occurring glyceryl esters contain three fatty acids bound to the glycerol molecule. They are known as **triacylglycerols** (formerly known as triglycerides). Nearly all commercially important fats and oils of animal and plant origin consist almost exclusively of triacylglycerols (Table 3.22).



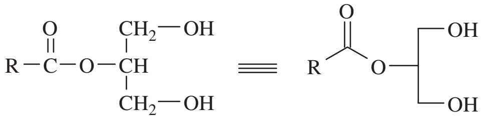
3-46, 1-monoacylglycerol



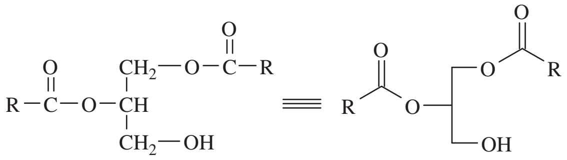
3-45, selachyl alcohol

Table 3.22 Composition of glycerol esters in refined edible oils.

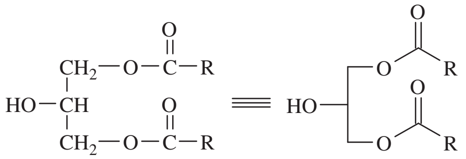
Type of ester	Content (%)	
	Rapeseed oil	Sunflower oil
1-Monoacylglycerols	0.6	0.2
2-Monoacylglycerols	0.1	0.05
1,3-Diacylglycerols	1.9	0.9
1,2-Diacylglycerols	0.2	0.1
Triacylglycerols	96.5	97.8



3-47, 2-monoacylglycerol

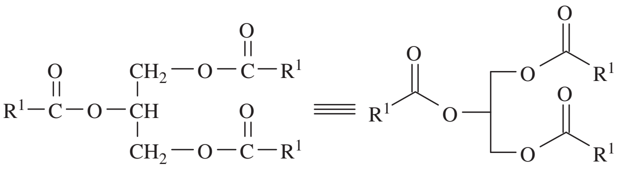


3-48, 1,2-diacylglycerol

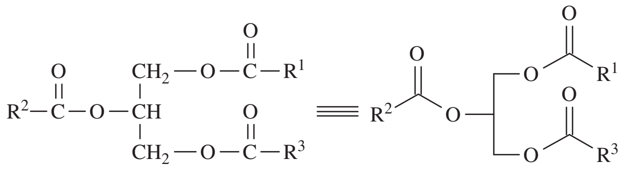


3-49, 1,3-diacylglycerol

All three fatty acids bound in triacylglycerols can be the same, and in this case we may speak about **simple triacylglycerols** (**3-50**). For example, the triacylglycerol with three identical acyls, derived from palmitic acid, is 1,2,3-tripalmitoylglycerol or simply tripalmitoylglycerol, or tripalmitin to give it its trivial name. Three acyl residues derived from oleic acid are found in triolein and three stearic acid residues are found in tristearin. Alternatively, the two or three fatty acids bound in triacylglycerols can be different, and in this case we speak about **mixed triacylglycerols** (**3-51**).

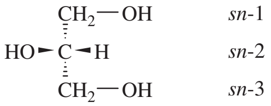


3-50, simple triacylglycerol



3-51, mixed triacylglycerol

For example, 1-palmitoyl-2-stearoyl-3-oleoylglycerol (formerly also known as 1-palmito-2-stearo-3-oleine) is different from 1-palmitoyl-2-oleoyl-3-stearoylglycerol and other positional isomers. These positional isomers lead to great diversity in the composition of natural fats and oils. When the two primary hydroxyl groups (in positions C-1 and C-3) of glycerol are esterified with different fatty acids, the resulting triacylglycerol is asymmetric and optically active and the diversity of composition of natural fats and oils thus increases. Natural fats contain optically active triacylglycerols because they are formed by esterification through the catalytic action of hydrolases that are stereospecific. Since the bound fatty acids have very similar properties, these stereoisomers do not differ significantly in their optical rotations. Nevertheless, an exact definition of the composition of fats should also mention their steric structure. To express the exact composition and stereo configuration of triacylglycerols, the so-called stereo specific numbering system (*sn*-system) is used, as recommended by a IUPAC-IUB commission, which defines the numbering of atoms in prochiral glycerol ('L-glycerol' derivatives) as that shown in formula **3-52**. The conventional D/L or *R*/*S* systems are not used. The secondary hydroxyl group is shown to the left of C-2 and the carbon atom above this then becomes C-1, while that below becomes C-3 and the prefix *sn* is placed before the stem name of the compound. The term triacyl-*sn*-glycerol should then be used instead of triacylglycerol.



3-52, *sn* numbering of glycerol in Fischer projection

Three different fatty acids can occur from 27 different mixed triglycerides. To simplify the description, one- or two-letter abbreviations of fatty acids are used, such as B = butanoic (butyric), D = decanoic (capric or caprinic), H = hexanoic (caproic), L = linoleic, La = lauric, Ln = linolenic, M = myristic, O = oleic, Oc = octanoic (caprylic), P = palmitic, Po = palmitoleic, S = saturated, St = stearic, U = unsaturated and V = vaccenic. For example, the mixed triacylglycerol esterified with palmitic acid in position *sn*-1, with stearic acid in the position *sn*-2 and oleic acid in the position *sn*-3 of glycerol is then called 1-palmitoyl-2-stearoyl-3-oleoyl-*sn*-glycerol (abbreviated to *sn*-PStO). Racemate is a mixture of *sn*-PStO and and *sn*-OStP in a molar ratio of 1 : 1

(or rac-PStO), where the fatty acids in positions *sn*-1 and *sn*-3 are reversed. Triacylglycerol PStO can generally be a mixture of up to six optically active substances.

3.4.3.2 Biochemistry and physiology

3.4.3.2.1 Biosynthesis

Synthesis (lipogenesis) of triacylglycerols occurs primarily in the cytoplasm of the liver, adipose tissue, central nervous system and the lactating mammary gland. The fatty acids are derived from the hydrolysis of fats, as well as from the synthesis of acetyl CoA through the oxidation of fats, glucose and some amino acids. In animals, the liver and intestines are the most active, although most of the body stores of triacylglycerols are in adipocytes, the fat-storing cells of adipose tissue. Two main biosynthetic pathways are known. The most important route is the *sn*-glycerol 3-phosphate pathway (also known as the Kennedy pathway), which predominates in the liver, adipose tissue and skeletal muscle, and the 3-monoacyl-*sn*-glycerol pathway in the intestines. More than 90% of liver triacylglycerols are produced by the *sn*-glycerol 3-phosphate pathway. After a meal, up to 75% of the triacylglycerols are formed in the enterocytes of the intestines, via the 3-monoacyl-*sn*-glycerol pathway. In some animal tissues, a third, less well known biosynthetic pathway has been recognised. In this pathway, triacylglycerols are synthesised by transacylation between two racemic diacylglycerols.

The building block for the biosynthesis of glycerol is the glycolytic product (*R*)-phosphoglyceric acid.[12] In the first step, it is hydrolysed to (*R*)-glyceric acid by glycerate kinase, glyceric acid is oxidised by specific aldehyde dehydrogenase to (*R*)-glyceraldehyde (D-glyceraldehyde) and the reduction is then catalysed by glycerol dehydrogenase to yield glycerol. Glycerol is activated by phosphorylation with glycerol kinase to prochiral *sn*-glycerol 3-phosphate, which is esterified by fatty acid residues in acyl-CoA with catalysis by glycerol 3-phosphate *O*-acyltransferase. The first reaction product is 1-acylglycerol 3-phosphate (3-*sn*-lysophosphatidic) acid, which is esterified to 2-diacylglycerol 3-phosphate (3-*sn*-phosphatidic acid) by 1-acylglycerol 3-phosphate *O*-acyltransferase. Hydrolysis of the phosphate by phosphatidate phosphatase yields 1,2-diacylglycerol. The last esterification of 1,2-diacylglycerol to triacylglycerol is catalysed by diacylglycerol *O*-acyltransferase. Phosphatidic acid also serves as a precursor of glycerophospholipids.

3.4.3.2.2 Fat digestion, absorption, transport and mobilisation

The human fat-digestive enzymes include triacylglycerol lipases and phospholipases. The triacylglycerol digestive enzymes comprise the pre-duodenal lingual, gastric and extra-duodenal pancreatic lipase. Although a small amount of lipase is secreted by the Ebner's glands on the tongue and by the stomach, these digestive actions are not significant in children and adults as almost no real breakdown of fat occurs. However, the stomach is a part of the process of fat digestion because of its churning action, which helps to create an emulsion. The fat enters the first section of the small intestine (duodenum) in the form of gastric chyme and stimulates the secretion of the peptide hormone cholecystokinin synthesised in the mucosal epithelium of the small intestine. The secretion of cholecystokinin causes the gall bladder to release bile acids that further emulsify the fat and release of the colipase-dependent pancreatic lipase by the pancreas, which is activated in the intestinal lumen by trypsin. The hydrolysis by pancreatic lipase results in almost complete hydrolysis of triacylglycerols in the intestinal lumen. Most of the bile acids are returned to the liver for re-use. In newborns, the pancreatic secretion of lipase is low. The digestion of fat is mainly augmented by the lipases secreted from the glands of the tongue (lingual lipase) and by the lipase occurring in human milk.

Lipases catalyse the hydrolysis of dietary triacylglycerols primarily to fatty acids (their sodium or potassium salts) and 2-monoacyl-*sn*-glycerol via 1,2-diacyl-*sn*-glycerol or 2,3-diacyl-*sn*-glycerol. The hydrolytic attack is regiospecific and occurs at the *sn*-1 or *sn*-3 positions, but not at the *sn*-2 position of triacylglycerols. To some extent, 2-monoacylglycerol is partly spontaneously racemised to 1-monoacylglycerols, which may be subsequently completely hydrolysed to fatty acid and glycerol.

Phospholipids are hydrolysed by pancreatic phospholipase A_1 (phosphatidylcholine 1-acylhydrolase) and phospholipase A_2 (phosphatidylcholine 2-acylhydrolase) present as a zymogen that requires activation by trypsin. The products of 1,2-diacyl-*sn*-glycero-3-phosphocholine breakdown are fatty acids and lysophospholipids, that is, 2-acyl-*sn*-glycero-3-phosphocholine and 1-acyl-*sn*-glycero-3-phosphocholine, respectively. Cholesterol esters are hydrolysed by pancreatic steryl ester acylhydrolase (cholesterol ester hydrolase) to give cholesterol and fatty acids.

The digestion products of triacylglycerols retain their association with bile acids and lipase and combine with other lipids to form small aggregates called micelles that are suspended within the ingesta. The micelles bump into the brush border of the enterocytes (columnar epithelial absorptive cells of the intestinal wall) into which the digestion products pass by diffusion.

Glycerol is transported to the liver or kidneys and is either converted into glucose via glycerol 3-phosphate (gluconeogenesis) or used to help the breakdown of glucose into energy (glycolysis). Fatty acids with a chain length of less than 14 carbon atoms are absorbed directly into the blood via intestine capillaries as complexes with albumin, enter into the portal vein (which can also act as an absorptive route for dietary long chain fatty acids) and are transported to the liver. Monoacylglycerols and fatty acids with 14 or more carbons are not released directly into the intestinal capillaries and need to be reesterified to triacylglycerols. The re-esterification proceeds by the 3-monoacyl-*sn*-glycerol pathway that produces more than 75% of postprandial triacylglycerols. In addition to the 3-monoacyl-*sn*-glycerol pathway, the intestine can also synthesise triacylglycerols via the glycerol 3-phosphate pathway,

[12] To a lesser extent, 1,3-dihydroxyacetone phosphate (formed as a product of glycolysis and photosynthesis in plants) is employed for the biosynthesis of glycerol. In the depot tissue (in adipocytes), 1,3-dihydroxyacetone phosphate is the only precursor of triacylglycerols. It can either be reduced to glycerol 3-phosphate by glycerol 3-phosphate dehydrogenase or first acylated to 1-acylglycerol, which is reduced by acylglyceronphosphate reductase to 3-*sn*-lysophosphatidic acid.

which is the dominant triacylglycerol synthetic pathway in other tissues, such as adipose and liver. Beginning in the endoplasmic reticulum, the main site of lipid synthesis, and continuing in the Golgi apparatus (an organelle that is a part of the cellular endomembrane system), triacylglycerols are assembled, along with other compounds, into a lipoprotein particle called chylomicron, which consists of triacylglycerols (85%), phospholipids (6–12%), cholesterol and cholesteryl esters (1–3%) and proteins (apolipoproteins, 1–2%). Chylomicron is transported into the villi, the finger-like projections that cover the walls of the small intestine, and enters the circulation via the lymphatic capillary known as the lacteal, which finally merges into the thoracic duct. The thoracic duct empties the chylomicrons into the bloodstream via the left subclavian vein for transport to tissues where triacylglycerols are stored or metabolised for energy.

In the target tissues, the chylomicron triacylglycerols are hydrolysed by lipoprotein lipase, located on the interior walls of the capillary blood vessels, to fatty acids and 2-monoacylglycerols. Most fatty acids and 2-monoacylglycerols are absorbed by the cells (adipose cells or muscle fibres) and employed for triacylglycerol re-synthesis. A significant proportion of digested fat is typically stored as body fat in the adipocytes found mostly in the abdominal cavity and subcutaneous tissue. Within all cell types, triacylglycerols are stored as cytoplasmic lipid droplets called adiposomes, organelles enclosed by a monolayer of phospholipids and hydrophobic proteins, such as the perilipins in adipose tissue. The remnants of the chylomicron are transported to the liver, hydrolysed and the products absorbed. Fat soluble vitamins (vitamins A, D, E and K) and cholesterol are also delivered to the liver as part of the chylomicron remnants.

Animals also accept fats in the diet in very small amounts through the mechanism of pinocytosis (the process of taking fluid, together with its contents, into the cell by forming narrow channels through its membrane that divide off into vesicles). The bulk of dietary lipids are triacylglycerols that must be enzymatically digested to yield fatty acids and monoacylglycerols.

Triacylglycerols represent a form of energy storage for most organisms (in animal adipose tissue and plant seeds), but also act as membrane components and as signalling molecules. The fat reserves in humans are usually 10–30 kg, which would be sufficient to cover the energy needs for several months. The energy content of lipids is about 38 kJ/g, which is roughly twice the energy content of carbohydrates or proteins of the same weight. During storage in the body they do not bind water, so that this stock of energy does not weigh too much.

If the body needs energy, it supplies triacylglycerols in the form of hydrophilic lipoproteins to the relevant cells, where triacylglycerols are hydrolysed and fatty acids are oxidised, mainly by a series of reactions termed β-oxidation, to produce energy and building blocks for growth. The use of fatty acids for energy production and re-synthesis of triacylglycerols is predominantly performed in the liver. The major source of lipids entering the liver does so in free fatty acid form released from adipose tissue and transported in the systemic blood plasma complexed with albumin. The fatty acids within the liver can be utilised for a variety of purposes, from oxidation (see Section 3.3.2.4) to the synthesis of structural lipids.

3.4.3.3 Nutrition

The human diet contains fats of animal and vegetable origin. Some fats are obvious (such as those added during cooking), but roughly the same amounts are hidden fats already present in the raw materials (mainly of animal origin). Triacylglycerols derived from the diet of the populations in industrialised countries deliver 30–40% of the energy requirements. In developed countries, this energy intake is usually excessive (more than 100% of the recommended amount). In Europe it would be prudent ('it is recommended') to reduce ('to lower') the contribution of fat to total energy intake below 30% to prevent the major public health problems associated with fat inadequate intake (such as the risk of developing high blood pressure, diabetes, cardiovascular diseases and certain forms of cancer). However, the proportion of fat must not fall below 20% of energy supplied, otherwise various disorders may occur, mainly due to an inadequate supply of lipophilic vitamins and essential fatty acids. The proportion of saturated fatty acids in the total energy intake from fat should be less than 10%, the proportion of *trans* fatty acids should be less than 2%, the proportion of polyunsaturated fatty acids of the *n*-6 series should be less than 4–8% and unsaturated fatty acids of the *n*-3 series should correspond to 2 g of linoleic acid and 200 mg of fatty acids with longer chains.

3.4.3.4 Occurrence and composition

3.4.3.4.1 Occurrence

The total content of lipids in common foods is given in Table 3.23. The dietary fats occur almost exclusively as triacylglycerols. However, they may contain 1–10% of the partial esters of glycerol, a smaller amount of phospholipids and about 1% of accompanying compounds. Humans mainly receive fats by eating plant tissues and animal reserve tissues in which they are stored. According to their origin, fats are divided into:

- plant fats
- animal fats
- other fats.

In plants, fats are mainly found in seeds, but also in the pericarp layers, the outside exocarp layer (peel), the middle layer (pith) and the inner endocarp layer. Fat is also present in the germs of seeds, in which starch is the main reserve substance (e.g. the germ of cereals). Fat composition is due mainly to the fatty acid content, but specific properties of lipases also play a role.

Animal fats are further divided into the fats of terrestrial animals (including milk and depot fats) and seafood (including the fat of marine mammals, such as whales, and fish oils). In animal products, it is mainly the subcutaneous adipose tissue that is consumed, but fat is also stored in the muscle and offal, and in the liver of some fish (such as cod).

Fats are also present in microorganisms, higher fungi, algae and other organisms, but these sources are of negligible significance in human nutrition.

Table 3.23 Lipids contents of some common foods.

Foods	Lipid content (%)		Foods	Lipid content (%)	
	Fresh weight	Dry weight		Fresh weight	Dry weight
Foods of animal origin			Bread (white)	0.8–1.1	1.3–1.7
Pork meat (lean)	18	51	Bakery products (white)	2–3	8–12
Pork meat (fatty)	41	75	Confectionary products	14–34	22–44
Beef meat	2–36	9–63	Chocolate	32–38	33–40
Calf meat	3–7	4–10	Fruits	0.2–0.7	1.0–2.8
Poultry (fowl)	1–35	5–50	Leafy vegetables	0.2–1.0	2.8–6.2
Poultry (waterfowl)	17–33	40–65	Root vegetables	0.3–0.4	1.3–1.8
Offal	2–15	8–45	Potatoes	0.2	0.8
Sausages	25–48	60–65	Walnuts	64	66
Fish	0.4–16	2–44	Almonds	54	57
Milk (full fat)	3.8	30	Soybeans	13–20	14–22
Milk (reduced fat)	1.8	12	Beans	1.6	1.8
Milk (condensed)	9.5	12	Pea	1.4	1.6
Milk (dry, full fat)	27	28	Margarine	80–82	98–99
Cream	34	87	Reduced fat content	62–71	98–99
Butter	81	99	Low fat content	41–61	98–99
Cheeses	12–28	20–68	Very low fat content	31–61	98–99
Egg yolk	33	66	Shortening	80–100	100
Egg white	0.02	0.15	Vegetable oil	100	100
Egg (whole, dried)	42	44	***Other foods***		
Foods of plant origin			Mayonnaise	80	95
Wheat flour (whole-grain)	2.5	2.8	Yeast	0,4	1.3
Wheat flour (white)	1.0–1.5	1.1–1.7	Mushrooms	0.4	3.3

In recent decades, the belief in the need to reduce fat intake in the diet has become widespread, which has also been reflected in the food products made available. Data on the fat content of meat in Table 3.23 relate to traditional products, but new breeds of pigs have very low fat content in muscle (only 2–3%). Also, new breeds of dairy cows have somewhat reduced fat content of milk (only 3.5–3.6%). Specially processed cheeses can have fat contents significantly lower than 20%. Palatability in such products is achieved by increasing their viscosity using soluble proteins or polysaccharides. The fat content in fish depends on their type and the time of year they are caught; for example, fatty fish include eel, carp and herring, while cod is an example of a lean fish. Emulsified fats often now have only 20–70% fat, margarine-type products and butter spreads tend to have only 30–40% or even lower amounts of fat. Reduced-fat mayonnaise and yoghurts are also available, along with many other reduced-fat products.

3.4.3.4.2 Composition

Previously, the belief was that fats were mixtures of simple triacylglycerols. However, it was then found that mixed triacylglycerols exist and that natural fats consist mainly of mixed triacylglycerols. It was also thought that fatty acids in the triacylglycerol molecules occurred randomly, but even this assumption was not correct. According to another theory, the composition of fatty acids depends on distribution of saturated (S) and unsaturated (U) fatty acids in triacylglycerols, therefore four possible types of triacylglycerols (G = glycerol) with random distributions of fatty acids are possible: SSS (GS3), SSU (GS2U), SUU (GSU2) and UUU (GU3). In triacylglycerols of a given type, saturated fatty acids (palmitic and stearic acids predominate) may substitute for each other. The same principle applies to unsaturated fatty acids (mainly oleic and linoleic acids). Because the experimental data did not correspond to this assumption, it was proposed that each fatty acid

tended to occur in as many molecules of triacylglycerols as possible. According to this theory, a fatty acid, which occurs in less than 33% of the total fatty acids, can be represented in each triacylglycerol molecule only once. If its ratio is between 33 and 67%, it can occur in the triacylglycerol molecule once or twice. Only if it is present in amounts higher than 67% can single triacylglycerols be formed in which this fatty acid occurs three times. From Figure 3.4, it is possible to deduct a percentage of each type of the triacylglycerols in which two fatty acids A and X occur in different ratios. Experimental data did support this theory for a long time, but it was necessary to revise this theory based on the assumption that the first compounds formed are specific 2-monoacylglycerols and then their positions C-1 and C-3 in the glycerol molecule are randomly occupied by the remaining fatty acids.

Today, these strict principles are not asserted because acyltransferases are not quite specific and deviations from this scheme occur often. There is a high variation in stereoisomers in oils and fats of different biological origin, typically with strong species specificity. Lard is unique among animal depot fats, because it has a strong predominance of palmitic acid in the *sn*-2 position (90–100%), most stearic acid is found in the *sn*-1 position, whereas position *sn*-3 is rich in oleic acid (Table 3.24). In beef tallow and other bovine adipose tissues, nearly 50% of the fatty acids in the *sn*-2 position are oleic acid and other acids, in decreasing order, are palmitic and stearic acids. Palmitic, stearic, and oleic acids are the major fatty acids in the *sn*-1 and *sn*-3 positions. In eggs, a high degree of asymmetry between positions *sn*-1 and *sn*-3 is found. Palmitic acid is mainly in the *sn*-1 position, whereas >60% of *sn*-2 fatty acids and *sn*-3 fatty acids is oleic acid. Linoleic acid predominates in the *sn*-2 position. Seed oils tend to have polyunsaturated fatty acids in the *sn*-2 position, but relatively little difference can be found between the positions *sn*-1 and *sn*-3, although less abundant fatty

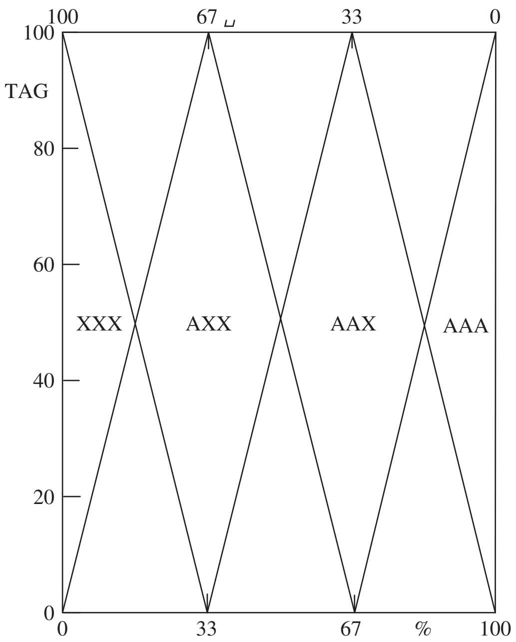


Figure 3.4 Distribution of fatty acids with acyls A and X in triacylglycerols of natural fats: TAG = % of triacylglycerols, % = % of fatty acid, XXX = TAG without acyl A, AXX = with one acyl A, AAX = with two acyls A, AAA = with three acyls A.

acids are often concentrated in the *sn*-3 position. Generally, saturated fatty acids (mainly palmitic acid) are in the *sn*-1 position and unsaturated fatty acids (mainly oleic acid) are in position *sn*-2. In triacylglycerols of marine mammals containing highly unsaturated fatty acids, such as DHA or EPA, prevail with combinations of two palmitic acids and DHA or EPA in the *sn*-1 position. In contrast,

P	U	U	2.9	6.4
S	U	U	8.3	8.9
3 Unsaturated fatty acids				
U	U	U	16.1	0.7

[a] P = saturated fatty acid C_{16} and lower, S = saturated fatty acid C_{18} and higher, U = unsaturated fatty acids.

binding of DHA or EPA is mainly at the *sn*-2 position in fish. The binding position tendency of DHA or EPA in triacylglycerol positional isomers consisting of two highly polyunsaturated fatty acids and one palmitic acid is the same as that for the combinations of one DHA (EPA) and two palmitic acids. The simplified composition of triacylglycerols of some other fats and oils is shown in Table 3.25.

The milk fat of mammals is very different from the fat depot, particularly in that it contains much higher amounts of triacylglycerols of fatty acids with shorter hydrocarbon chains and lower amounts of triacylglycerols of unsaturated fatty acids (Table 3.8). Characteristic triacylglycerols of milk fat have a number of carbons in fatty acids C_{44} (7.35%), C_{42} (7.62%), C_{34} (6.73%) and C_{32} (2.92% of total triacylglycerols), which can be used for detection of vegetable and animal fats in milk fat. Other triacylglycerols are: C_{54} (3.32%), C_{52} (7.76%), C_{50} (9.97%), C_{48} (9.09%), C_{46} (7.91%), C_{40} (9.70%), C_{38} (12.92%), C_{36} (12.12%), C_{30} (1.31%), C_{28} (0.66%), C_{26} (0.26%) and C_{24} (0,04). The last of these triacylglycerols can contain, for example, three bound caprylic acid or one butyric acid, one caprylic acid and one lauric acid, and so on.

The composition of triacylglycerols of plant seeds is usually very different from the composition of triacylglycerols in the pericarp, which is of practical importance for olive oil and palm oil. The difference is shown in Table 3.9. Also, the composition of the storage fat in animals differs (Table 3.10). Intermuscular fat of fish and chondrichthyans is fairly different from the liver oil (Table 3.12).

Table 3.25 Main groups of triacylglycerols in some fats and oils (in mol %).

Fat or oil	Type[a] SSS	SSU	SUU	UUU
Coconut[b]	82	18	0	0
Palm kernel[b]	61	38	1	0
Beef tallow	18	42	32	8
Pork lard	7	34	43	16
Cocoa butter	1	84	15	0
Palm	7	51	33	9
Maize germ	0	4	34	62
Cotton	<1	18	48	34
Peanut	0	9	44	47
Olive	0	5	35	60
Sunflower	0	3	26	71
Soybean	0	5	29	66
Linseed	0	5	43	52
Rapeseed 00	0	0	20	80

[a]S = Saturated fatty acid, U = unsaturated fatty acid.
[b]Fat contains mainly lauric and myristic acids.

Subcutaneous fat (the layer of adipose tissue) of mammals usually contains more triacylglycerols with unsaturated fatty acids than visceral fat (found around the viscera, especially the kidneys) that occurs in the abdominal cavity and is known as soft fat and leaf lard. However, these differences are not very significant.

3.4.3.5 Use

Most fats are used for nutritional purposes or as animal feed, either directly or after isolation from the food raw materials. Part of what is consumed, that added during cooking or frying, or that used as a spreadable fat is obvious fat, while part is concealed from the consumer, who is not directly aware that the food contains hidden fat. The ratio of both types of fats in human diet is approximately 1 : 1.

Oils and fats are also used for non-food purposes, such as the production of motor fuels, in oleochemistry and cosmetics. For these purposes, common edible oils and fats of lower quality are used. Some oils are obtained specifically for technological purposes, such as castor oil or tung oil. A typical example of the use of oils as fuel for diesel engines is the production of fatty acid methyl esters, especially from rapeseed oil. Oleochemicals from oils and fats manufacturing include fatty acids, fatty alcohols and other derivatives for the production of surfactants and subsequently detergents, paints, plastics, adhesives, building materials and many other products.

3.4.3.6 Procedures for obtaining fats and oils

The various methods for obtaining fats vary according to the raw material, and whether it is of animal or vegetable origin. Special procedures exist for bacterial fats that are designed for feed purposes. Owing to their high price, the use of bacterial fats is not very widespread. Metabolic engineering approaches are able to generate microbial strains with enhanced accumulation of triacylglycerols or free fatty acids that can be used as biodiesel precursors.

3.4.3.6.1 Procedures for vegetable fats and oils

On an industrial scale, the most commonly processed raw material is oil seeds. A summary of the important typical raw materials is given in Table 3.26. In terms of world oil production, the major oils are soybean, palm, rapeseed, sunflower, cotton, peanut, coconut, palm kernel, sesame and olive oils. A large number of other oils have only local significance, and a number of other oils are obtained solely for pharmaceutical, cosmetic and oleochemical purposes (linseed, castor and perilla oils in particular). Oils from the pericarp (pulp) of fruits, such as palm and olive oils, are obtained by specific procedures, unlike the oils from seeds.

The vegetable oils from seeds and beans are typically obtained by both physical extraction (mechanical expeller pressing) and chemical extraction, usually with hexane as a solvent (a petroleum-derived fraction without any aromatic hydrocarbons) and by a combination of both processes. If the seed oil content is lower than 25%, the oil is obtained by direct extraction. From seeds with higher

Table 3.26 Fat content in some raw materials.

Oil	Latin name of plant	Processed part of plant	Lipid content (%)
Coconut	*Cocos nucifera*	Seed (copra)	63–68
Palm	*Elaeis guineensis*	Pericarp	44–53
Palm kernel	*Elaeis guineensis*	Seed (kernel)	50–60
Olive	*Olea europea*	Pericarp	35–70
Olive kernel	*Olea europea*	Seed (kernel)	30–45
Almond	*Prunus amygdalus*	Seed	45–53
Hazelnut	*Corylus avellana*	Seed	50–65
Avocado	*Persea americana*	Seed	10–30
Sunflower	*Helianthus annuus*	Seed	22–36[a]
Peanut	*Arachis hypogaea*	Seed	45–55
Safflower (carthamus, kurdee)	*Carthamus tinctorius*	Seed	25–37
Sesame	*Sesamum indicum*	Seed	44–54
Cotton	*Gossypium hirsutum*	Seed (unpealed)	15–24[b]
Poppyseed	*Papaver somniferum*	Seed	36–50
Rapeseed (traditional)	*Brassica napus*[c]	Seed	38–45
Rapeseed (low erucic acid)	*Brassica napus*[d]	Seed	30–40
Mustard	*Leucosinapis alba*[e]	Seed	30–42
Soybean	*Soja max*	Seed	17–22
Linseed	*Linum usitatissimum*	Seed	35–45
Perilla	*Perilla frutescens*	Seed	42–51
Hempseed	*Cannabis sativa*	Seed	30–35
Maize	*Zea mays*	Germ	12–20
Wheat	*Triticum aestivum*	Germ	8–14
Rice	*Oryza sativa*	Bran	15–20

[a] Kernels contain up to 55% of oil.
[b] Kernels contain 30–38% of oil.
[c] Also known as turnip rape oil, colza oil, ravison oil, sarson oil: toria oil; produced from seeds of *Brassica napus*, *Brassica campestris*, *Brassica juncea* and *Brassica tournefortii* species.
[d] Also known as low erucic acid turnip rape oil, low erucic acid colza oil and canola oil; produced from low erucic acid oil-bearing seeds of varieties derived from the *Brassica napus*, *Brassica campestris* and *Brassica juncea* species.
[e] Derived from the seeds of white mustard (*Leucosinapis alba*, syn. *Sinapis alba* or *Brassica hirta*), brown and yellow mustard (*Brassica juncea*) and of black mustard (*Brassica nigra*).

oil content, most of the oil is obtained by pre-pressing thus reducing the fat content to 17–20% in the meal. Pre-treatment is necessary to produce leakage of the oil from the seeds, which consists of milling followed by exposure to water at elevated temperatures. This causes tissue disruption and then the subsequent disruption of cell walls and membranes. The remaining oil in the meal is usually obtained by extraction using a continuously operating extractor, which lowers the residual fat content in meal to 1.5–2%. The solution obtained by extraction contains 30–40% of the oil in hexane, the so-called **miscela**, from which the solvent is evaporated in an evaporator under reduced pressure, and any residual solvent is then removed by steam distillation under reduced pressure. The so-called crude oils (obtained by physical extraction and chemical extraction) have higher acid contents and their organoleptic characteristics render them unsuitable for consumption in the natural state. Thus these oils have to be refined.

The so-called **virgin oils**, suitable for direct consumption, are obtained by grinding the material and extracting the oil by mechanical means (pressing). The most important virgin oils are oils from olives, but other virgin oils are now also appearing on the market.

Virgin olive oil is the oil obtained from the fruit of the olive tree (*Olea europea*, Oleaceae) by mechanical or other physical means, under conditions (particularly thermal) which do not lead to alteration of the oil (see Section 3.4.3.7).

In addition to homolipids, crude vegetable oils contain heterolipids and other components of plant material. The heterolipids content depends on the technology used. The oil obtained through pressing contains 0.1%, while the extracted oil contains 1–2% and soybean oil contains 3–4% phospholipids. The heterolipids content of virgin oils is much lower, about 0.01%.

3.4.3.6.2 Procedures for animal fats

Animal fats are mostly obtained by the action of hot water, when the fat is washed from the tissue and then separated from the aqueous phase. Previously animal fats were obtained using hot steam and by direct heating (rendering), as is still practiced in the home. Rendered fats have a distinctive flavour due to the pyrolytic products of proteins contained in adipose tissue, while the unrendered fat obtained using hot water is virtually odourless and tasteless.

Milk fat is usually obtained from milk in the form of butter. The milk fraction rich in fat (cream) is separated from the aqueous phase poor in fat (skimmed milk) by centrifugation. The cream is an oil-in-water emulsion (in short o/w emulsion) from which the fat (butter) is mechanically separated by inversion to a water-in-oil emulsion (w/o), in which milk proteins act as emulsifiers. The residual liquid, which remains is buttermilk. Butter contains at least 80% fat, about a 2% non-fat portion (proteins, carbohydrates and other substances) and the rest is water. It generally has a pale yellow colour, which is dependent on the animals' feed. Some food colourings, most commonly annatto or β-carotene, are used in the commercial manufacturing process. Butter is most frequently made from cows' milk, but can also be manufactured from the milk of other mammals, including sheep, goats, buffalo and yaks. For specific applications, anhydrous milk fat can be obtained. In India, Pakistan and the Middle East anhydrous milk fat, known as ghee, is prepared by heating butter to evaporate the water and separate the precipitated proteins. Butter for particular applications can also be processed by fractional crystallisation.

3.4.3.7 Vegetable oil refining

Unlike animal fats, which are usually used without further treatment, vegetable oils obtained from seeds by mechanical expelling and solvent extraction have unpleasant organoleptic properties. Therefore, these oils are refined in order to be more acceptable to consumers. The refining process includes:

- **degumming** (hydration)
- **deacidification** (neutralisation)
- **bleaching**
- **deodorisation** or **physical refining**.

The crude oil is first centrifuged or filtered to remove solid particles (impurities, seeds or parts of the cellular tissue), which are the main causes of undesirable enzyme activities. The next step is hydration, which separates out a substantial portion of the heterolipids (mainly phospholipids) as hydrated gums that are highly insoluble in oil and can be quickly separated out as a hydration sludge. Plant mucilages (see Section 4.5.1.8), carbohydrates and proteins are also separated. Hydration is based on heating crude oil with water or, in modern processes such as superdegumming, total degumming and so on, with concentrated hydrochloric, phosphoric or citric acids and subsequent separation of the hydration sludge. During the process of hydration with water, the hydration sludge is evaporated and used in the production of lecithin.

In the next step, fatty acids are separated from the oil by neutralisation (deacidification or alkaline refining) with sodium hydroxide solution (which is also effective in the removal of toxic gossypol from cottonseed oil; see Section 9.11). The free fatty acid content varies widely within 0.5–1.5% in seed oils from raw materials grown in a temperate zone. After neutralisation, the fatty acid content falls below 0.1%. The resulting soaps are separated as soap stock and typically used in animal feed. Tropical oils, such as palm and coconut oils, contain 3–7% free fatty acids. It is therefore preferable to separate the free fatty acids together with volatiles by distillation in the end stage of physical refining process. In this case, the main components of the distillate are free fatty acids.

Bleaching is achieved by adsorption on activated bleaching clays (sorbents of the aluminium silicate type) or in combination with other adsorbents (such as activated carbon, also known as activated charcoal) to remove oil soluble pigments (such as carotenoids and chlorophylls), residual phospholipids, and eventually soap residues resulting from the deacidification process. Volatile substances are removed by deodorisation via steam distillation under reduced pressure. The volatile compounds are mainly responsible for the unpleasant smell and aftertaste of crude oil, so this process provides organoleptically neutral, indifferent oils.

Because the deodorisation process conditions (as well as those for physical refining) are adjusted for free fatty acids distillation, during deodorisation a partial loss of tocopherols and sterols occurs. They pass into the distillate, or deodorisation condensate, from which it is possible to recover them subsequently. An undesirable phenomenon in deodorising (physical refining), in addition to partial loss of sterols and tocopherols, is partial geometrical isomerisation of double bonds of polyenoic fatty acids. By adjusting the process parameters, these adverse effects can be minimised. The refining process simultaneously leads to decomposition of hydroperoxides, and other oxidation products of fatty acids and volatile secondary oxidation products are distilled off. The vitamin and carotenoid pigments content of the lipophilics is partly reduced, but the nutritional value of the oil is not altered significantly. The resulting refined oil is virtually a pure mixture of triacylglycerols with small amounts of partial esters of glycerol, residual free fatty acids and some desirable accompanying substances (in particular phytosterols, tocopherols, fat-soluble vitamins and carotenoids).

Winterisation is the process of removing components with high melting point (such as waxes) from some vegetable oils, for example sunflower, rice bran and cotton seed oils or partially hydrogenated

soya bean oil. For vegetable oils this is necessary to ensure that the oil remains a clear liquid even when stored at low temperatures for extended periods of time. The bleached oil is cooled down to the winterisation temperature and after maintaining this for a certain length of time the wax crystals are separated from the oil by means of pressure filtration or centrifugal separators.

According to the International Olive Oil Council (IOOC), there are four commercial types of olive oils: extra virgin olive oil, virgin olive oil, olive oil and pomace oil. Virgin oils are obtained entirely through physical methods (pressing and heating), extra virgin olive oil contains up to 0.8% of free fatty acids (expressed as oleic acid) and virgin olive oil contains up to 2.0% of this acid. Virgin olive oils are only filtered and not refined. Olive oil is a mixture of refined oil (oils of lower quality are refined by filtration through activated carbon) with virgin oil. Pomace oil (obtained from pomace, which is the ground pulp and seeds, by solvent extraction and other physical methods and refining of the oil thus obtained) is also a blend of refined and virgin olive oil. The oleic acid content of the last two types is up to 1.0%.

3.4.3.8 Crystallisation and emulsification of fats

Vegetable oils are often eaten directly (100% cooking fats or oils). The basic problem is that most vegetable oils are liquid, while what are usually required are solid fats of suitable consistency, which have similar properties to traditionally used animal fats, such as butter and lard. Therefore, vegetable oils are processed further to fats of suitable consistency. Vegetable oil used for the production of margarines and other water-in-oil emulsified spreads and shortenings for use as dough fat or filling fat is called **fat blend**. Fat blend is made by mixing the so-called **structural fat** and liquid oil. Structural fat contains a mixture of triacylglycerols of higher melting points, which crystallise in the fat blend and create a crystalline structure. The fat blend for the manufacture of shortenings requires the formation of a dispersion of crystals in oil (β-crystalline modification; see Section 3.4.3.9), while fat blend for the manufacture of margarines requires the formation of a spatial network (β′-crystalline modification). Triacylglycerol crystals produce the so-called solid fat content (SFC), which is defined as the percentage content of the solid phase at a constant temperature (usually in the temperature range of 10–40 °C). Liquid triacylglycerols (the fat liquid content) are adsorbed (immobilised) on the surface of the crystals or in the spatial network of crystals. Structural fat carries the fat blend structure and its physical and textural characteristics. Structural fat can be produced by:

- **partial catalytic hydrogenation**
- **ester interchange (transesterification)**
- **fractionation**.

Structural fat is currently no longer produced by partial catalytic hydrogenation, because the presence of *trans*-isomers in fats is considered undesirable from a nutritional point of view. Fractionation of triacylglycerols (fractional crystallisation) is also marginally employed. The main process of structural fats production is transesterification of triacylglycerols.

Shortenings are made of fat blends, which crystallise in a controlled manner, forming a dispersion of crystals of structural triacylglycerols (ideally, crystals of triacylglycerols form a special network) in which the dispersion medium are liquid triacylglycerols. Shortenings are used for frying and as fats that are added to most doughs and batters to increase the plasticity and workability of doughs, and to impart a crisp and crumbly texture to baked products. In terms of consistency, shortenings can be liquid, semiliquid or hard. Whipped fats are solid foams with inert gas (nitrogen) as a dispersed (internal) phase at a level of 15–20% by volume, and are suitable for frying.

A classic emulsified fat is **margarine**, which contains at least 80% of fat and the rest is the aqueous phase (minimum 16% of total emulsion content by weight). It is obtained by mechanically emulsifying fat blends, containing an emulsifier (usually monoacylglycerols with the addition of diacylglycerols, often mixed with lecithin), with an aqueous phase and by subsequent crystallisation. Margarine and butter both consist of a water-in-oil emulsion (w/o). Emulsification occurs in parallel with the gradual crystallisation of structural lipids (triacylglycerols of higher melting points). Emulsified oil is a three-phase colloidal system consisting of a dispersion medium of liquid triacylglycerols, droplets of water (10–80 μm in diameter) that represents the dispersed phase forming the emulsion and a dispersion of triacylglycerol crystals in a stable crystalline form. Ideally, triacylglycerol crystals create a spatial network and form a gel. Margarines are produced either as spreadable fats or in a harder consistency for baking purposes. Today, most emulsified fats are produced with a lower lipid phase content (70, 60 or only 40% of fat, or only 20–25% of fat), which are used as fat spreads.

Another type of emulsified fat is **mayonnaise**, which is flavoured with oil and water emulsions, where the emulsifier is egg yolk (or strictly the phospholipids present in it). Today, many similar products with lower oil contents are produced in abundance. Thus, mayonnaise consists of an oil-in-water emulsion (o/w). A similar composition is found in tartar sauce and some salad dressings, but the fat content is usually lower in these products. Non-food fat emulsions are used for paints, cosmetics, pharmaceuticals and other purposes.

3.4.3.9 Composition, crystallisation and properties of fats and oils

Food products referred to as fats and oils are not just a mixture of triacylglycerols with small amounts of monoacylglycerols and diacylglycerols. They also contain up to 1–2% of accompanying substances (sometimes more), which are mainly sterols and other terpenoids. Small amounts of lipophilic vitamins, hydrocarbons, phospholipids and traces of other compounds are also present. Fats and oils are insoluble in water and very slightly soluble in alcohol. Their properties are mainly determined by their fatty acid composition.

Fats can be hard and brittle substances (cocoa butter), hard substance (beef tallow), gooey solids (pork lard, palm oil) and viscous liquids (vegetable oils). The melting and solidification points of some fats are listed in Table 3.27. The range of values is mainly related to the variability of the composition of fatty acids and triacylglycerols.

Solid fats, as well as fatty acids, are polymorphic substances. Although the triacylglycerols form the main crystalline phase, the minor components can often play a significant role in how crystallisation occurs and this may be substantially different in refined oils to that in the unrefined starting material. On slow cooling from the liquid, the lipid molecules have time to organise and can eventually form coherent, three-dimensional crystals. The arrangement of the molecules into the crystalline state depends on such factors as the cooling rate, the temperature at which crystallisation occurs, the agitation rate and the composition of the lipid phase. Crystallisation of pure triacylglycerols can lead first to less stable γ- and α-polymorphic forms of low density, from which the metastable β′-polymorphic forms arise that are then transformed into the more stable β-forms of highest density with the highest melting points (Table 3.28). For example, on cooling, liquid tristearin generates first the α-form, which is, on further cooling, transformed into the β-form. Cooling the melt a few degrees centigrade higher than the temperature that corresponds to the melting point of the α-form creates the β′-form, heating of the β′-form to a higher temperature than the melting point creates the β-form. The orderliness of the molecules in the crystal lattice increases with increasing density, but the entropy and Gibbs energy decrease and reach minimum values in the stable modification.

The individual modifications differ in the arrangement of triacylglycerol molecules in the crystal lattice. The α-modifications of triacylglycerols form crystals in a hexagonal, β′-modifications in an orthorhombic and β-modifications in a triclinic crystal lattice. In the crystalline lattice, triacylglycerol molecules are oriented in a chair or tuning fork configuration. Crystals of triacylglycerols in the α-modification containing residues of the same fatty acids tend to form tuning fork configurations with the fatty acid chains perpendicular to the crystal planes. Crystals in the β′-modification have tuning fork configuration with angled fatty acids chains. Chains of fatty acids in positions C-1 and C-3 of glycerol are opposite to the acid chain in position C-2 and inclined to the crystal planes. Crystals of triacylglycerols in the β-modification have chair configuration (Figure 3.5).

Natural triglycerides contain different fatty acids in the individual positions of the glycerol, therefore there are numerous deviations from the above described behaviour during crystallisation. For example, one of the bound fatty acids can differ significantly from the other two fatty acids in its chain length (by four or more carbon atoms), or in the case of unsaturated fatty acid, the layer of fatty acids does not have the depth of two (type β-2), but of three chains (type β-3) of fatty acids (Figure 3.6). Usually there are several polymorphic forms, one of which predominates.

Table 3.27 Melting and solidification points of solid fats.

Fat	Melting point (°C)	Solidification point (°C)	Fat	Melting point (°C)	Solidification point (°C)
Pork lard	28–40	22–32	Coconut oil	20–28	18–23
Beef tallow	40–50	30–38	Palm oil	30–37	27–43
Cows' milk fat	28–38	15–25	Cocoa butter	32–36	21–27
Breast milk fat	30–32	22–23	Hydrogenated vegetable oils	28–42	23–36

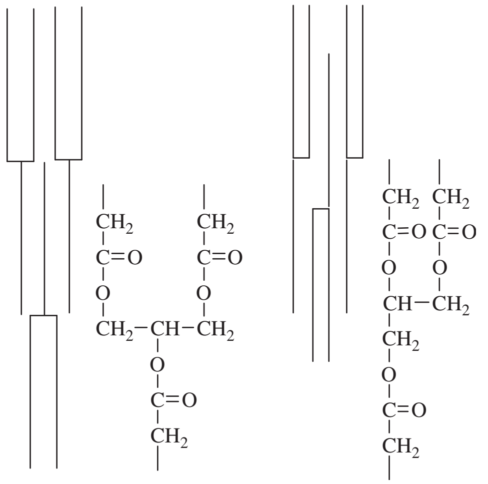

Figure 3.5 Tuning fork (β′-modification) and chair configuration (β-modification) of triacylglycerols in crystal lattices.

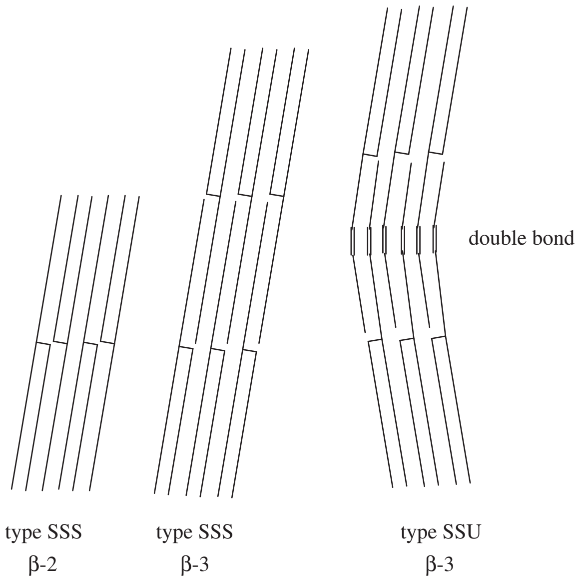

Figure 3.6 Arrangement of polymorphic forms of triacylglycerols in crystals.

Heterogeneous fats containing different fatty acids of different chain lengths and fats with asymmetric distribution of fatty acids (SSU or UUS types) tend to occur in the metastabile β′-modification, which is slowly transformed into the β-modification. Homogeneous fats containing fatty acids of roughly the same length and fats with a symmetrical distribution of fatty acids (SUS type) are very quickly transformed into the stable β-modification.

Coconut and palm kernel oil, palm oil, traditional rapeseed oil and cottonseed oil, beef tallow and butter tend to preferentially crystallise in the metastabile β′-modification, which has characteristic small needle-like crystals. These triacylglycerols characteristically form clusters and aggregates to form the crystal spatial network, ideally they form a gel structure, which shows thixotropy. Fats crystallising in this modification are suitable for the production of margarines and shortenings. At a suitable temperature, when a part of the crystals occur in the matrix formed by the liquid fat, these fats impart the desired consistency to products. In dough and pastry, these fats help incorporate air bubbles and suspended particles of flour and sugar.

Olive, peanut, sunflower, soybean, low erucic acid rapeseed and safflower oils, cocoa butter and pork lard crystallise in the stable β-modification, for which large fat crystals conferring grainy texture to the fats are characteristic. Such crystals arise, for example, in pork lard during storage in a refrigerator. Association of crystals in the β-modification is significantly less than in the β′-modification, and therefore fats in this configuration of the crystal lattice do not create a crystalline network, but a simple dispersion of fat crystals in liquid triacylglycerols, which is a sol (see Section 7.8.3.1).

In many food products, it is important to control lipid crystallisation in order to obtain the desired number, size distribution, polymorph and dispersion of the crystalline phase. Proper control of the crystalline microstructure leads to products with the desired textural properties and physical characteristics. For example, tempering of chocolate prior to molding or enrobing is designed to controlled crystallisation of the cocoa butter into a large number of very small crystals that are all in the desired polymorphic form. When controlled properly, the cocoa butter crystals in chocolate contribute to the desired appearance (the shine or gloss), meltdown rate upon consumption and stability during shelf life (prevention of fat bloom, the gray film of fat on the surface). Natural cocoa butter has a total of six polymorphic forms (γ, α, β'_2, β'_1, β_2 and β), the melting points of which range from 17.3 to 36.3 °C. Only the fifth form (β_2) with a layer corresponding to three lengths of the fatty acid chains (the main triacylglycerols are StOSt, POSt and POP, Table 3.24) and melting at 33.8 °C has the desirable organoleptic properties. To ensure that this form is created in the production of chocolate requires tempering. Liquid chocolate is allowed to cool during tempering. When the fat begins to crystallise, it is heated to a temperature just below the melting point of the desired polymorphic form when the undesired polymorphic forms melt. Chocolate is stirred at this temperature for some time to ensure that a greater proportion of fat is crystallised into small fine crystals. Inappropriately tempered chocolate, or chocolate exposed to fluctuations in temperature, creates a fat bloom as a result of the fat transformation into more stable polymorphic forms, which then crystallise on the chocolate surface.

3.4.4 Esters of polyhydric alcohols

This group includes industrially produced substances. Esters of sorbitol or saccharose with one or two molecules of fatty acids are used as emulsifiers of fats. Sucrose esters with 5–8 molecules of fatty acids are used as fat substitutes (called Olestra), with the advantage that they have physical properties similar to fat and give the same sensory impression, but they are unusable in the human body and therefore do not supply the body with energy. These substances are described in more detail in the section dealing with food additives (see Section 11.5.2.1.5).

3.5 Heterolipids

Unlike homolipids, heterolipids contain not only bound fatty acids and alcohols, but also other components, and, depending on these, they are further subdivided into:

- **phospholipids**
- **glycolipids**
- **sulfolipids**.

The most important group of phospholipids are **glycerophospholipids**. Homolipids derived from glycerol (such as mono-, di- and triacylglycerols), glycerophospholipids and **glyceroglycolipids** together constitute one class of lipids known as **glycerolipids**. Another major group of lipids are **sphingolipids**, which are not derived from glycerol and are not very important in nutrition. Sphingolipids include fatty acid amides derived from nitrogen-containing alcohols known as **sphingosines**. Sphingolipids are further divided into **sphingohomolipids** (***N*-acylsphingosines** called **ceramides**) and **sphingoheterolipids** (that include **sphingophospholipids** and **sphingoglycolipids**). Glycerophospholipids (formerly known as phosphoglycerides), glyceroglycolipids and sphingolipids are structural lipids of biological membranes.

3.5.1 Phospholipids

3.5.1.1 Structure and nomenclature

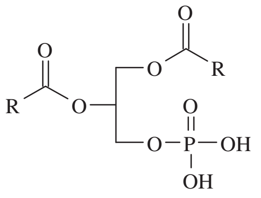
The most important group of phospholipids are glycerophospholipids, which are glycerol derivatives esterified with both fatty acids and phosphoric acid. Glycerophospholipids are divided into three groups according to the number of bound fatty acids, other types of bonds and the structure of the bound components:

- **phosphatides**
- **lysophosphatides**
- **plasmalogenes**.

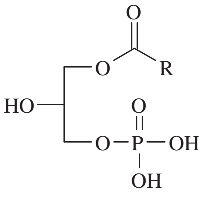
3.5.1.1.1 Phosphatides and lysophosphatides

Phosphatides are derivatives of phosphatidyl residues, which are based on 1,2-diacyl-*sn*-glycerol, which contains bound phosphoric acid on the C-3 hydroxyl. The basic compound is 3-*sn*-phosphatidic acid (1,2-diacyl-*sn*-glycerol 3-phosphoric acid) (**3-53**). If only position C-1 (which is more often than position C-2) is occupied by an acyl, the resulting residue derived from 1-acyl-*sn*-glycerol is called lysophosphatidyl. The corresponding acid is 3-*sn*-lysophosphatidic acid (1-acyl-*sn*-glycerol 3-phosphoric acid) (**3-54**).

In phosphatides and lysophosphatides, phosphoric acid is further esterified by some hydroxy compounds, namely by choline (*N*,*N*,*N*-trimethylethanolamine), ethanolamine (2-aminoethanol), L-serine, *myo*-inositol and glycerol.

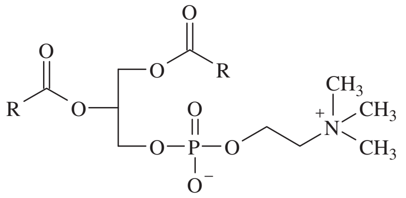


3-53, phosphatidic acid

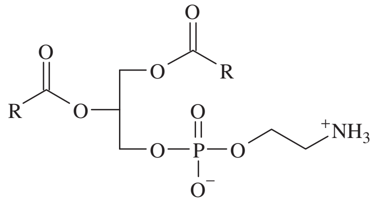


3-54, lysophosphatidic acid

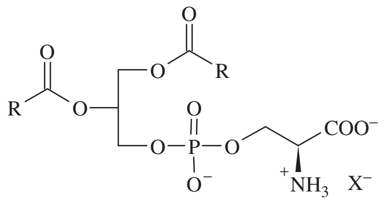
The most frequently occurring phosphatide is the ester with amino alcohol choline, which is known as (3-*sn*-phosphatidyl)choline or 1,2-diacyl-*sn*-glycero-3-phosphocholine, or phosphatidylcholine for short (**3-55**). Previously, this ester was known as lecithin, but this name should no longer be used for the pure compound, but only for the industrial concentrate of phospholipids. If ethanolamine (colamine) is bound to the phosphatidyl residue, the resulting phospholipid is called (3-*sn*-phosphatidyl)ethanolamine or 1,2-diacyl-*sn*-glycero-3-phosphoethanolamine (phosphatidylethanolamine; **3-56**). Previously, the fraction containing phosphatidylethanolamine, together with other phospholipids, was known as cephalin. This name has been used only rarely in non-chemical literature, and should not be used because it is a poorly defined mixture of compounds. Another phospholipid is (3-*sn*-phosphatidyl)-L-serine or 1,2-diacyl-*sn*-glycero-3-phospho-L-serine (phosphatidylserine, **3-57**). In the toxic skin secretion of fish of the Ostraciidae family



3-55, phosphatidylcholine



3-56, phosphatidylethanolamine



3-57, phosphatidylserine (X$^-$ = counter anion)

choline is bound as esters of 3-acylhexadecanoic acids (see Section 10.3.2.11.2).

The compound of this group that does not contain nitrogen is (3-*sn*-phosphatidyl)-*myo*-inositol or 1,2-diacyl-*sn*-glycero-3-phospho-*myo*-inositol (or phosphatidyl-*myo*-inositol for short, **3-58**), which may have the second phosphoric acid bound to *myo*-inositol via the C-4 hydroxyl group (see Section 4.3.1.1.2). Another compound of this group that does not contain nitrogen is (3-*sn*-phosphatidyl)-*sn*-glycerol or 1,2-diacyl-*sn*-glycero-3-phospho-*sn*-glycerol (phosphatidylglycerol, **3-59**). Phosphatidylglycerol is found as a minor component in various animal and plant tissues, particularly in chloroplasts. The structurally related compound is cardiolipin (**3-60**), an acyl derivative of 1′,3′-di-*O*-(3-*sn*-phosphatidyl)-*sn*-glycerol, which was first isolated from cardiac muscle, hence its name.

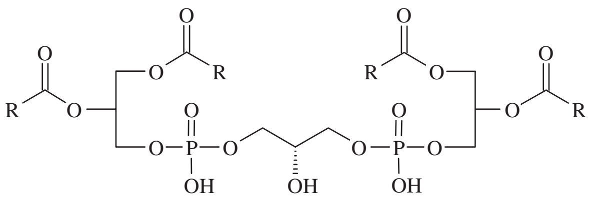
3-59, phosphatidylglycerol



3-60, cardiolipin

3.5.1.1.2 Plasmalogens

The acyl in the *sn*-1 position of glycerol in plasmalogenes (phosphate esters of glycerylethers) is replaced by a higher aliphatic aldehyde bound as a hemiacetal. It usually occurs in a dehydrated form (**3-61**), but may be also present as a hydrate (**3-62**). If the *sn*-3 position of glycerol is esterified with phosphoric acid then this plasmalogen is formally derived from 3-*sn*-plasmenic acid, the systematic name for which is 2-acyl-1-(alk-1′-en-1′-yl)-3-*sn*-glycerol 3-phosphate (**3-63**). Depending on the nitrogenous bases bound in plasmalogenes, 2-acyl-1-(alk-1′-en-1′-yl)-3-*sn*-phosphocholine (for short plasmenylcholine), 2-acyl-1-(alk-1-en-1-yl)-3-*sn*-phosphoethanolamine (plasmenylethanolamine) and 2-acyl-1-(alk-1-en-1-yl)-3-*sn*-phospho-L-serine (plasmenylserine) are recognised. The corresponding compounds with a saturated chain in the *sn*-1 position also exist. They are derived from 3-*sn*-plasmanic acid, that is, 2-acyl-1-alkyl-*sn*-glycerol 3-phosphate (**3-64**). Such a compound is, for example, 2-acyl-1-alkyl-3-*sn*-phosphocholine (briefly plasmanylcholine). Plasmalogenes probably show cytostatic effects based on the inability of tumour cells to metabolise their molecules.

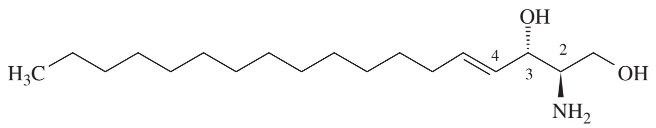
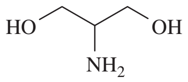
3.5.1.1.3 Sphingophospholipids

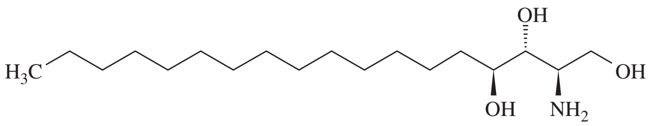
An important group of phospholipids, the sphingophospholipids, do not contain glycerol, but the *N*-analogues of glycerol generally known as sphingosines. Sphingosines (2-amino-1,3-dihydroxyalkanes), are bases with a long chain substituted on the nitrogen atom by acyls of fatty acids with 14–26 carbon atoms. In mammals, this base is usually (*E*)-sphing-4-enine, (2*S*,3*R*,4*E*)-2-aminooctadec-4-ene-1,3-diol also known as (*E*)-D-*erythro*-2-amino-1,3-dihydroxyoctadec-2-ene or sphingosine (**3-65**). Plants contain up to eight sphingoid-C_{18} bases derived from D-*erythro*-sphinganine, also known as (2*S*,3*R*)-sphinganine. As a result of *cis*- or *trans*-dehydrogenation at C-8, the prevalent regioisomers are (*E*/*Z*)-sphing-8-enine (C18:1), (4*E*/8*E*/*Z*)-sphingadi-4,8-enine (18:2) and (8*E*/*Z*)-4-hydroxysphing-8-enine. In bacterial lipids, a common component is 2-aminopropane-1,3-diol derived from L-serine, which is called serinol (**3-66**). In the yeast *Saccharomyces cerevisiae* 3-hydroxysphinganine predominates, which is known by its systematic name of (2*S*,3*S*,4*R*)-2-aminooctadecan-1,3,4-triol, or also phytosphinganine, C18:0 (**3-67**).



3-65, sphingosine

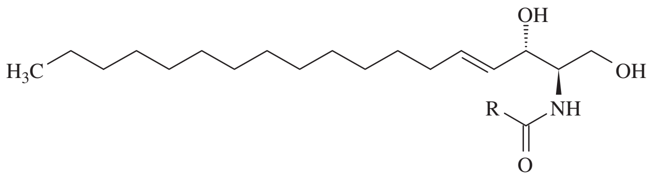


3-66, serinol

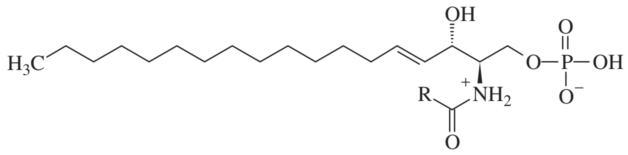


3-67, phytosphinganine

The amino group of sphingosine linked to a fatty acid via an amide bond occurs in the *N*-acylsphingosines known as ceramides (**3-68**), which belong to the homolipids. If the primary hydroxyl group of ceramide (sphingosine) is esterified with phosphoric acid, the resulting phospholipid is called ceramide phosphate (**3-69**). Ceramide phosphate esterified with choline is known as sphingomyelin (or ceramide phosphorylcholine) (**3-70**). Sphingomyelin is thus the sphingolipid analogue of phosphatidylcholine.



3-68, ceramide



3-69, ceramide phosphate

The composition of fatty acids linked to phospholipids differs from the fatty acid composition of lipid reserves of the

Table 3.29 Fatty acid composition of phospholipids of different origin (% of total fatty acids).

	Phospholipid

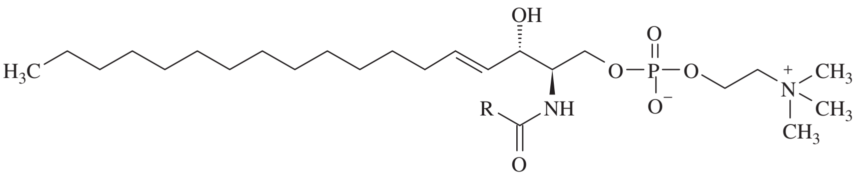
Linolenic	4	0	1	0	0

same organism. Phospholipids typically contain higher amounts of palmitic acid, usually bound in the *sn*-1 position, and linoleic acid, which is most often bound in the *sn*-2 position. Some phospholipids contain large amounts of higher aliphatic hydroxy acids. The fatty acid composition of phospholipids of different origins is given in Table 3.29. The composition of fatty acids in individual soybean phospholipids is shown in Table 3.30. Phospholipids, particularly phospholipids of seafood, contain small amounts of arsenic analogues (see Section 6.2.3.1).

3.5.1.2 Biochemistry, physiology and nutrition

Phospholipids are essential components of animal and vegetable organisms, in which they are present as a part of the cellular and intracellular membrane and as components of lipoproteins that are stabilised due to the emulsifying ability of phospholipids. The phospholipids content also affects the solubility of low density lipoproteins (see Section 3.2.1) in blood plasma.

Phospholipids are formed from precursors by the action of several phospholipases (Table 3.31), which catalyse the connection of individual components to glycerol. The same enzymes catalyse the cleavage of phospholipids. Phospholipids are not an essential food for humans because the body can synthesise the basic building blocks through at least two different mechanisms. The first uses the appropriate alcohol (such as choline and ethanolamine) activated by binding to CDP (cytidine 5′-monophosphate), which is then connected to phosphatidic acid. Another possibility is the reaction of an alcohol with 1,2-diacylglycerols (activated by binding to CDP). In the absence of the basic building units, a further, third, possibility that can take place in the body is the direct synthesis of phospholipids. Decarboxylation of glycerophosphatidylserine



3-70, sphingomyelin

Phospholipase	Activity	Origin and characteristics
A	A1: splits fatty acids bound in the *sn*-1 position; A2: splits fatty acids bound in the *sn*-2 position	Pancreas, intestinal mucosa, microorganisms (e.g. *Escherichia coli* and *Saccharomyces cerevisiae*)
B	Splits acyl in the *sn*-2 position, then acyl in the *sn*-1 position	Microorganisms (e.g. *Penicillium notatum*)
C	Splits bonds between the residue of glyceroland bound phosphotic acid	Microorganisms (e.g. *Bacillus cereus*, *Clostridium perfringens* and *Clostridium welchii*)
D	Splits bonds between phosphoric acidand nitrogen base	Vegetables, nuts, legumes

yields glycerophosphatidylethanolamine and, subsequently, glycerophosphatidylcholine is produced by methylation of the amino group of the ethanolamine residue. Of course, it is advantageous if the diet contains adequate amounts of phospholipids, because the body has sufficient building material for their re-synthesis. For this reason, various phospholipid preparations are currently recommended for dietetic purposes.

3.5.1.3 Occurrence

Phospholipids are found in all plants and animals as a part of the cellular and intracellular membranes. Their content is about 1% of dry matter (Table 3.32) and is not increased even in depot fat. Some animal tissues are particularly rich in phospholipids, especially the nervous tissue and egg yolk. Egg yolk contains about 28% of phospholipids and constitutes an appropriate source of phospholipids for pharmaceutical purposes. Soybeans are also a relatively rich source of phospholipids, but their phospholipid composition is very different to that in eggs (Table 3.33). Soy and egg phospholipids are used as emulsifiers.

When obtaining oil from oilseeds, a considerable amount of the phospholipids are extracted into the lipid phase, from which it is possible to isolate the phospholipid fraction by adding water or acidic solutions, such as phosphoric or citric acids that release phospholipids from their salts. The phospholipids are hydrated, become less lipophilic, and therefore are excluded from the lipid phase. The obtained product is called **lecithin**.

3.5.1.4 Lecithin

As already mentioned, the process of degumming converts the majority of phospholipids into hydrated gums that are highly insoluble in oil and are quickly separated as a hydration sludge. Evaporation of water under reduced pressure gives a dark brown phospholipid concentrate, which is called lecithin. Lecithin contains 30–50% of homolipids (acylglycerols), free fatty acids, sterols and tocopherols and various other substances (e.g. sugars, which represent about 6.5% of soy lecithin, amino acids and metal ions) as well as chlorophylls and carotenoid pigments. In addition to glycerophospholipids, lecithin contains other heterolipids of which the major group is glyceroglycolipids (6–7% of soy lecithin).

Food lecithin is made from specially selected high quality crude oils, because its refining is difficult and bleaching using hydrogen peroxide is not permitted in Europe. For some purposes, lecithin is subjected to fractionation to increase the phosphatidylcholine content, which is a more valued compound than other phospholipids.

Table 3.32 Content of phospholipids in foods.

Food	Content (% dry matter)	Food	Content (% dry matter)
Animal materials		Pork lard	0.01–0.1
Brain	5–6	Butter	0.6–1.4
Liver	3–4	***Plant materials***	
Heart	2.6–3.0	Vegetable oils	0.02 (refined)
Kidney	1.6–3.0		0.6–3.2 (raw)
Egg yolk	28	Fruits, vegatables, cereals	0.5–1.5

	Phospholipid				
Compound	**Rapeseed**	**Soybean**	**Milk**	**Egg**	**Liver**
Phosphatidylcholine	26–38	24–46	20–29	66–83	43–55
Phosphatidylethanolamine	19–30	21–34	28–36	8–24	23–28
Phosphatidylinositol	12–26	13–21	0–1	0–1	6–9
Phosphatidylserine	traces	5–6	0–8	1–3	3–4
Lysophospholipids	3–9	1–5	traces	3–7	0–2
Sphingolipids	–	–	15–29	1–3	3–5
Phosphatidic acid	0–3	0–14	–	–	0–1

Another way to increase the phosphatidylcholine content in lecithin is enzymatic transesterification after the addition of choline. Alternatively, modification can be achieved by the addition of free fatty acids, which make the product more fluid. Chemical modification of lecithin (hydrogenation and hydroxylation of the double bonds of fatty acids) is used to increase its stability against oxidation. For specific purposes, a phospholipid concentrate (>90% of phospholipids) is produced by a selective extraction that separates neutral lipids, especially triacylglycerols and free fatty acids. The most important product for industrial purposes is soy lecithin. Its composition is shown in Table 3.33. Rapeseed lecithin and sunflower lecithin have quite a different phospholipid fraction composition.

3.5.1.5 Use

The majority of lecithin is used as feed (as extraction meals dipped in hydration sludge) and only a smaller part of a better quality product is used in the food industry, mostly in the bakery industry. Lecithin is used as a substance for improving dough properties, as it increases the amount of gas retained in the rigid dough foam and reduces the rate of amylose retrogradation. It is also used as an emulsifier in the production of mayonnaise and emulsified fats of the margarine type (it allows the creation of both o/w and w/o emulsions), and is used to reduce the viscosity of the chocolate mass in chocolate production. The phospholipid concentrate is used in the production of instant powdered products such as dried milk drinks. The use of lecithin for non-food purposes is very diverse. Previously, a substitute for lecithin was manufactured by phosphorylation of diacylglycerols and subsequent neutralisation of the phosphatidic acids formed (Section 11.5.2.1.1).

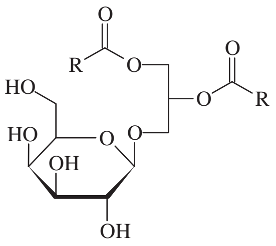
3.5.2 Glycolipids

Glycolipids are fatty acid derivatives that contain bound sugars. If they also contain bound glycerol, they are called glyceroglycolipids, whereas if they contain bound sphingosine, they are called sphingoglycolipids. The most common sugar bound in glycolipids is D-galactose (sometimes several galactose units are linked to each other in one glycolipid molecule), and rarely D-glucose or D-fructose, as well as some other sugars. Glycolipids sometimes contain bound phenolic acids and may then act as antioxidants. Glycolipids accompany phospholipids as a part of cell structures and are also bound in lipoproteins. Reactions of glycolipids are similar to reactions of other heterolipids, but they also exhibit the typical reactions of sugars. The hydrolysis of glycolipids in lecithin yields free sugars that react with the free amino groups of amino

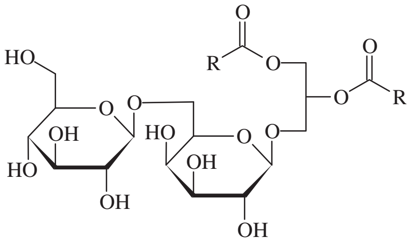
compounds (in the Maillard reaction), which leads to browning of lecithin and formation of undesirable odours.

3.5.2.1 Glyceroglycolipids

Galactolipids (monogalactosyldiacylglycerols and digalactosyldiacylglycerols) are, along with sulfolipids, major components of lipid membranes of chloroplasts and related organelles in photosynthetic organisms (higher plants, algae and some bacteria). The predominant compounds are 1,2-di-*O*-acyl-3-*O*-β-D-galactopyranosyl-*sn*-glycerol (**3-71**) and 1,2-di-*O*-acyl-3-*O*-(6′-*O*-α-D-β-galactopyranosyl-D-galactopyranosyl)-*sn*-glycerol (**3-72**). Higher homologues also exist. For example, trigalactosylglycerol has been found in potatoes and tetragalactosylglycerol occurs in oats.[13]



3-71, monogalactopyranosyldiacylglycerol



3-72, digalactopyranosyldiacylglycerol

The main fatty acids of galactolipids in photosynthetic tissues of higher plants are polyene fatty acids, of which α-linolenic acid dominates. Its concentration is up to 95% of total fatty acids. In pea (18:3 plants), α-linolenic acid is practically the only fatty acid bound in positions *sn*-1 and *sn*-2 of monogalactopyranosyldiacylglycerol. The model plant *Arabidopsis thaliana* (16:3 plants) contains exclusively hexadecatrienoic acid bound in the position *sn*-2. Palmitic acid is only found in digalactosyldiacylglycerols, and only in small quantities. Other tissues (tubers, roots and seeds) contain fatty acids with lower number of double bonds. Wheat flour, for example, contains 1.5–2.5% of lipids, of which the smaller part (25%) is bound to starch as the so called starch lipids and the rest are non-starch lipids. The composition of both types of lipids differs significantly. The main components of starch lipids are glycerophospholipids (89.4%) and glyceroglycolipids (5.0%), while triacylglycerols (1.4%) are minor components. The non-starch lipids contain as the major components triacylglycerols (46.7%); other major components are glyceroglycolipids (26.9%) and glycerophospholipids (14.7%). The detailed composition of wheat flour glyceroglycolipids is shown in Table 3.34.

3.5.2.2 Sphingoglycolipids

In addition to *N*-acylsphingosines (ceramides) and sphingophospholipids, sphingosine also occurs in the form of glycosides. These compounds belong to the sphingoglycolipids group. The common sugar bound in sphingoglycolipids is D-galactose. An example of sphingosine galactoside is psychosine (1-*O*-β-D-galactopyranosylsphingosine, **3-73**). Amides of fatty acids (mostly saturated) and sphingosine are glycosides of ceramides (1-*O*-β-D-galactopyranosylceramides, **3-74**), called **cerebrosides**. Also, sphingophospholipids may still contain bound sugar, again mostly galactose.

[13]In addition to these glyceroglycolipids, a number of plants and some bacteria contain linear galactolipids in which two to four galactose units are linked by the β-(1→6) glycosidic bond. Oats and rice sprouts contain interesting diacylgalactosylglycerols with an estolide bond composed of 15-hydroxylinoleic acid esterified with linoleic acid and bound to the glycerol *sn*-2 hydroxyl group. The rice germ contains galactolipids together with 1,2-di-*O*-acyl-3-*O*-β-D-glucopyranosyl-*sn*-glycerol, rice seeds also contain triglycosyldiacylglycerols that contain bound galactose and glucose.

Table 3.34 Fatty acid composition of galactolipids of wheat flour (in % of total fatty acids).

	Fatty acid				
Position in galactolipid	16:0	18:0	9*c*-18:1	9*c*12*c*-18:2	9*c*12*c*15*c*-18:3

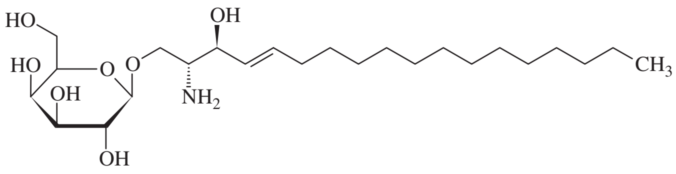
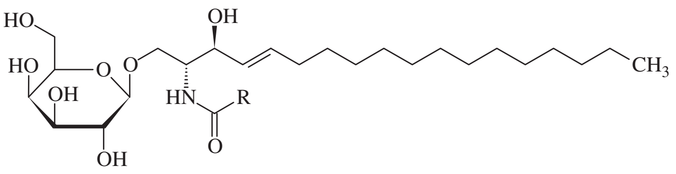
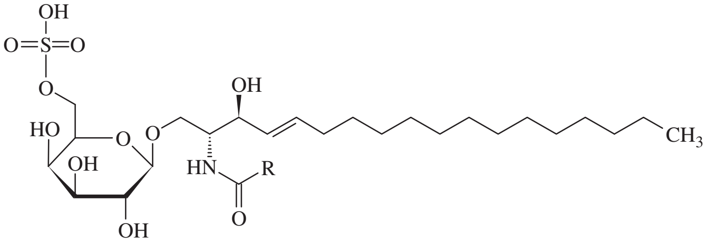
sn-2	2	traces	7	83	7



3-73, psychosine



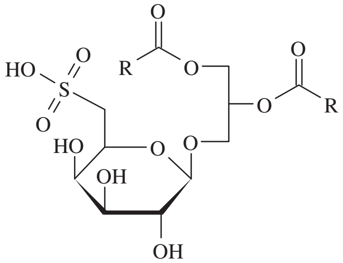
3-74, cerebroside



3-75, glycosylceramide sulfates

3.5.3 Sulfolipids and lipid sulfates

Some heterolipids contain bound sulfuric acid. For example, these heterolipids include **sulfoglycosylsphingolipids**, formerly called sulfatides. For example, members of this lipid group are glycosylceramide sulfates, exemplified by 1-*O*-β-D-galactopyranosylceramide sulfate (**3-75**). Sulfur in some lipids is also bound as sulfonic acid. An examples of these compounds is 2,3-diacyl-1-(6-deoxy-6-sulfo-β-D-galactopyranosyl)glycerol (**3-76**). Sulfolipids and lipid sulfates accompany phospholipids in nature, and are constituents of some complex lipids.



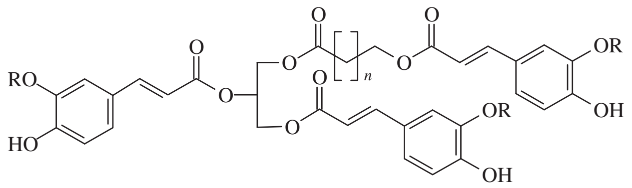
3-76, sulfolipids

3.5.4 Sialolipids

A physiologically important group of lipids is sialoglycosphingolipids, known as gangliosides, which contain bound sialic acid or several sialic acid residues (see Section 4.3.3.7). The level of the gangliosides can reach up to 6% by weight of the brain lipids, where they constitute 10–12% of the total lipids of neuronal membranes. These lipids are mostly oligoglycosphingolipids.

3.5.5 Other heterolipids

Vegetable oils often contain a variety of natural phenolic antioxidants, but usually only as admixtures. Phenolic acids, such as caffeic (R = H) and ferulic ($R = CH_3$) acids, occur in lipids relatively rarely, usually tied to the glycerol residue (**3-77**), and show antioxidant effects.

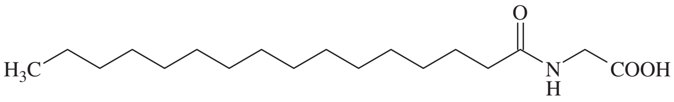


3-77, lipid containing bound phenolic acids (*n* = 24 or 26)

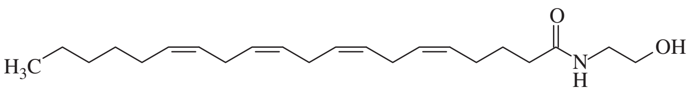
3.6 Miscellaneous simple and complex lipids

3.6.1 Lipoamino acids and fatty acid amides

Many different simple fatty acyl-amino acids also known as lipoamino acids are present in animal tissues and as constituents of bacterial lipids. Examples of simple lipoamino acids are *N*-palmitoylglycine (**3-78**) and *N*-oleoylglycine, which have roles in sensory neuronal signalling and regulation of body temperature and locomotion, respectively. *N*-Arachidonylglycine has been shown to suppress inflammatory pain. Biologically active compounds are also other other long-chain *N*-acylethanolamides, for example, *N*-palmitoylethanolamide and *N*-oleoylethanolamide, or oleamide.



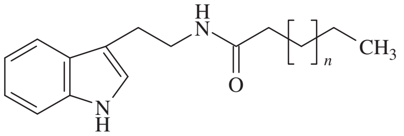
3-78, *N*-palmitoylglycine



3-79, anandamide

Some fatty acid amides that occur naturally can have profound biological functions. For example, *N*-acylethanolamides, such as *N*-arachidonoylethanolamide (anandamide, **3-79**), are ubiquitous trace constituents of animal and human cells, tissues and body fluids. The name is taken from the Sanskrit word ananda, which means bliss or delight. Anandamide is an endogenous cannabinoid neurotransmitter that occurs naturally in the brain and in some foods (as chocolate) and that binds to the same brain receptors as the cannabinoids (as tetrahydrocannabinol).

Fatty acid tryptamides (**3-80**) can be employed as indicator substances for detecting the shell content in cocoa products. The shell content is an important quality parameter for products that are made from roasted cocoa beans. The relevant substances are docosanoyl-2-(3-indolyl)ethylamide (behenic acid tryptamide) and tetracosanoyl-2-(3-indolyl)ethylamide (lignoceric acid tryptamide). Cocoa shells contain 330–395 mg/kg behenic acid tryptamide and lignoceric acid tryptamide, but the cotyledons only 7–10 mg/kg.



3-80, fatty acid tryptamides
behenic acid tryptamide, $n = 17$
lignoceric acid tryptamide, $n = 19$

3.6.2 Complex lipids

Complex lipids are macromolecular substances whose lipid constituent is bound to the non-lipid components by hydrogen bonds, hydrophobic interactions and other physical bonds, but some may also be bound by covalent bonds. The non-lipid components are mostly proteins, but also polysaccharides, mixtures of protein with polysaccharides, lignin and other substances.

3.6.2.1 Lipoproteins

Lipoproteins are the most important and best researched complex lipids, and are composed of proteins and lipids. Lipids often form the core of macromolecules while the hydrated proteins form the coat. Therefore, lipoproteins dissolve (or at least are dispersed) in water, and serve to transport lipids. Lipoproteins usually consist of non-polar lipids, such as triacylglycerols or cholesterol esters, cholesterol and polar lipids (such as phospholipids), which facilitate the link between lipids and proteins. The best examined lipoproteins are serum lipoproteins, because they have great significance in the development of circulatory diseases. Historically, serum lipoproteins were divided according to their specific gravity (density). When lipoproteins contain more non-polar lipids their density is lower, and vice versa. The lower the density of lipoproteins, the weaker and less complex is the protein coat, which is maintained in an aqueous solution (Figure 3.7 and Figure 3.8). To date, five major groups of lipoproteins are recognised (Table 3.35):

- **chilomicrons**
- **very low density lipoproteins** (VLDL)
- **intermediate density lipoproteins** (IDL)
- **low density lipoproteins** (LDL)
- **high density lipoproteins** (HDL).

Chylomicrons are particles (100–1000 nm in diameter) that carry the ingested lipids (triacylglycerols) from the intestinal wall into the tissues (adipose tissue and muscles), where they are stored, while VLDL (30–80 nm) carry the newly synthesised triacylglycerols from the liver to adipose tissue. Milk fat globules (see Section 2.4.5.2) have a similar structure to chilomicrons. IDL (the degradation products of VLDL; 25–50 nm) circulate through the body and

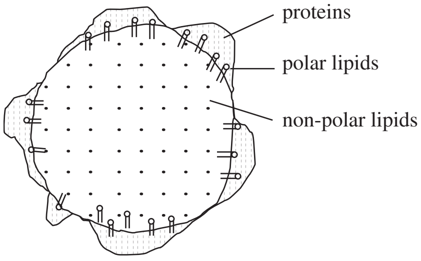


Figure 3.7 Schematic composition of low density lipoproteins.

Table 3.35 Overview of serum lipoproteins.

Lipoprotein type[a]	Density (kg/l)	Triacylglycerols (%)	Cholesterol/its esters (%)	Phospholipids (%)	Proteins (%)
Chylomicrons	<0.95	85-88	1/3	8	1-2
VLDL	0.95-1.006	50-55	8-10/12-15	18-20	7-10
IDL	1.006-1.019	25-30	8-10/32-35	25-27	10-12
LDL	1.019-1.063	10-15	8-10/37-48	20-28	20-22
HDL	>1.063	3-15	2-10/15-30	32-43	33-57

[a]VLDL = Very low density lipoprotein, LDL = low density lipoprotein, IDL = intermediate density lipoprotein, HDL = high density lipoprotein.

transport cholesterol. They also have the ability to promote plaque formation in vessels. LDL (18–28 nm) carry cholesterol from the liver to the body cells, while HDL (5–15 nm) carry cholesterol from the body cells to the liver. The LDL are much less stable than the HDL. Lipids from lipoproteins are readily cleared and temporarily stick to the walls of blood vessels.

Lipoproteins are also components of membranes, forming structures with bilayers of oriented molecules of polar lipids (Figure 3.9). Owing to their polar character induced by the double layer of lipids with an intermediate layer of protein, they are a suitable barrier for the transport of substances between cells or within individual intracellular structures. These properties are also used in the pharmaceutical industry for emulsifying fats with proteins to form liposomes that facilitate the transfer and absorption of certain medications. The creation of the liposomes can explain some changes in the properties of foods during processing. Reactions of lipoproteins involve all lipoprotein components, lipids and proteins. Protein reactions with free radicals yield modified structures, where the lipid part is tightly bound to protein. These structures are thought to be the major components of aterosclerotic deposits in blood vessels. Reactions with peroxyl radicals, which are derived from unsaturated lipids, lead to insoluble macromolecular brown coloured compounds called **ceroids** or **stichosterins** that are deposited in the walls of blood vessels and other places in the body such as the kidneys or uterus. Similar structures are found in deposits in nerve tissue, and are called age pigments (see Section 4.7.5.6). This granular yellow–brown pigment is called **lipofuscin**.[14]

3.6.2.2 Mucolipids

Significant mucolipids are gangliosides containing bound sialic acid that are present in neural tissues. The individual components are bound by covalent bonds, but also by physical links. Examples of gangliosides are listed in Table 3.36.

[14]Similar substances have been reported in animals fed with oxidised fish meal that caused the so called yellow fat disease accompanied by animal mortality. This pigment was first observed in the brain and other light coloured tissues of turkeys.

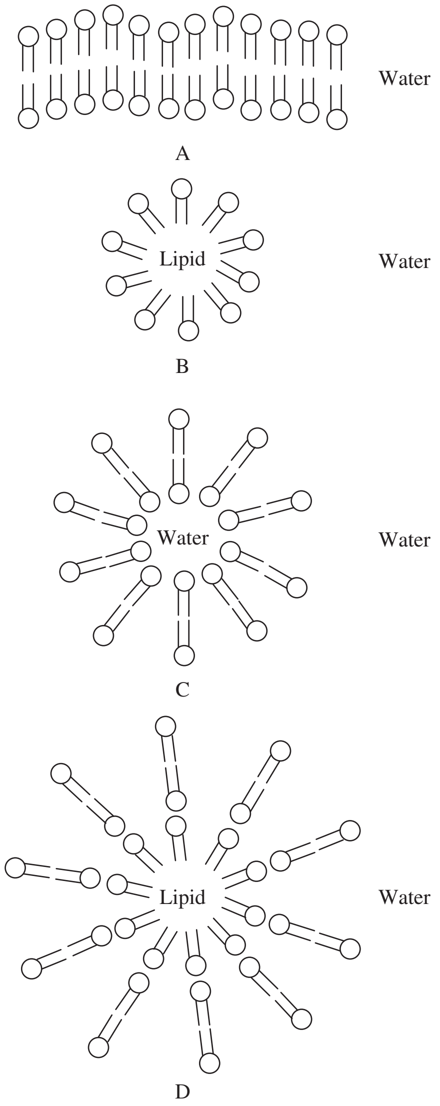

Figure 3.9 Schematic illustrations of lipid membranes in food materials: A = double lipid cell membrane, B = nanoparticles bound with simple lipid membrane with lipid phase within the particles, C = liposome bound by double lipid membrane with the aqueous phase inside the particle, D = fat particles stabilised by lamella structure bound by a double lipid membrane and by simple lipid membrane with fat phase inside the particle.

Table 3.36 Composition of gangliosides.[a]

Sialic acid units	Oligosaccharide	Ceramide	Sialic acid units	Oligosaccharide	Ceramide
II^3-NeuAc	Lac	Cer	V^3-NeuAc	GgO_5	Cer
II^3-NeuAc	triaose	Cer	II^3NeuGc	nLacO_4	Cer
IV^3-NeuAc_2	GgO_4	Cer	V^3NeuGc	iGgO_5	Cer

[a]NeuAc = acetylneuraminic acid, NeuGc = glycolylneuraminic acid; roman numerals at the beginning = bond position in sugar; exponent = to which oligosaccharide unit sialic acid is bound; index at the end = number of sialic acid units bound in a row; Lac = lactose; triaose (three sugar units); GgO = globoose, oligosaccharide with any sugar units, *n* = neobond (1→3); *i* = isobond (1→4); index at the end = number of sugar units, Cer = residue of any sphingoid base (generally identified as ceramide).

3.6.2.3 Lipid clathrates

Clathrates (cage or inclusion compounds)[15] are compounds that consist of a lattice of one type of molecule (a host molecule) trapping another type of molecule (a guest molecule) by intermolecular interactions. A clathrate is therefore a mechanical structure without chemical bonds. Such compounds include protein complexes containing β-carotene or lipids (fatty acids) bound in the starch macromolecules (see Section 4.5.1.1). In some technological processes, such as extrusion, part of the free lipids is bound in this way.

3.7 Substances accompanying lipids

Food raw materials and products contain, in addition to lipids, many lipophilic compounds sometimes called **lipoids**, which during the isolation of lipids pass into the lipid fraction due to its low polarity. They are therefore called lipid accompanying substances, although this does not necessarily mean that they accompany lipids in the original material or that they are somehow functionally related to lipids. The lipid accompanying substances include higher hydrocarbons, higher primary and secondary alcohols, ketones and diketones, various steroids, lipophilic vitamins, pigments and other lipophilic compounds specific to certain materials.

Lipophilic polycyclic aromatic hydrocarbons (see Section 12.2.5), condensed aromatic heterocycles (see Section 12.2.1) and other lipophilic compounds formed in processed foods or compounds derived from external sources are not considered to be accompanying substances of lipids. They are classified as food contaminants.

3.7.1 Hydrocarbons

Higher hydrocarbons are found mainly in waxes, where they can form as much as a few percent of the weight of the wax, but they can also be found in small quantities in common edible fats and oils. They come mainly from the waxy surface layer of seeds. The majority of hydrocarbons have 15–35 carbon atoms in the molecule. The most frequently occurring hydrocarbons are alkanes (*n*-alkanes) with an odd number of carbon atoms. Less common are isoalkanes (mainly with an odd number of carbon atoms) and ante-isoalkanes (mainly with an even number of carbon atoms). Sometimes higher alkenes are also present. Qualitative and quantitative composition of hydrocarbons is often characteristic of certain foods and can be used to identify them. For example, the surface waxes of fruits and oilseeds, and therefore also most food oils, contain alkanes C_{27}, C_{29} and C_{31} as major components, but olive oil is dominated by alkanes C_{23}, C_{25}, C_{27} and C_{29} (Table 3.37).

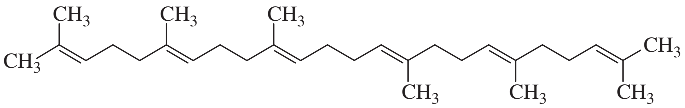
The total alkane contents in vegetable oils ranges from about 10 to 200 mg/kg. Their amount in sunflower oil is 105–170 mg/kg, and in olive oil approximately 30–100 mg/kg. The amount of alkanes in the cuticular wax of apples, for instance, is about 33% of the lipid accompanying substances. About 97% of all hydrocarbons in the cuticular wax are represented by nonacosane (C_{29}), about 2% by heptacosane (C_{27}) and the remaining 1% consists mainly of alkanes C_{26}, C_{28}, C_{30} and C_{31}. The cuticular wax of grapefruits is composed primarily of oxygenated compounds, while the content of alkanes is only around 1%. Fats of marine organisms (e.g. fish liver oils) contain saturated and unsaturated hydrocarbons C_{15} and C_{17} or C_{21} as the main components. The total content of alkanes is about 10–30 mg/kg.

In addition to the above mentioned hydrocarbons, oils also contain alkenes and monoterpenic and sesquiterpenic hydrocarbons. For example, the amount of alkenes in olive oils range from 0.5 to 2 mg/kg and includes a series of alk-9-enes from C_{22} to C_{27}, heptadec-8-ene and 6,10-dimethyl-undec-1-ene. An important compound is the linear triterpenic (C_{30}) hydrocarbon squalene (**3-81**), all-*trans*-2,6,10,15,19,23-hexamethyltetracosa-2,6,10,14,18,22-hexaene, which is the universal precursor of all triterpenoids and steroids. It was given this name because it was discovered in the liver of sharks (Squalidae). Shark liver oil contains about 30% squalene, about 7% pristane (2,6,10,14-tetramethylpentadecane) and smaller amounts of phytane (2,6,10,14-tetramethylhexadecane). Squalene occurs in small amounts in edible oils and especially in olive oil, where its content is in the tenths of a percent (1–7 g/kg).

[15]The most famous clathrates are clathrates of lipids with urea. Urea forms a cylindrical structure, formed by spiral molecules bound by hydrogen bonds, which entrap fatty acid or other derivatives with a long unbranched saturated chain (e.g. hydrocarbons). Branched or *cis*-unsaturated fatty acids bind much less tightly, triacylglycerols do not form clathrates with urea, because their volume is bigger and the molecules do not fit into the housing formed by urea molecules.

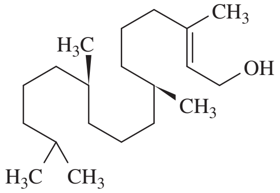
Table 3.37 Content of alkanes in sunflower and virgin olive oils.

Alkane	Name	Content (mg/kg oil)		Alkane	Name	Content (mg/kg oil)	
		Sunflower	Olive			Sunflower	Olive
C_{16}	Hexadecane	0.13	0.06	C_{25}	Pentacosane	1.52	17.98
C_{17}	Heptadecane	0.16	0.12	C_{26}	Hexacosane	0.41	2.04
C_{18}	Octadecane	0.90	0.08	C_{27}	Heptacosane	11.19	15.72
C_{19}	Nonadecane	0.12	0.13	C_{28}	Octakosane	2.38	1.84
C_{20}	Eicosane	0.02	0.08	C_{29}	Nonacosane	49.63	12.38
C_{21}	Heneicosane	0.04	0.81	C_{30}	Triacontane	5.52	1.70
C_{22}	Docosane	0.04	1.24	C_{31}	Hentriacontane	47.96	9.41
C_{23}	Tricosane	0.15	18.54	C_{32}	Dotriacontane	1.79	1.54
C_{24}	Tetracosane	0.17	9.54	C_{33}	Tritriacontane	3.60	5.66



3-81, squalene

In addition to the previoulsy mentioned less volatile higher hydrocarbons, hydrocarbons with a short chain, such as pentane and hexane, may also be found in fats. They form by cleavage of fatty acid hydroperoxides produced by oxidation of unsaturated fatty acids. These hydrocarbons, not ranked among the lipid accompanying compounds, are easily removed by heating, so they do not occur in freshly refined oils.



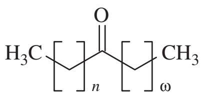
3-82, phytol

3.7.2 Aliphatic alcohols

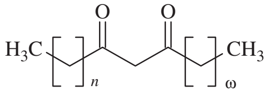
Aliphatic primary alcohols C_{12}–C_{36} accompany waxes, but may also occur in trace amounts in ordinary cooking oils, where they pass from the surface layers during seed extraction. Their structure therefore corresponds to the alcohols bound in waxes. For example, the major components of the wax on the surface of sunflower seeds (and of apple wax), along with a number of minor alcohols, are the alcohols C_{24}, C_{26}, C_{28} and C_{30}. In addition to these higher alcohols, called fatty alcohols, vegetable oils and animal fats also contain lower primary alcohols with 3–11 carbon atoms, which are formed from hydroperoxides by the hydrocarbon chain cleavage. In addition to primary alcohols, higher secondary alcohols also occur in vegetable oils. Their chain length corresponds to the alkanes from which they arise by oxidation. Their hydroxyl group is located near the centre of the hydrocarbon chain. A common secondary alcohol is nonacosan-15-ol. Vegetable oils may also contain traces of the diterpenic alcohol phytol (**3-82**), (2*E*,7*R*,11*R*)-3,7,11,15-tetramethylhexadec-2-en-1-ol, which is, for example, bound in chlorophyll dyes (see Section 9.2.2). Free alcohol arises during catabolic processes catalysed by chlorophyllase. Diterpenes, however, are not included as lipid accompanying substances.

3.7.3 Aliphatic ketones

Higher ketones (**3-83**), usually C_{24}–C_{33} compounds, arise as products of oxidation of alkanes via secondary alcohols. Higher β-diketones, mainly C_{31} and C_{33} compounds (**3-84**), also accompany higher ketones in smaller amounts.



3-83, aliphatic ketones



3-84, aliphatic β-diketones

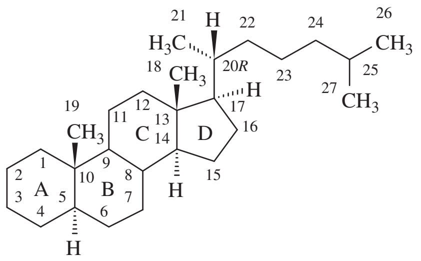
3.7.4 Triterpenoids and steroids

Triterpenoids and steroids are the major group of the lipid-accompanying substances in all natural lipids. Triterpenoids and steroids belong to a large group of compounds known as **terpenoids** or **isoprenoids** (through the oxidation or rearrangement modified terpenes). Six isoprene (2-methylbuta-1,3-diene) units

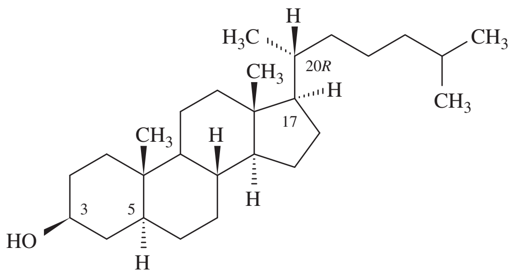
give **triterpenes** with 30 carbon atoms and their modifications yield **triterpenoids**. Several thousand natural triterpenoids include compounds with nearly 200 types of skeletons. **Steroids** are a group of terpenoids arising from triterpenoid precursors. Some steroids play a number of vital functions in living organisms. Examples of such compounds are the steroid hormones of animals, plant steroid hormones brassinoids, steroid glycoalkaloids (see Section 10.2.3.1.8), phytoanticipins and phytoalexins. Some compounds have found use in medicine (such as cardioactive steroid glycosides).

3.7.4.1 Structure and nomenclature

Triterpenoids are mostly C_6–C_6–C_5–C_6 tetracyclic or C_6–C_6–C_6–C_6–C_5 and C_6–C_6–C_6–C_6–C_6 pentacyclic compounds, but there are also acyclic, monocyclic, bicyclic, tricyclic and hexacyclic triterpenoids. Triterpenoids with a β-hydroxyl group at C-3 and a skeleton derived theoretically from the hydrocarbon α-cholestane (**3-85**), such as tetracyclic cyclopenta[*a*]phenanthrene, are structures with a (20*R*)-configuration and are called **steroids**. Almost all steroids are, in addition to 5α-cholestan-3β-ol (**3-86**), secondary alcohols with a perhydro-1,2-cyclopentanophenanthrene C_6–C_6–C_6–C_5 skeleton, which consists of three six-membered rings A, B and C in a nonlinear arrangement, with the circle C connected to a five-membered ring D.[16] The steroid skeleton contains a secondary hydroxy group in the C-3 position of ring A, therefore sterols are actually alicyclic alcohols. The positions C-10 and C-13 always contain methyl groups and the position C-17 contains a side chain with 8–10 carbon atoms. All of these substituents are in the β-position. Individual steroids vary in carbon number and the number and location of double bonds in the side chain attached to C-17. In addition, steroids differ in substituents at C-4 (hydrogen, one or two methyl groups), number and location of double bonds in ring B and also in the stereochemistry of some asymmetric centres. Some related compounds contain the fifth ring E formed by cyclisation of the side chain that is connected to ring D. These compounds are found, for example, as aglycones of many saponins (see Section 10.3.2.2).



3-85, 5-cholestane



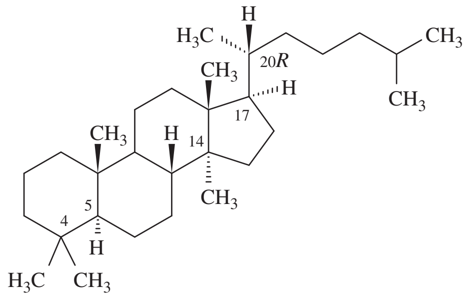
3-86, 5α-cholestan-3β-ol

Most steroids have trivial names, usually created by the Latin or Greek name of the material from which they were isolated. For less common steroids, systematic names are used, which are derived from basic structures. In addition to 5α-cholestane (**3-85**), other basic structures of hydrocarbons are 5α-lanostane (**3-87**), 5α-ergostane (**3-88**), 5α-campestane (**3-89**), 5α-poriferastane (**3-90**) and 5α-stigmastane (**3-91**), which differ in the structure of the side chain at C-17. The classification reflecting the biochemical origins distinguishes three groups of steroids by the number of methyl groups on carbon C-4. The recognised groups are:

- **4.4-dimethylsterols**
- **4-methylsterols**
- **4-demethylsterols** (as methyl groups in position 4 is missing) simply called sterols.

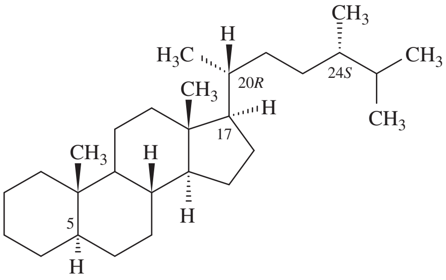
Steroids of the first two groups that contain 30 carbon atoms are also known as **triterpenic alcohols**. This name is often used for all 4,4-dimethylsterols and 4-methylsterols. Both types of steroids may, however, in addition to 4-demethylsterols, contain less or more than 30 carbon atoms in the molecule.

An overview of significant compounds is given in Table 3.38. Lanosterol, for example, is 4,4,14-trimethyl-5α-cholesta-8,24-diene-3β-ol or 5α-lanosta-8,24-diene-3β-ol. The hydrocarbon

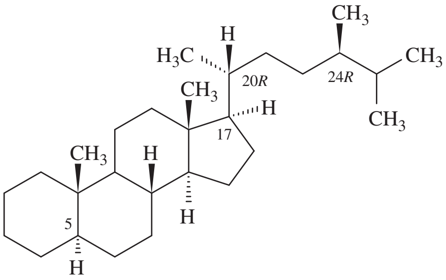


3-87, 5-lanostane

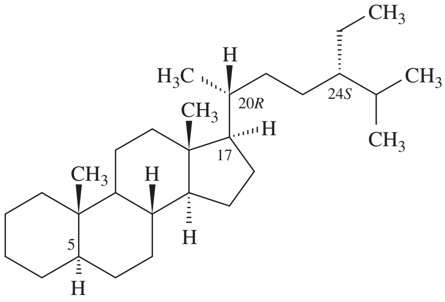
[16]Numbers 28, 29 and 30 are reserved for methyl groups of triterpenoids at C-4 and C-14. The basic structure has eight chiral centres (carbon atoms C-3, C-5, C-8, C-9, C-10, C-13, C-14 and C-17) and another in the side chain at C-17. Most natural steroids have the same basic structures. The circles AB, BC and CD are always in the *trans*-position. The steroid molecule is nearly a planar unit and individual substituents lie above or below this plane. The orientation point is a methyl group at C-10, which is always above the plane. Substituents that are in the *cis*-position to this methyl group (they also lie above the plane), are β-substituents, while the substituents in *trans*-position are called α-substituents. The name must always indicate the position of hydrogen on C-5, which in this case is in the 5α position.



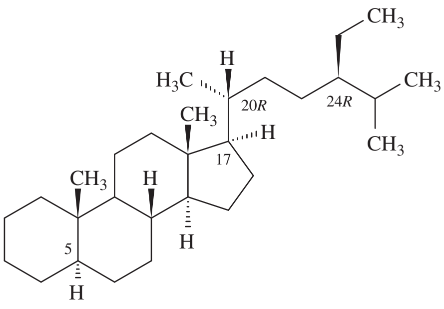
3-88, 5-ergostane



3-89, 5-campestane



3-90, 5-poriferastane



3-91, 5-stigmastane

lanostane (**3-87**), from which lanosterol is derived, is 4,4,14-trimethyl-5α-cholestane. Analogously, cycloartenol is 4,4,14-trimethyl-9,19-cyclo-5α,9β-cholesta-24-en-3β-ol or 9,19-cyclo-5α-lanost-24-en-3β-ol, campesterol is (24*R*)-24-methylcholesta-5-en-3β-ol or campest-5-en-3β-ol (**3-89**), stigmasterol is (24*S*)-24-ethylcholesta-5,22-dien-3β-ol or (*E*)-stigmasta-5,22-dien-3β-ol (**3-91**), β-sitosterol is (24*R*)-24-ethylcholest-5-en-3β-ol or stigmasta-5-en-3β-ol (**3-91**), ergosterol is (22*E*,24*R*)-24-methyl-cholesta-5,7,22-trien-3β-ol or (*E*)-ergosta-5,7,22-trien-3β-ol (**3-88**).

3.7.4.1.1 Dimethylsterols

The basic 4,4-dimethylsterols are C_{30} steroids lanosterol (**3-92**) and cycloartenol with a cyclopropane ring (**3-93**), derived from lanostane (4,4,14-trimethylcholestane). Lanosterol is the building block for the biosynthesis of all other zoosterols (including cholesterol), the biosynthesis of many other phytosterols is based on cycloartenol. Common compounds are also euphol (**3-94**) and its isomer butyrospermol (Δ^7-euphol or Δ^7-tirukallol, **3-95**) derived from the hydrocarbon euphane.

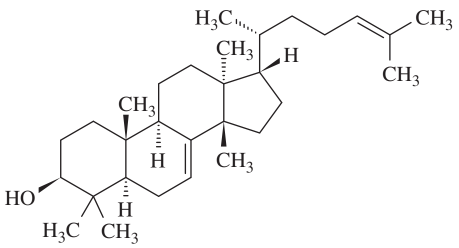
Table 3.38 Overview of trivial and systematic names of selected steroids.

Steroid name	
Trivial	**Systematic**
4,4-Dimethylsterols	
α-Amyrin	5α-Urs-12-en-3β-ol
β-Amyrin	5α-Olean-12-en-3β-ol
Betulinic Acid	5α-Eupha-7,24-dien-3β-ol-28-carboxylic acid
Butyrospermol	5α-Eupha-7,24-dien-3β-ol
Cycloartenol	9,19-Cyclo-5α-lanost-24-en-3β-ol
Cyclobranol	24-Methyl-9,19-cyclo-5α-lanost-24-en-3β-ol
Cyclolaudenol	(24*S*)-24-Methyl-9,19-cyclo-5α-lanost-25-en-3β-ol
Cyclosadol	24-Methyl-9,19-cyclo-5α-lanost-23-en-3β-ol
Erythrodiol	5α-Olean-12-en-3β,28-diol
Euphol	5α-Eupha-8,24-dien-3β-ol
Lanosterol	5α-Lanosta-8,24-dien-3β-ol
Lupeol	5α-Lup-20(29)-en-3β-ol
24-Methylenecycloartanol	24-Methylene-9,19-cyclo-5α-lanostan-3β-ol
Oleanolic acid	5α-Olean-12-en-3β-ol-28-carboxylic acid
Parkeol	5α-Lanosta-9(11),24-dien-3β-ol
Ursolic acid	5α-Urs-12-en-3β-ol-28-carboxylic acid
Uvaol	5α-Urs-12-en-3β,28-diol
4-Methylsterols	
Citrastadienol	4α-Methyl-24-ethylidene-5α-cholest-7-en-3β-ol
Cycloeucalenol	4α,14α-Dimethyl-24-methylene-9β,19-cyclo-5α-cholestan-3β-ol
Gramisterol	4α-Methyl-24-methylene-5α-cholest-7-en-3β-ol
Lophenol	4α-Methyl-5α-cholest-7-en-3β-ol
Obtusifoliol	4α,14α-Dimethyl-24-methylene-5α-cholest-8-en-3β-ol
4-Demethylsterols	
Δ^5-Avenasterol	(*Z*)-Stigmasta-5,24(28)-dien-3β-ol
Δ^7-Avenasterol	(*Z*)-Stigmasta-7,24(28)-dien-3β-ol
Brassicasterol	(*R*)-24-Methylcholesta-5,22-dien-3β-ol
Desmosterol	Cholesta-5,24-dien-3β-ol
Fucosterol	(*E*)-Stigmasta-5,24(28)-dien-3β-ol
Cholesterol	Cholest-5-en-3β-ol
Campesterol	(*R*)-24-methylcholest-5-en-3β-ol
Clerosterol	(*Z*)-Stigmasta-5,25(26)-dien-3β-ol
Lathosterol	Cholest-7-en-3β-ol
Lichesterol	(*Z*)-Ergosta-5,8,22-trien-3β-ol
Poriferasterol	(*E*)-Stigmasta-5,22-dien-3β-ol
β-Sitosterol	(*R*)-24-Ethylcholest-5-en-3β-ol or stigmasta-5-en-3β-ol
Spinasterol	(*Z*)-Stigmasta-5,22-dien-3β-ol or (24*R*)-24-ethylcholesta-5,22-dien-3β-ol
Stigmasterol	(*S*)-24-Ethylcholesta-5,22-dien-3β-ol or (22*E*)-stigmasta-5,22-dien-3β-ol
Ergosterol	(*E*)-Ergosta-5,7,22-trien-3β-ol or (24*R*)-24-methylcholesta-5,7,22-trien-3β-ol



3-95, butyrospermol

Steroids (C_{30}) with four C_6 cycles and one C_5 cycle E, which are derived from the hydrocarbon lupane, are lupeol (**3-96**) and a product of its oxidation on C-28 known as betulinic acid (**3-97**). C_{30} Steroids also occur with five C_6 cycles. The most important of these compounds are α-amyrin (**3-98**), derived from the hydrocarbon ursane, and β-amyrin (**3-99**), which is derived from the hydrocarbon oleane. Also common is taraxasterol (**3-100**), which is structurally related to α-amyrin. Fruit waxes very often contain terpenoid (steroid) C_{30} diols and acids formed by oxidation of the C-27 methyl group. Determination of uvaol (**3-101**) and erythrodiol (**3-102**) concentrations can be used to distinguish olive oils from other vegetable oils. Widespread in cuticular wax of apples, pears, grapefruits and other fruits is ursolic acid (**3-103**), which is structurally related to α-amyrin. Some citrus fruits contain oleanolic acid (**3-104**), related to β-amyrin, in significant quantities. These substances, correspondingly derived saponins (see Section 10.3.2.2), show a number of interesting physiological effects.

The common C_{31} 4,4-dimethylsterols are represented by isomeric compounds with a cyclopropane ring, such as cycloartenol and 24-methylenecycloartanol (**3-105**), cyclosadol (**3-106**), cyclobranol (**3-107**) and cyclolaudenol (**3-108**), which are derived from the hydrocarbon lanostane.

3.7.4.1.2 Methylsterols

Typical 4-methylsterols are the C_{30} compounds cycloeucalenol (**3-109**) and obtusifoliol (**3-110**), which are intermediates in the biosynthesis of phytosterols from cycloartenol. Other C_{30} compounds include citrastadienol (24-ethylidenelophenol, **3-111**), which is the intermediate in the biosynthesis of β-sitosterol and stigmasterol. The C_{29} compounds are represented by gramisterol (episterol, **3-112**) and C_{28} compounds by lophenol (**3-113**).

3.7.4.1.3 Sterols

Sterols (demethylsterols) are still commonly divided into categories according to their occurrence in nature. The recognised categories are:

- **zoosterols** (animal sterols)
- **phytosterols** (plant sterols)
- **mycosterols** (sterols of fungi).

This classification has a number of weaknesses. Some bacteria, for example, accept the zoosterol cholesterol from the host animals and use it as a component of membranes, some types of prokaryotic organisms even synthesise sterols *de novo*, some eubacteria (species of the genus *Methylobacterium* and *Methylosphaera*) synthesise 4-methylsterols and 4,4-dimethylsterols (including lanosterol). In many species of bacteria the so-called hopanoids, pentacyclic

triterpenoids with the $C_6–C_6–C_6–C_5–C_6$ skeleton of the hydrocarbon hopane (with cyclopentane ring E) play the role of sterols.

Modern classification is based on the structure of the sterols. The most frequently occurring compounds are sterols with a double bond in position C-5 in ring B (Δ^5-sterols) and a saturated or unsaturated side chain at position C-17, less common are Δ^7- and $\Delta^{5,7}$-sterols. In plants, these sterols are accompanied by small quantities of saturated sterols known as phytostanols that are analogues of Δ^5-sterols without the double bond in ring B. They occur in cereals in relatively high amounts.

The basic C_{27} sterol is cholesterol, cholesta-5-en-3β-ol or (3β)-cholest-5-en-3-ol (**3-114**), with a saturated C_8 side chain. The same side chain also occurs in its precursor lathosterol (**3-115**); unsaturated C_8 side chain has its other precursor desmosterol (**3-116**). Normally, there are also sterols with 28 carbon atoms in the molecule. Their representatives are the Δ^5-sterols campesterol (**3-117**) and brassicasterol (**3-118**). The most common C_{29} Δ^5-sterol is sitosterol (also called β-sitosterol, **3-119**). Also found, at lower levels, are stigmasterol (**3-120**), avenasterol (or Δ^5-avenasterol or 5-avenasterol, **3-121**), clerosterol (**3-122**), poriferasterol, fucosterol (**3-123**) and Δ^7-sterols, such as spinasterol (**3-124**), Δ^7-campesterol, Δ^7-avenasterol and Δ^7-stigmasterol. An important $\Delta^{5,7}$-sterol is ergosterol (**3-125**).

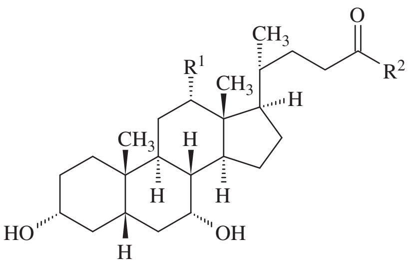
3.7.4.2 Biochemistry, physiology and nutrition

Steroids are synthesised in organisms via complex mechanisms from isoprene units, isopentenyl diphosphate and dimethylallyl diphosphate, which first yield geranyl diphosphate. Reaction with another molecule of isopentenyl diphosphate gives an important intermediate, farnesyl diphosphate (Figure 3.10). Two molecules of farnesyl phosphate give rise to triterpenic hydrocarbon squalene (**3-81**), which in the body of animals yields triterpenic alcohol lanosterol (**3-92**) and the triterpenic alcohol cycloartenol (**3-93**) in plants.

Plants synthesise a number of steroid substances from cycloartenol, including 4,4-dimethylsterols, 4-methylsterols and demethylsterols. Cycloartenol is a precursor of many other steroids that are aglycons of saponins, of steroidal glycoalkaloids and of other compounds. Lanosterol in animals is a precursor for the biosynthesis of the most important zoosterol cholesterol (**3-114**). An intermediate in the biosynthesis of cholesterol is 7-dehydrocholesterol, which is a precursor of vitamin D_3 (see Section 5.3.1). Cholesterol in the body is used for the biosynthesis of steroid hormones[17] and bile acids[18] (**3-126**).



3-126, bile acids and their conjugates

chenodeoxycholic acid, $R^1 = H$, $R^2 = OH$
glycochenodeoxycholic acid, $R^1 = H$, $R^2 = NHCH_2COOH$
taurodeoxycholic acid, $R^1 = H$, $R^2 = NHCH_2CH_2SO_3H$
cholic acid, $R^1 = OH$, $R^2 = OH$
glycocholic acid, $R^1 = OH$, $R^2 = NHCH_2COOH$
taurocholic acid, $R^1 = OH$, $R^2 = NHCH_2\ CH_2SO_3H$

The main bile acids are cholic acid and chenodeoxycholic acid (**3-126**). These acids are excreted from the liver as glycine salts or taurine conjugates (see Section 5.15) into the gallbladder and then into the small intestine. In the duodenum, bile acids act as emulsifiers in the absorption and digestion of fats and fat soluble vitamins.

Sterols are essential components of lipoproteins and lipid membranes in animals. They are particularly important in nerve tissues and in the transport of lipids (fatty acids), which are bound in lipoproteins. In humans, dietary cholesterol intake is lower than the daily requirement, therefore the body synthesises the majority of cholesterol that is needed (a larger intake in the diet decreases the amount synthesised by the body). Cholesterol in the diet is easily absorbed, but problems may occur during transport of cholesterol from the intestinal wall during lymph and blood circulation. Excessive cholesterol transport in low-density lipoproteins (LDL) may cause health problems. It is therefore recommended that the intake of dietary cholesterol should not exceed 300 mg per day.

[17]Steroid hormones are divided into five groups: progestins, glucocorticoids, mineralocorticoids, androgens and oestrogens (see Section 10.3.2.5.1). They mediate many important functions in living organisms.

[18]The recycling system allows bile acids to re-enter the bloodstream and return to the liver for re-use. They are partially (some 1000 mg per day) metabolised in the colon by microorganisms, which cleave the peptide bond of conjugates and bile acids and are converted into deoxycholic ($R^1 = OH$, $R^2 = OH$) and lithocholic ($R^1 = H$, $R^2 = OH$) acids (the hydroxyl group at C-7 is replaced by H atom in both compounds), which is excreted in the faeces from the body. This is the only way of removing cholesterol indirectly from the body. The amount of excluded bile acids may be increased due to their binding to the soluble fibre, such as pectin, fructooligosaccharides or arabinoxylans.

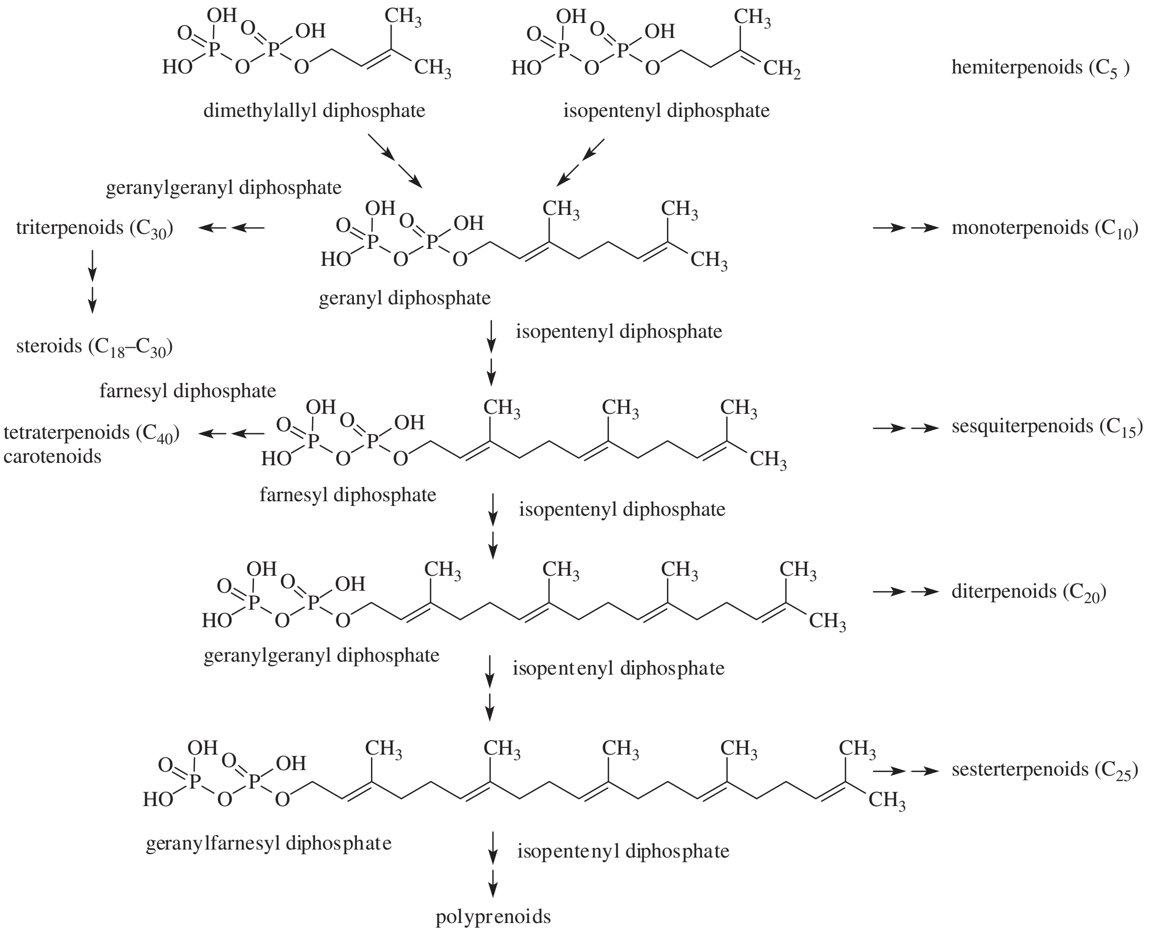


Figure 3.10 Biosynthesis of steroids and other terpenoids.

However, its intake is often more than twice as high in developed countries, therefore reducing dietary fat is recommended to reduce the intake of dietary cholesterol.

Dietary phytosterols have some influence on the biosynthesis of cholesterol in the body, although they are not used for making membranes and in the body they break down. To reduce the amount of cholesterol in blood plasma, the Recommended Daily Intake of phytosterols is about 250 mg. There are now margarines containing about 10% phytosterols (in the form of phytostanol esters derived from tall oil or in the form of sterol esters isolated from soybean oil). The importance of triterpene alcohols in the diet is not known.

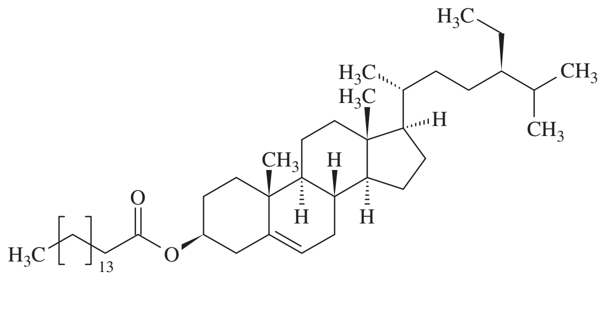
3.7.4.3 Occurrence

Steroids in food of animal and vegetable origin appear as:

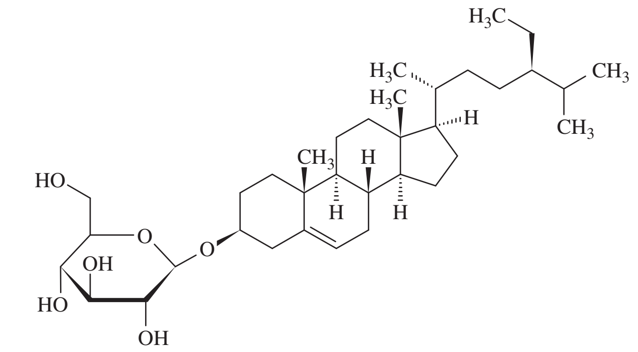
- **free compounds**
- **esters** with higher fatty acids and cinnamic acids
- **glycosides** (common sugars are D-glucose and D-mannose)
- **glycoside esters** of higher fatty acids (called acylsterylglycosides).

Examples of these compounds are β-sitosteryl palmitate (**3-127**), β-D-glucopyranosyl-β-sitosterol (**3-128**) and its ester with palmitic acid (**3-129**). In sunflower oil, for example, the amount of steroids is 0.32%, 0.07% of steroids occur as esters, 0.03% as glycosides and the rest are free sterols. Fatty acids bound in sterol esters are mainly palmitic, stearic, oleic, linoleic and linolenic acids, but the fatty acid composition of sterol esters may not match the composition of fatty acids in triacylglycerols.

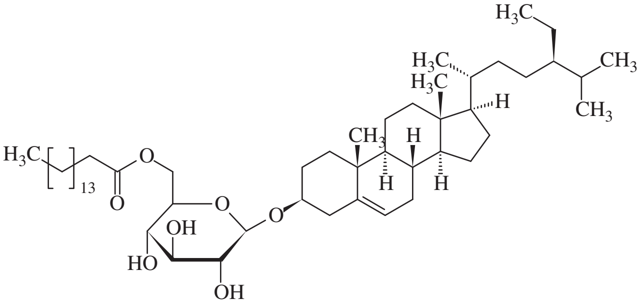
Ferulic acid esters of phytosterols (steryl ferulates) have been identified in rice, wheat, rye, triticale and barley. The highest amounts of ferulated phytosterols occur in rice. They are also



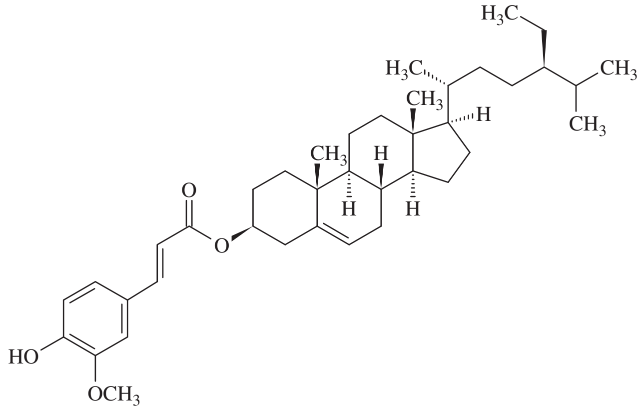
3-127, β-sitosteryl palmitate



3-128, β-D-glucopyranosyl-β-sitosterol



3-129, 6-*O*-palmitoyl-β-D-glucopyranosyl-β-sitosterol



3-130, β-sitosteryl ferulate

found in rice bran oil, but are removed during refining. Their mixture is called **γ-oryzanol**. Ferulic acid esters of 4,4′-dimethylsterols (cycloartenyl ferulate and 24-methylenecycloartanyl ferulate) and of 4-demethylsterols (campesteryl ferulate, campestanyl ferulate, stigmasteryl ferulate and β-sitosteryl ferulate, **3-130**) have been identified as major components of γ-oryzanol. The γ-oryzanol content in brown rice of European origin ranges from 260 to 630 mg/kg. The main components in wheat and rye grains are campestanyl ferulate and sitostanyl ferulate, followed by campesteryl ferulate and β-sitosteryl ferulate. Steryl ferulates are valued for their antioxidant properties.

3.7.4.3.1 Animal fats

In practice, cholesterol is mainly found in animal fats and in human tissues (Table 3.39). In lower animals other sterols, known collectively as zoosterols may also be present.

Cholesterol and its esters are present in all membranes and in blood lipids, but particularly rich sources are nervous tissues, especially the brain. Therefore, the cerebellum would be a food with the highest cholesterol content. Also, egg yolks contain high amounts of cholesterol. Other important sources include meat, milk and cheeses, but also animal fats, lard and butter to a greater extent. Together with cholesterol and other steroids, wool fat contains 4,4-dimethylsterol, known as lanosterol, as the main steroid.

3.7.4.3.2 Vegetable oils

Several steroid compounds are usually present in plants and other organisms, but the major steroids are phytosterols. Those found in higher plants (β-sitosterol being the most predominat) and some other organisms is shown in Table 3.40.

The composition of major sterols found in several vegetable oils is shown in Table 3.41. The total content of phytosterols in vegetable oils is given in Table 3.42. Usually, vegetable oils contain a mixture of phytosterols and related compounds, which are characteristic of a particular oil. Cholesterol is also a phytosterol as it is found in many vegetable oils, but is usually present at very low levels that have no practical importance in the nutritional balance. Vegetable oils also contain numerous 4,4-dimethylsterols and 4-methylsterols in small quantities. The contents of these compounds and other steroids in maize oil are given in Table 3.43 as an example.

3.7.4.3.3 Other lipids

In yeast and fungi (molds and higher fungi) the main sterol is ergosterol (**3-125**), which belongs, along with related compounds (precursors and their metabolites), to the C_{28} mycosterols. Ergosterol usually represents 60–70% of the total sterols present. Other sterols are primarily derived from ergosterol, such as ergosta-5-en-3β-ol, ergosta-7-en-3β-ol, ergosta-5,7-dien-3β-ol (dihydroergosterol), ergosta-5,22-dien-3β-ol, ergosta-7,22-dien-3β-ol, ergosta-5,24(28)-dien-3β-ol, ergosta-7,24(28)-dien-3β-ol and ergosta-5,7,9(11),22-tetraen-3β-ol.

Other minor steroids are C_{27} sterols, such as cholesterol and desmosterol, and C_{29} sterols, for example β-sitosterol, stigmasterol and other sterols. Sterols are found in fungi as free compounds, as fatty acid esters (mainly esters of linoleic, oleic and palmitic acids) and as glycosides in which the sugar component is D-glucose.

3.7.4.4 Properties

Sterols are solid crystalline substances with high melting points, which are insoluble in water, poorly soluble in alcohol, but soluble in non-polar solvents. Pure sterols are relatively stable in air during storage, but they are easily oxidised in solutions. Catalytic hydrogenation of oils transforms sterols into the corresponding saturated compounds.

Table 3.39 Cholesterol content in foods of animal origin.

Food		Content (mg/kg edible portion)
Meat, meat products, poultry, fish	Beef	590–670
	Mutton	700–720
	Veal	650–700
	Pork	600–760
	Sausages	470–1150
	Poultry	650–900
	Fish	420–1500
Milk and dairy products	Milk	120–140
	Yoghurt	40–100
	Cream	190–1050
	Cheesses	290–1050
	Curd	50–130
Fats	Beef tallow	1000
	Butter	2400
	Pork lard	940
Eggs	Egg yolk	8400–13 100
	Egg white	0
	Eggs (whole)	2000–3540
Pastry[a]	Mayonnaise	1100
	Pastry (various products)	150–2800

[a] Almost exclusively from eggs and animal fats.

Table 3.40 Main sterols in plants and other organisms.

Organism	Main sterols	Organism	Main sterols
Bacteria	Cholesterol, β-sitosterol	Brown algae	Fucosterol, 24-methylenecholesterol
Lower fungi	Ergosterol	Red algae	Cholesterol, desmosterol
Higher fungi	Ergosterol	Mosses	β-Sitosterol
Lichens	Ergosterol, lichesterol, poriferasterol	Ferns	β-Sitosterol
Green algae	Various Δ^5-, Δ^7- and $\Delta^{5,7}$-sterols	Higher plants	β-Sitosterol, other Δ^5- and Δ^7-sterols

3.7.4.5 Use

Sterols are a regular part of the diet. The most common sterol is cholesterol, which is used in the cosmetics and pharmaceutical industries as an emulsifier and as a starting material for the synthesis of various biologically active derivatives, such as vitamin D_3 or steroid hormones. During deodorising of vegetable oils, a mixture of phytosterols can be obtained, which can become a viable addition to a variety of dietary products such as margarines (see Section 3.7.4.2).

3.7.5 Lipophylic vitamins

Edible vegetable oils regularly contain varying amounts of tocopherols (vitamin E) or, rarely, their esters. Synthetic all-rac-α-tocopheryl acetate (D,L-α-tocopheryl acetate) is often added to oils and other products as a food additive. The fat products often contain synthetic retinyl acetate (vitamin A), which is more stable than retinol. Emulsified fats sometimes contain vitamin D. Animal fats contain only small amounts of lipophilic vitamins, except for

Table 3.41 Composition of sterols in vegetable oils (expressed as % of total sterols).

Sterol	Rapeseed oil	Soybean oil	Sunflower oil	Palm oil
Cholesterol	0.5-1.3	0.6-1.4	<0.5	2.6-6.7
Brassicasterol	5.0-13.0	0.0-0.3	<0.1	0
Δ^5-Campesterol	24.7-38.6	15.8-24.2	8-12	18.7-27.5
Stigmasterol	0.0-0.7	15.9-19.1	7-11	8.5-13.9
β-Sitosterol	45.1-57.9	51.7-57.6	50-62	50.2-62.1
Δ^5-Avenasterol	3.1-6.6	1.9-3.7	1.5-7	0-2.8
Δ^7-Stigmasterol	0.0-1.3	1.4-5.2	20	0.2-2.4

Sesame	4 01-18 957	Almond	2660
Safflower	2095-2647	Hazelnut	1200
Soybean	1837-4089	Hempen	3700

fish oils, which are sometimes very rich in vitamins A (see Section 5.2.5.3) and D (see Section 5.3.5.1).

3.7.6 Lipophilic pigments

Plant lipids contain various natural dyes, particularly carotenoids (see Section 9.9.2.3.3) and chlorophylls (see Section 9.2.2). Of the animal fats, only butter has an important natural carotenoid pigment content. Carotenoid pigments are added to margarines as additives (see Section 11.4.1.5).

3.7.7 Natural antioxidants

In addition to tocopherols, vegetable oils, especially olive, sesame and soybean oils, contain natural antioxidants that are described elsewhere (see Section 11.2.2.4).

Table 3.43 Major steroids in maize oil.

Steroids	Composition (%)	Steroids	Composition (%)
4,4-Dimethylsterols		***4-Demethylsterols***	
Cycloartenol	0.6	Cholesterol	traces

3.8 Reactions

3.8.1 Reactions of fatty acids

Chemical reactions of fatty acids involve the carboxyl group, as well as the hydrocarbon residue of the molecule, particularly the double bonds and neighbouring methylene groups. The reactions of the hydrocarbon chain are common to free fatty acids and to their esters.

3.8.1.1 Formation of salts

Although fatty acids are relatively weak acids, they readily form salts with metal cations or organic bases, most easily with alkali metal cations and with ammonia. These compounds are called **soaps**.

Soaps of alkali metals are called tensides. Sodium soaps of unsaturated fatty acids and medium-chain saturated fatty acids are very soluble in water (this corresponds to a high critical micellar concentration), but soaps of saturated acids with long chains ($>C_{14}$) dissolve better if the temperature is raised (this corresponds to a very low critical micellar concentration). Technologically this is utilised specifically in the formation of sodium soaps in alkaline neutralisation (refining) of vegetable oils, when free fatty acids are soluble in oil, but their soaps are soluble in water. This reaction occurs at the water/oil interface in an emulsion. Sodium salts of fatty acids are important for the production of toilet soaps, detergents and cleaning agents. Potassium soaps are more alkaline and have a significantly higher detergent effect, but are now limited in their production.

Soaps of divalent cations and aluminium soaps are called **metal soaps**. They have a hydrophobic character and therefore are of great significance in non-food applications in industry and construction. They are seldom found in foods. Calcium and magnesium soaps commonly arise from alkaline soaps in hard water, but they are also natural components of foods at low levels. The concentrations at which soaps occur naturally have no significant effect on the sensory and nutritional value of a food or its functional properties. However, higher concentrations of soaps may lower the acidity and negatively affect some functional properties of the food and cause diarrhoea. Calcium soaps may be used as a source of calcium in the diet of dairy cows.

Soaps only form true solutions in water at a high dilution. Concentrated solutions of soaps, after exceeding the so-called critical micellar concentration, form micelles, which are agglomerations of many molecules where the polar groups are directed to the surface and the hydrocarbon chains into the interior of micelles. Solutions of alkali soaps hydrolyse in water and thus produce an alkaline solution. Salts of divalent cations, mainly of calcium and magnesium, are practically insoluble in water and in organic solvents they only dissolve with difficulty. These salts are mixtures of varying compositions and with different ratios of cations and acyls. Soaps of fatty acids and other acidic components, such as phosphoric acid derivatives, can also occur in foods.

3.8.1.2 Esterification reactions

One of the main reactions of the carboxyl group of fatty acids is esterification. This is an ionic reaction, which is usually catalysed by acids, that proceeds similarly to the esterification of other organic carboxylic acids. Esterification of higher fatty acid usually takes place at high temperatures (autocatalysis) or under catalysis of strong acids (Figure 3.11). In fatty acids in foods the process is often catalysed by lipases. Esterification or interesterification of fatty acids, which is used in specific instances, is catalysed by microbial lipases. This is discussed again in the section dealing with reactions of triacylglycerols, because it is of greater significance in their conversion.

In food technology, esterification is usually employed in the production of monoacylglycerol emulsifiers, obtained by esterification of glycerol with fatty acids. The main reaction products are mono- and diacylglycerols. Interesterification (glycerolysis) of fat is usually a more convenient reaction. Similarly, various other emulsifiers that are used as food additives (see Section 11.5.2) are produced from glycols, glycerol, hydroxy acids and sugars. Esterification is also utilised in the manufacture of particular dietary fats (triacylglycerols) with medium chain fatty acids (caproic and capric). A wide range of esters that act as wax analogues, such as 2-propyltetradecanoate (2-propylmyristate), are manufactured by the pharmaceutical and cosmetics industries.

The carboxyl group can react also with the hydroxyl group of hydroxy acids that are produced either during the oxidation of fats or occur naturally in the fats. These reactions (which are in fact polycondensations) yield products called estolides (Figure 3.12).

3.8.1.3 Formation of amides

Naturally occurring fatty acid amides are described in Section 3.6.1. In non-food uses of lipids, fatty amides are produced synthetically in industry for use as ingredients of detergents, lubricants, inks and many other products. Ammonium salts of fatty acids are gradually dehydrated to amides and aliphatic nitriles that are used for the production of fatty primary amines, which are then used as reactants for the synthesis of cationic and amphoteric surfactants.

Amides of fatty acids are also formed from fatty acids during thermal treatments by reaction with ammonium salts, amines or amino acids (see Section 8.2.10.1.3).

3.8.1.4 Isomerisation reactions of unsaturated acids

Double bonds of unsaturated fatty acids can isomerise so that they change their steric configuration (*cis–trans* isomerisation, also

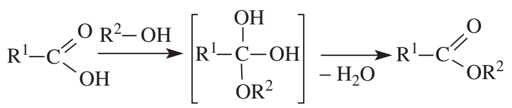

Figure 3.11 Esterification of fatty acids.

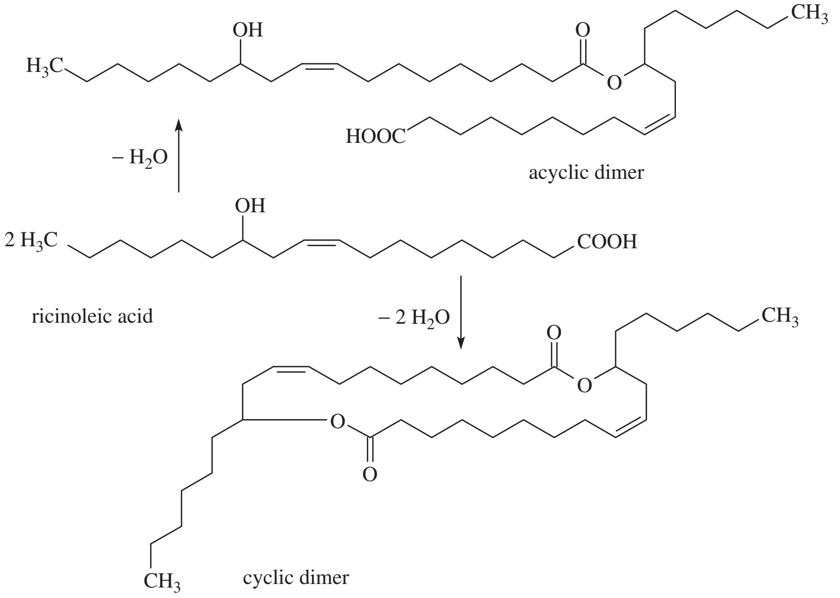

Figure 3.12 Formation of estolides from ricinoleic acid.

known as geometrical isomerisation) or so that the double bond shifts in the hydrocarbon chain (positional isomerisation).

3.8.1.4.1 Geometrical isomerisation

Double bonds of unsaturated fatty acids in natural lipids are almost exclusively in the *cis* configuration, although *trans* double bonds are thermodynamically more stable. Under equilibrium conditions, the ratio of *cis* to *trans* double bonds is approximately 30:70. Therefore, under appropriate conditions (if free radicals are temporarily created and electrons can move to the carbon with an sp^2 hybridisation) an interconversion between *cis* and *trans* isomers occurs. This happens, for example, during heating, autoxidation and hydrogenation.

Thermally induced geometrical isomerisation is a non-equilibrium reaction, which means that the isomerisation proceeds until exhaustion of the *cis* double bonds. The degree of isomerisation achieved is thus a function of temperature and time of heating. This isomerisation occurs in particular during deodorising and physical refining of oils and fats. Monoenoic fatty acids (such as oleic acid) require heating to temperatures around 270 °C at which *cis–trans* isomerisation of the allylic system of one double bond proceeds at a reasonable rate. Pentadienoic systems of isolated double bonds in dienoic acids, which have two double bonds separated by methylene group, are far less stable.

The splitting off of a hydrogen radical from the methylene group adjacent to the double bonds creates a free radical transformed into the mesomeric form (Figure 3.13 and Figure 3.14). The

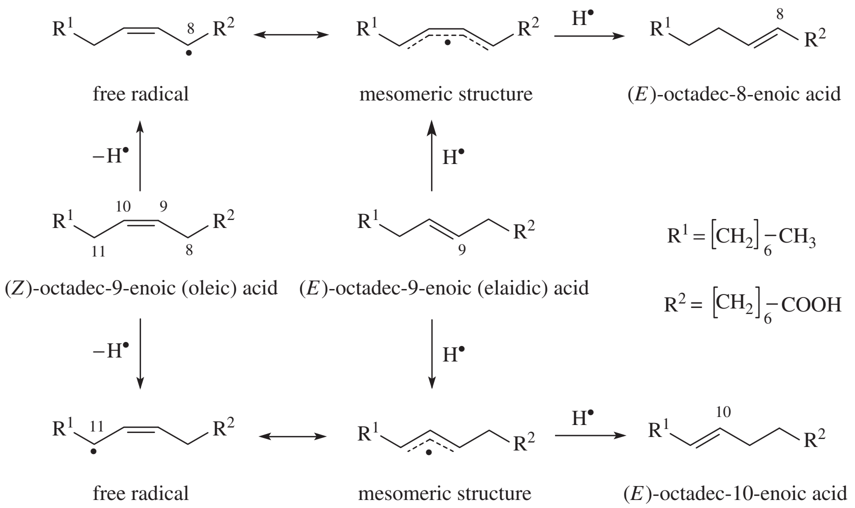

Figure 3.13 Isomerisation of monoenoic fatty acids.

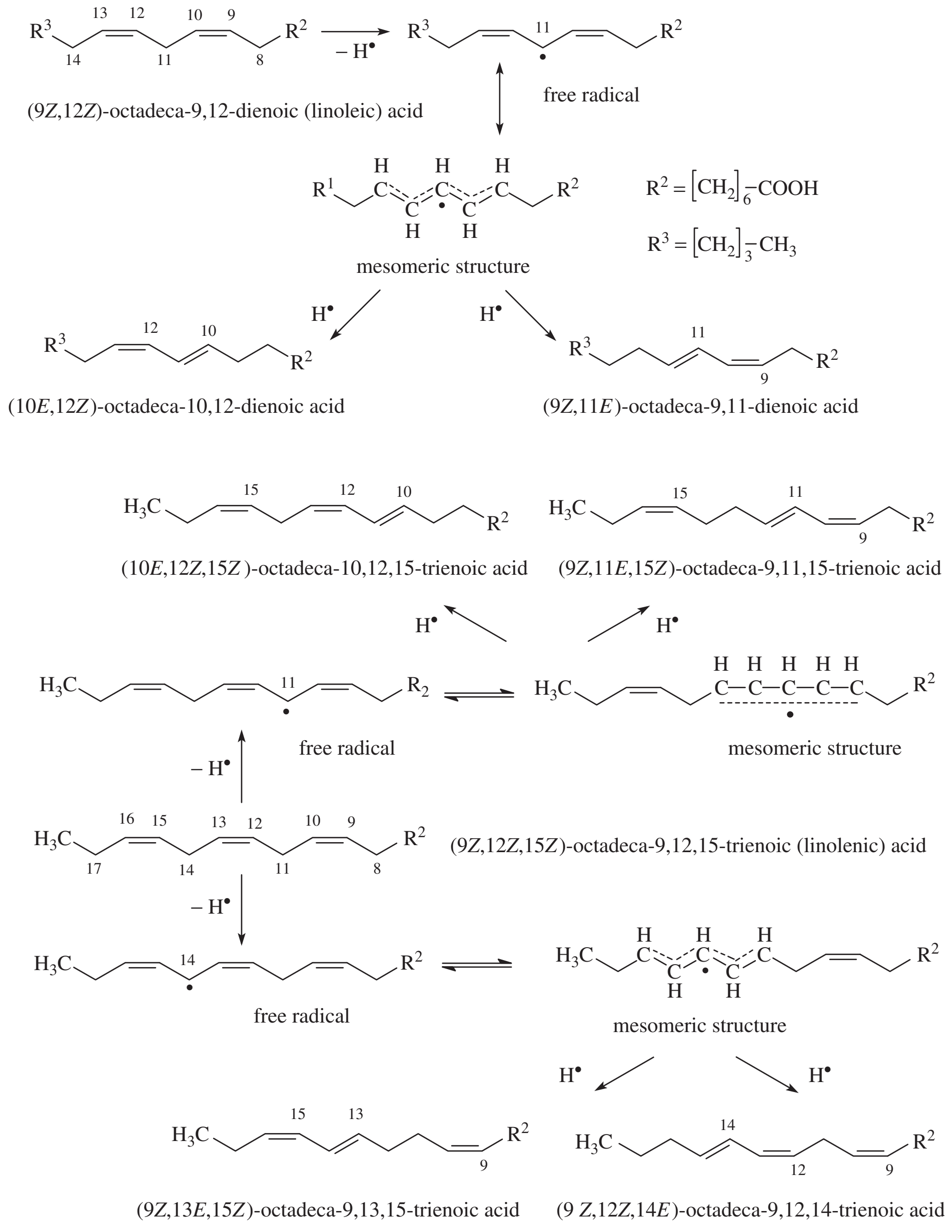

Figure 3.14 Isomerisation of polyenoic fatty acids.

reaction of the mesomeric form with a hydrogen radical forms the most stable system possible, which is usually a system with one or two *trans* double bonds. Therefore, *cis–trans* isomers and *trans–trans* isomers of linoleic acid form at a significant rate at temperatures 240 °C and higher. Therefore, deodorised edible oils always contain small amounts of isomerised dienoic acids. Acids with three double bonds have an even greater tendency to isomerise, because each acyl contains two labile methylene groups. Linoleic acid yields *cis–trans*, *trans–cis* and *trans–trans* isomers. Linolenic acid mainly produces *cis–cis–trans*, *trans–cis–cis*, *cis–trans–cis* and *trans–cis–trans* isomers at a significant rate at temperatures of 210–220 °C and higher. Oils with a higher content of trienoic, tetraenoic, pentaenoic and hexaenoic acids are very easily isomerised at temperatures above 200 °C, which means that in practice these oils cannot be deodorised.

In parallel with saturation of the double bonds during the catalytic hydrogenation of oils, geometrical isomerisation of fatty acids via intermediate free radicals also occurs. Isomerisation using a nickel catalyst proceeds to equilibrium; therefore, partially hydrogenated fats can contain 50–60% of *trans* isomers of fatty acids, especially of octadecenoic acids. The main isomer is usually elaidic acid. Similarly, *trans* isomers of octadecenoic acid are formed by biohydrogenation in the composite stomach of ruminants where the main *trans* isomer is vaccenic acid. The process, in this case, is far from equilibrium so the *trans* isomers content in the milk fat of ruminants is about 3–6%.

The double bond also isomerises during oxidation, which begins with the formation of a free radical at the position adjacent to the double bond. In this case, the amount of *trans* isomers is proportional to the amount of formed hydroperoxides.

3.8.1.4.2 Positional isomerisation

In unsaturated fatty acids, positional isomerisation is also possible, when the double bond shifts by one carbon atom either away from the carboxyl or towards the carboxyl. Positional isomerisation is usually associated with *cis–trans* isomerisation and takes place under similar conditions to the *cis–trans* isomerisation, on heating to temperatures higher than about 240 °C. Isolated double bonds are relatively stable, but the pentadiene systems easily isomerise to conjugated systems. Two conjugated isomers are formed from linoleic acid, whereas linolenic acid yields four conjugated isomers (Figure 3.14).

In deodorised oils, where the oil temperature reaches 220–260 °C for several tens of minutes, conjugated dienes are always present in small amounts. The isomerisation is catalysed by bleaching clays and other materials with an active surface. Conjugated triene systems do not accumulate in oils, as they are quickly cyclised or polymerised.

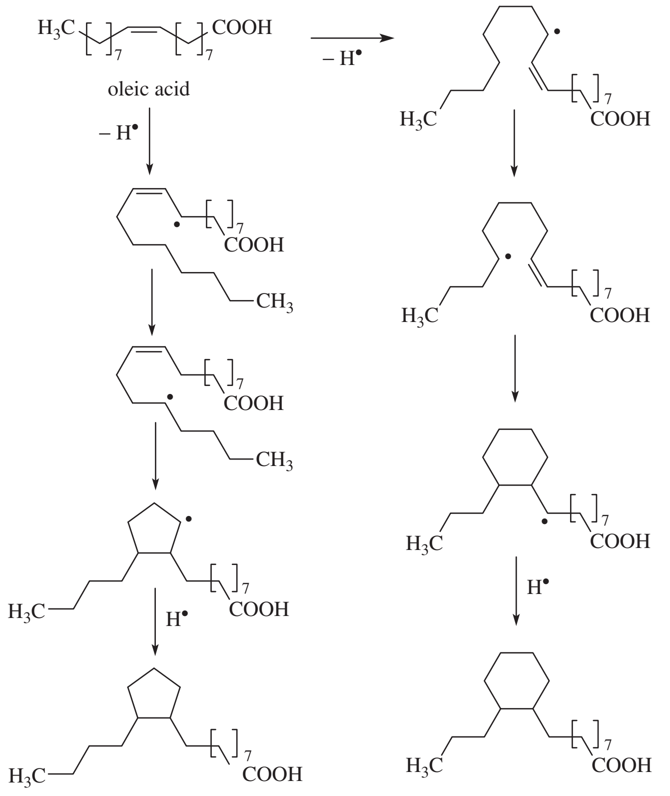
Conjugated unsaturated fatty acids also form at the beginning of hydrogenation and during autoxidation of unsaturated fatty acids. In these processes, even isolated double bonds isomerise. The partially hydrogenated oils, which originally contained linoleic and linolenic acids, in addition to isomers with double bonds at positions C-9, C-12 and C-15, thus also contain other isomers of octadecenoic acids with double bonds in positions C-5 to C-16.

Geometric and positional isomers arising from biohydrogenation of unsaturated fatty acids in the rumen of ruminants become components of lipids of milk and meat. Linoleic acid yields a mixture of positional and geometric isomers called conjugated linoleic acid. The main constituents of this mixture are (9*Z*,11*E*)- and (9*E*,11*Z*)-octadecadienoic acids. The first acid represents about 90% of conjugated acids of cows' milk and more than 75% of the conjugated acids of tallow. Also formed in small amounts are (8*E*,10*Z*), (9*Z*,11*Z*)-, (9*E*,11*E*)-, (10*Z*,12*Z*)- and (10*E*,12*E*)-octadecadienoic acids and so on. Conjugated linoleic acid has some beneficial effects, for example anticarcinogenic, antiatherogenic, antidiabetic and immunomodulatory.

3.8.1.5 Cyclisation of unsaturated acids

The unsaturated fatty acids are also transformed, via the radicals formed during heating to higher temperatures (e.g. during frying), into cyclic fatty acids with five- and six-membered rings. Cyclic acids derived from oleic acids are saturated compounds. The products formed from linoleic acid have one double bond. These products include cyclopentene acids and cyclopentane and cyclohexane acids with one *cis* double bond in the side chain. Linolenic acid forms products with two double bonds, such as cyclopentene and cyclohexene acids with one *cis* double bond in the side chain.

After deep frying, oils contain cyclic fatty acids bound in triacylglycerols (free acids evaporate during frying) at a concentration



9-(2-butylcyclopentyl)nonanoic acid 9-(2-propylcyclohexyl)nonanoic acid

Figure 3.15 Mechanism of cyclic fatty acids formation.

of 0.1–7 g/kg. There are approximately twice as many acids with five-membered rings as with six-membered ring. The mechanism for the formation of cyclic fatty acids from oleic acid is given in Figure 3.15. The structures of other products derived from oleic acid are represented in formulae **3-131** and **3-132**, two of the numerous products of linoleic acid cyclisation are given in formulae **3-133** and **3-134**, whilst formulae **3-135** and **3-136** show two of the many cyclisation products of linolenic acids.

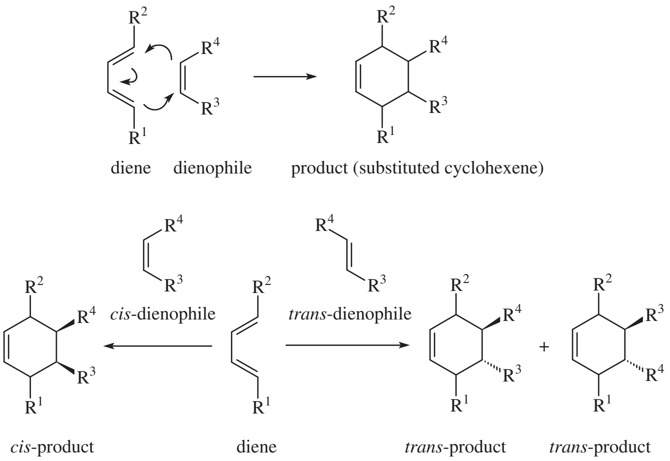

Figure 3.16 Diels–Alder mechanism of polymerisation of polyenoic fatty acids (R^1, R^3 = residues of hydrocarbon chains, R^2, R^4 = residues of chains with carboxylic groups).

3.8.1.6 Polymerisation of unsaturated acids

Polymerisation refers to processes in which the overall composition of a compound does not substantially alter, but the molecular weight increases by a multiple of the weight of the monomer. Polymers usually arise when a system can create free radicals. Therefore, polymerisation reactions usually accompany isomerisation reactions and the formation of cyclic fatty acids under extreme heating. In the fully refined (and thus also deodorised) edible oils, polymers represent several tenths of a percent, but their content increases during heating. Oils with a polymer content of more than 10% are not recommended for use.

Under a low partial pressure of oxygen and at higher temperatures (such as during frying), cyclic and linear polymers are formed, in which the original fatty acids are bound together mainly by C–C bonds. When an adequate supply of air is present (in an environment with a high partial pressure of oxygen) and at lower temperatures, the oxidation of polyenoic fatty acids produces a large number of free radicals containing oxygen. In addition to cyclic and linear polymers of the type C–C, their recombination yields linear polymers with ether bonds (C–O–C) and linear polymers with peroxide bonds (C–O–O–C). Therefore, oxidation is always accompanied by polymerisation, especially in more advanced stages of the reaction. Such a polymerisation is called **oxypolymerisation**. Oxypolymerisation is associated with secondary polymeric products of autoxidation of fatty acids. Under typical conditions encountered during food processing, monoenoic fatty acids barely polymerise and dienoic fatty acids usually only form dimers. Trienoic fatty acids, however, polymerise very readily, and can also form higher oligomers.

Cyclic dimers, which are actually substituted cyclohexene derivatives, arise during polymerisation by the Diels–Alder reaction. This reaction takes place via a cyclic transition state and is therefore also referrd to as cycloaddition. In this reaction, the so-called dienophile, a substituted alkene (olefin), which is a monoenoic fatty acid, reacts with a conjugated *cis,cis*-dienoic fatty acid (Figure 3.16).

If the dienophile has two different substituents, various stereoisomers may be formed. If the substituents in the dienophile are in the *cis* position, the reaction product (substituted cyclohexene) also has substituents in the *cis* position and vice versa.

The reaction can take place intermolecularly, between two fatty acids bound in two different triacylglycerol molecules, or intramolecularly, within a single triacylglycerol fatty acid. An example of a cyclic dimer of the cyclohexene type is the reaction of linoleic acid with 10,12-octadecadienoic acid (Figure 3.17). An example of a cyclohexene structure resulting from the intramolecular reaction of two unsaturated fatty acids bound in a triacylglycerol molecule is shown in Figure 3.18. Cyclic dimers of the cyclohexene type containing an additional double bond and also a system of conjugated double bonds may react further to form tricyclic dimers (Figure 3.19). If the trienoic fatty acids forming a dimer still contain

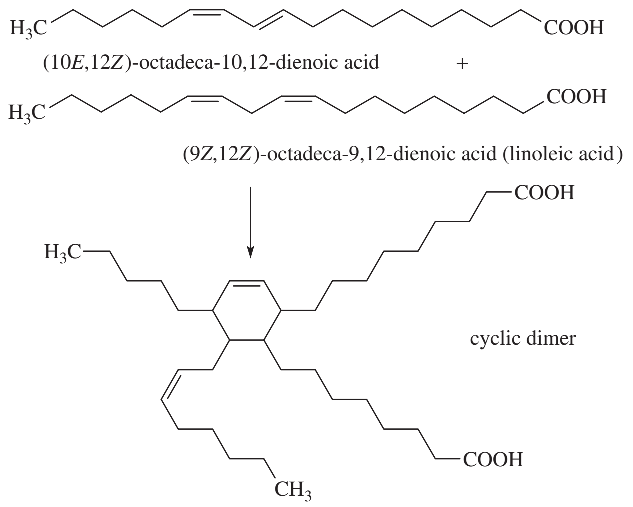

Figure 3.17 Dimerisation of dienoic fatty acids to cyclohexene derivatives.

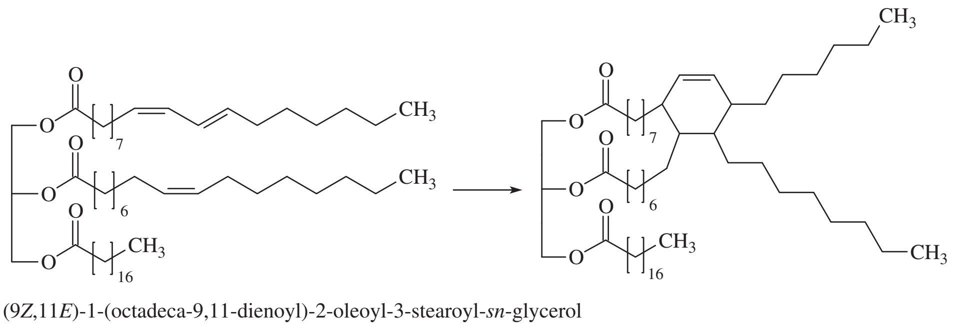

Figure 3.18 Structure of cyclic dimers in a triacylglycerol molecule.

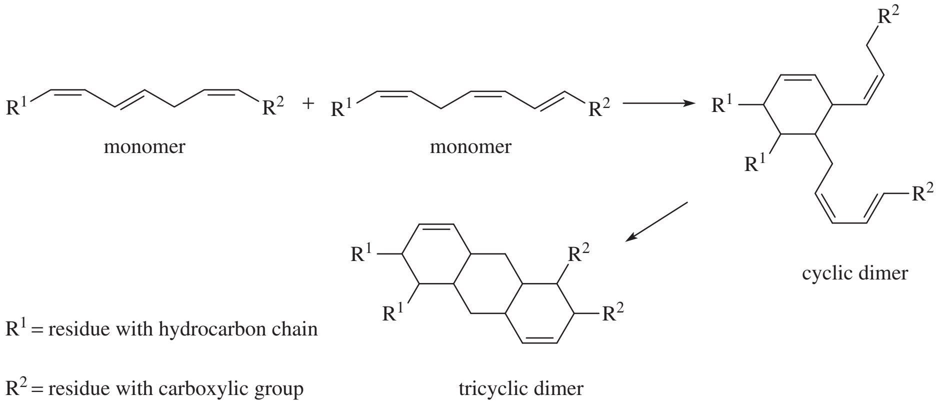

Figure 3.19 Formation of condensed bicyclic dimers.

a system of two conjugated double bonds in the molecule, there is the possibility of further reaction to form a trimer (Figure 3.20).

In addition to the cyclic dimers of the cyclohexene type, some cyclic cyclopentane C–C dimers and acyclic C–C dimers may also be formed. The mechanism of their formation (Figure 3.21) is demonstrated for reactions of one of the four main free radicals generated from oleic acid. An acyclic dimer forms by recombination of two radicals (reaction A in Figure 3.21), but also by addition of a radical to the double bond of another radical (reactions B and C in Figure 3.21) and by a reaction (termination) with a hydrogen radical (reaction D in Figure 3.21). The formation of bicyclic derivatives is illustrated in Figure 3.22.

In practice, mixed linear polymers in fats arise from radicals of different fatty acids. Free radicals can also be formed by splitting

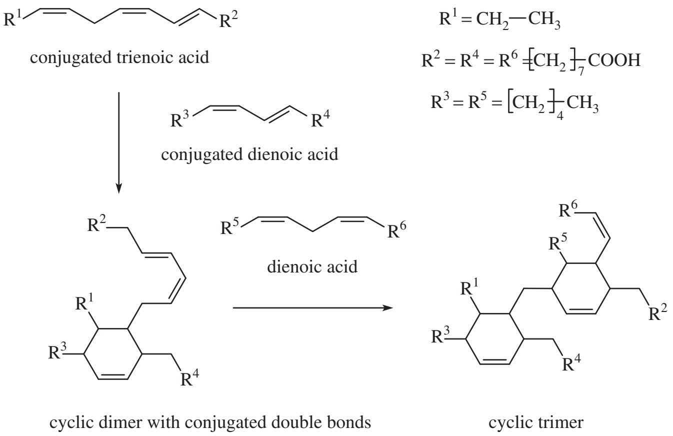

Figure 3.20 Formation of oligomers from trienoic fatty acids.

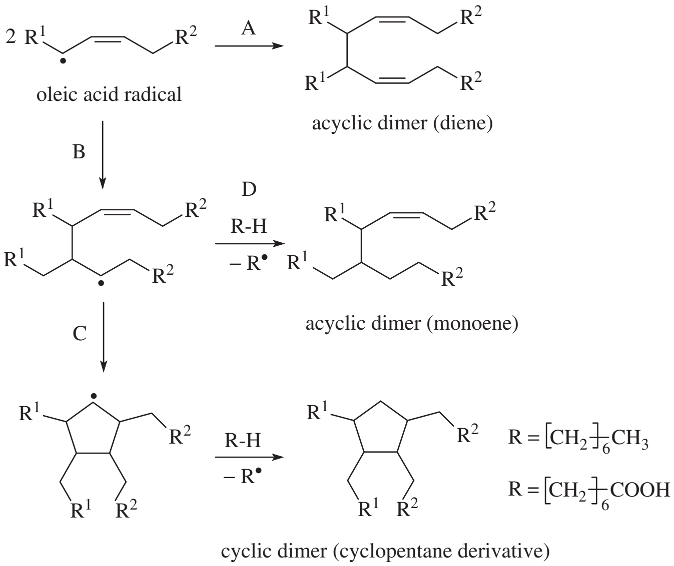

Figure 3.21 Formation of dimers from free radicals of oleic acid.

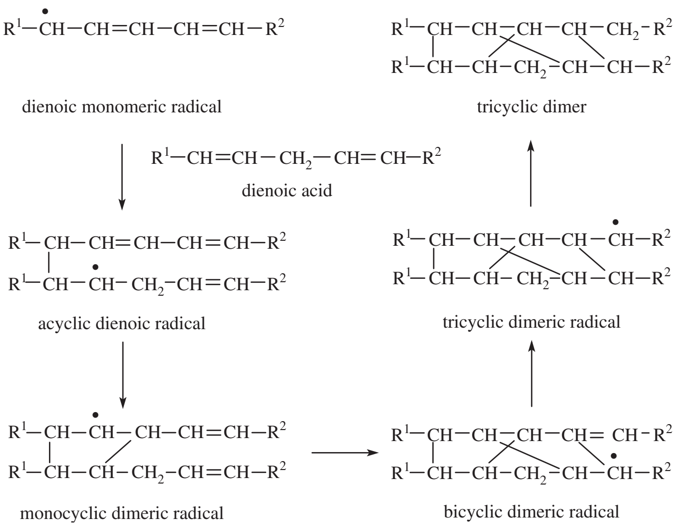

Figure 3.22 Formation of oligocyclic dimers in heated dienoic fatty acids.

the chain around the double bond. They therefore have a smaller number of carbon atoms, and their combinations with free radicals of fatty acid that have not split yield a dimer with the number of carbon atoms being between a monomer and a dimer. In oils used for frying, cyclohexene and cyclopentane structures, bicyclic derivatives, acyclic dienes and other products have been identified. Polymerisation mainly occurs in fats exposed to higher temperatures for a long time, for example in frying oils. It manifests itself through colour changes and deterioration of fat functional properties, mainly by foaming and increased viscosity.

For example, oleochemistry produces specific so-called dimeric fatty acids for the production of adhesives.

3.8.1.7 Hydrogenation reaction of unsaturated acids

Hydrogenation of double bonds of fatty acids, technically this is commonly known as hardening of oils and fats, is a chemical modification of oils and fats in the double bonds of unsaturated fatty acids. The common confusion between the terms 'hydrogenation' and 'hardening' reflects the fact that the primary objective when introducing this technology was to change the consistency of liquid oils and fats into viscoplastic substances of a required consistency. Hydrogenation was an important technological development in the fat industry. Owing to the growth of human population in the 19th and 20th centuries, the traditional animal fats, lard and butter, that were suitable for baking, for addition to dough, for use as spreadable fats and other purposes, became scarce. At the same time, there was a relative abundance of fish oils and whale blubber[19] in the world, but these fats were not suitable for direct use because of their adverse physical and organoleptic properties. Therefore, suitable procedures were sought to produce solid fats (correctly known as viscoplastic thixotropic substances) from liquid oils. The best procedure seemed to be the industrial hydrogenation of double bonds, which was introduced in 1902–1910. Paradoxically, in Europe, specifically oils and fats of animal origin were originally hydrogenated, while in the United States soybean and cottonseed oils began to be hydrogenated gradually before World War II. In Europe, vegetable oils began increasingly hydrogenated in the 50th when the whaling era ended.

3.8.1.7.1 Hydrogenation of double bonds

Oils can be either partially or fully hydrogenated through the hydrogenation process. Partially hydrogenated oils, such as those found in salad dressings, produce hardened – but not solid – fats. Fully hydrogenated oils, such as shortenings, are solid fats. Food items that contain hydrogenated oils can remain solid or semisolid at room temperature and have a comparatively long shelf life, because they are more stable against autoxidation than the original oils.

The hydrogenation of unsaturated organic compounds, that is treatment with gaseous hydrogen in the liquid phase on solid metal catalysts (based on Cu, Fe, Co and Ni) to decrease the number of double bonds, was developed at a time when there was demand for solid fats. The procedure developed by Wilhelm Norman in 1901 introduced a nickel-based catalyst on a solid carrier. This active catalyst was formed by depositing partially reduced nickel from nickel oxide (NiO) on a diatomaceous earth. Molecules of the reaction partners, hydrogen and triacylglycerols, are adsorbed, through the double bond, onto the surface of the active metal. The hydrogenation is then conducted via the adsorbed free radicals of the fatty acids bound in the triacylglycerols that form a complex with the catalyst. This complex reacts with hydrogen and dissociates to give a hydrogenated fatty acid and the catalyst (Figure 3.23). In addition to the reduction of the double bond, positional isomerisation (migration of the double bond) and, in particular, geometric isomerisation (*cis*–*trans* isomerisation) also proceed. Unsaturated fatty acids in the *trans* configuration have melting points much higher than the corresponding *cis* unsaturated fatty acids, thus contributing to the consistency of solid hydrogenated oils. The extent of *cis*–*trans* isomerisation and positional isomerisation is often even greater than that of the hydrogenation reactions, for example in the production of fats for making candies and icings. It is therefore more representative to describe this situation by the term **hardening**, which includes both hydrogenation and isomerisation reactions.

The hydrogenation reaction is controlled by the nature of the fatty acid to be hydrogenated, the nature and concentration of the catalyst, hydrogen pressure, reaction temperature and degree of agitation. Hydrogenation of fatty acids in triacylglycerols is not a function of their location. The individual steps taking place in a hydrogenation process include transfer and/or diffusion of

[19]The thick layer of fat under the skin of marine mammals provides an energy store and an effective insulating layer, preventing the loss of body heat to the surrounding water. Blubber has been used (when boiled down) in food processing, engineering, cosmetics and printing, but all of these products can now be produced synthetically.

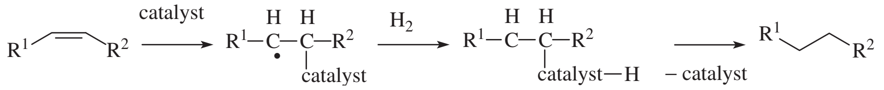

Figure 3.23 Scheme of hydrogenation of unsaturated fatty acids and their esters.

reactants and products to and from the bulk of the liquid oil phase and the outer surface of the catalyst, adsorption, hydrogenation and isomerisation, desorption and transfer. Adsorption of the reactants on the catalyst surface is important to control the selectivity of the hydrogenation and isomerisation reactions during the process. Once oil has been hydrogenated, the result is a substance that is made up of stiffened fat molecules. Because the crucial aspects are the physical properties of hydrogenated oil (melting point and consistency), the hydrogenation of double bonds is usually incomplete and only 25–40% of double bonds are reduced. This procedure is called partial catalytic hydrogenation.

A significant property of partial catalytic hydrogenation is the selectivity of hydrogenation. The hydrogenation of trienoic acids is the fastest reaction. The hydrogenation of dienoic fatty acids is a slower reaction, and the slowest reaction is the hydrogenation of monoenoic fatty acids (in oils originally containing linolenic, linoleic and oleic acids). The selectivity of hydrogenation can be expressed as the ratio of the reaction (hydrogenation) rate of linoleic acid transformed into monoenoic acids to the reaction rate of monoenoic acids transformed into saturated acids (Figure 3.24). In a very selective hydrogenation ($k_1 > k_2$), for example, linoleic acid in sunflower oil is selectively hydrogenated to octadecenoic acid isomers (incorrectly called isooleic acids). In a non-selective hydrogenation ($k_1 = k_2$ or $k_1 < k_2$), a larger amount of stearic acid is formed. Octadecenoic acids are transformed into stearic acid faster than they are generated. The selectivity of triacylglycerols defines the resulting distribution of stearic acid in the triacylglycerol molecules. It is maximum at a uniform distribution of stearic acid in triacylglycerols and zero if stearic acid accumulates in the form of tristearoylglycerols that have a high melting point, which causes the hydrogenated tallowy flavour of hydrogenated oils.

Oils previously used in blends of emulsified and edible fats were only partially hydrogenated (their melting point did not exceeded the temperature of the oral cavity, because they would then have had a tallowy flavour). The process ends with the reduction of the double bonds to about 30% on using selective conditions, where two double bonds of trienoic fatty acids and one double bond of dienes were hydrogenated, which ensured a minimum increase in the stearic acid content. The main reaction products of partially hydrogenated oils are monoenoic fatty acids, in which the ratio of *cis* and *trans* isomers is about 30 : 70. The content of saturated acids in partially hydrogenated oils does not increase significantly, while the *trans* unsaturated fatty acids content reaches several tens of percent. The predominating *trans* isomer is elaidic acid. Examples of the composition of hydrogenated oils are listed in Table 3.44.

The extent of geometric isomerisation during hydrogenation can be somewhat reduced by using catalysts based on precious metals. The resulting products are usually liquid and contain lower amounts of *trans*-monoenoic fatty acid and of stearic acid. The *trans* isomers content still remains at 1–10%.

Unfortunately, a significant degree of *cis*–*trans* isomerisation during hydrogenation of oils simultaneously leads to the formation of *trans* fatty acids in some triacylglycerols, which represent a

serious risk of cardiovascular diseases. This negative effect of *trans* isomers of fatty acids occurring in partially hydrogenated oils has stimulated efforts to achieve their full elimination, which for industry means producing no partially hydrogenated fats. Major manufacturers have actually abandoned this technology and have been forced to replace it by another process, which is usually a transesterification procedure in combination with fractionation of triacylglycerols (fractional crystallisation). Hydrogenation of oils for food purposes is now only used for the production of **fully hydrogenated fats**, where the residual content of monoenoic fatty acids is 1–1.5% and the residual content of *trans*-monoenoic fatty acids is 0.7–1.0%. Owing to the long reaction time, hydrolysis of triacylglycerols on the surface of the Ni-catalyst occurs (the water content in oil is 0.03–0.05%, which corresponds to one mole of water per 40 moles of triacylglycerols) and there is an increase in the free fatty acids, which must be removed by refining. These fats, due to their very high melting points, have no direct use and are employed as raw materials for transesterification.

3.8.1.7.2 Side reaction during hydrogenation

During partial catalytic hydrogenation, various side reactions also proceed, the most important of which is double bond geometric and positional isomerisation, includes the special case of conjugated double bond formation. After adsorption on the surface of the catalyst, the fatty acid is not necessarily hydrogenated because it is often desorbed just before the adsorbed double bond reacts with hydrogen. The double bond adsorbed on the surface of the catalyst can isomerise and the fatty acid can be desorbed as a *trans* fatty acid. Indeed, in partially hydrogenated fats, up to 70% of double bonds of fatty acids can be in the *trans* configuration. Double bonds can also migrate to different positions in the chain (Figure 3.25).

For example, partially hydrogenated oleic acid contains isomers with double bonds in positions Δ7 to Δ11. The unsaturated fatty acids content is 42% of the total unsaturated fatty acids, in which the main geometrical isomer is elaidic acid (13%), followed by Δ8 (10%), Δ10 (10%), Δ7 (7%) and Δ11 (7%) positional isomers. In natural menhaden oil mainly *cis*-Δ11 isomers occur, but in hydrogenated oil positional isomers are present with double bonds in positions Δ3–Δ17, of which *cis*-Δ6, *cis*-Δ9 and *cis*-Δ11, *trans*-Δ11 and *trans*-Δ13 isomers predominate. Partially hydrogenated vegetable oils and fats contain mainly isomers of octadecenoic acids. The representation of individual isomers may vary depending on the fatty acid composition of the starting oil. The hydrogenated oils, originally containing oleic, linoleic and linolenic acids, contain Δ4–Δ16 fatty acid isomers. Their distribution is monomodal and the major positional isomer is elaidic acid. Other isomers are *trans*-Δ10, *trans*-Δ11 and *trans*-Δ12 isomers. Distribution of *trans*-octadecenoic acids in hydrogenated fats is very different from their distribution in cows' milk fat (Table 3.45). The nutritional value of various positional isomers has not been fully investigsted.

3.8.1.7.3 Hydrogenation of carboxyl or ester groups

At high temperatures, under pressure and using Adkinson catalysts from intermetallic compounds, the fatty acid carboxyl groups are

also hydrogenated to primary hydroxyl groups and the hydrogenation of esters gives two alcohols (Figure 3.26). Alcohol R^2–OH is usually methanol. These hydrogenations are very important in oleochemistry for the production of fatty alcohols as hydrophobic substances for the production of surfactants (e.g. dodecanol and tetradecanol from coconut and palm kernel oils).

3.8.1.7.4 Enzymatic hydrogenation in ruminants

The diet of ruminants consists mainly of grass and leaves, where the lipids contain a large amount of linolenic acid. After ingestion, the food remains in the rumen for a long time before digestion. The rumen microorganisms breakdown the food to make it more palatable. The main concern is the cellulose, which is hydrolysed by cellulases. Rumen microorganisms also produce enzymes that hydrogenate polyenoic fatty acids. This enzyme-catalysed reaction proceeds by a mechanism similar to industrial catalytic hydrogenation. Analogous side reactions also occur that produce geometric and positional isomers of unsaturated fatty acids. Linolenic acid yields mainly (9*Z*,11*E*)-octadeca-9,11-dienoic (rumenic) acid, which exhibits antiatherogenic effects. To a lesser extent (10*E*,12*Z*)-10-octadeca-10,12-dienoic acid is produced, which provides anticarcinogenic and other beneficial effects and acts as a precursor of (*E*)-octadec-11-enoic (*trans*-vaccenic) acid, the major positional isomer of *trans*-octadecenoic acids in cows' milk fat. Therefore, depot and milk fats of ruminants contain higher amounts of *trans*-unsaturated fatty acids (Table 3.17) than fats of monogastric animals or vegetable oils, which contain up to 2% of *trans*-fatty acids.

3.8.1.8 Oxidation reactions

3.8.1.8.1 Classification

Oxidation reactions of the fatty acid hydrocarbon chains are common to free fatty acids and their esters, such as triacylglycerols. Carboxyl groups of free fatty acids, however, accelerate the decomposition of fatty acid hydroperoxides and can react with some oxidation products. In foods, the following types of oxidation reactions of lipids may occur:

- **autoxidation by triplet oxygen**
- **oxidation by hydrogen peroxide or hydroperoxides**
- **oxidation by singlet oxygen** (mostly photooxidation)
- **oxidation catalysed by enzymes** (lipoxygenases)
- **oxidation by metals** in higher valency
- **oxidation by quinones** and related compounds.

3.8.1.8.2 Autoxidation

Autoxidation of fatty acids is the most common type of oxidation under conditions suitable for the processing or storage of food. At normal temperatures, only unsaturated fatty acids are oxidised by atmospheric (triplet) oxygen. At higher temperatures, such as during baking, frying and roasting, autoxidation of saturated fatty acids also proceeds.

Autoxidation of the hydrocarbon chain of fatty acids, and of many other hydrocarbons, is a radical chain reaction that proceeds in three stages. The simplified reaction mechanism is shown in Figure 3.27. The first stage of the reaction is the formation of a free **hydrogen radical** ($H^•$) and a free fatty acid radical ($R^•$) formed by homolytic cleavage of the covalent bond **H**–C of the hydrocarbon chain. Energy needed to break down the **H**–C bond of fatty acids may be obtained from various sources. It may be heat energy (from a heating source), ultraviolet or radioactive radiation, or visible radiation (in the presence of photosensitisers in the case of a two electron oxidation by singlet oxygen; see Section 3.8.1.8.4). The dissociation energy of the **H**–CH– bond in the middle of the saturated fatty acid chain is 422 kJ/mol, the dissociation energy of the H_3C–CH–**H** bond at the end of its chain is 410 kJ/mol, the dissociation energy of the methylene group adjacent to the double bonds, –**H**–CH–CH=CH–, is 322 kJ/mol, but the dissociation energy of the methylene group between two double bonds is only 272 kJ/mol. The fission of the fatty acid (lipid) molecule also occurs by reaction with another free radical (immediate reaction of the hydrocarbon chain directly with oxygen is thermodynamically difficult) or by reaction with transition metals (see Section 3.8.1.8.6). This first stage is called the **initiation stage** (initiation) of an autoxidation reaction.

The resulting fatty acid (lipid) free radical ($R^•$) is very reactive, so it easily combines with an oxygen molecule, which is actually

Initiation reaction

R–H (fatty acid residue in lipid) → $R^•$ (free radical)

a biradical. This results in the formation of a peroxyl radical (R–O–O•). The peroxyl radical is also very reactive and splits off a hydrogen atom from another unsaturated fatty acid molecule with the formation of a **hydroperoxide** (R–O–OH) and another fatty acid free radical (R•). This second stage of the autoxidation reaction is called the **propagation stage** (propagation). The sequence of these two reactions in the propagation stage may be repeated just once or many more times; chains having more than 1000 steps have been observed. Therefore, autoxidation is called a radical chain reaction. The reaction of a fatty acid free radical with oxygen is much faster than the reaction of a peroxyl radical with a hydrocarbon chain of fatty acid. As a peroxyl radical reacts with a fatty acid molecule relatively slowly, this reaction therefore determines the reaction rate of the autoxidation.

If the concentration of free radicals in the reaction system is quite high, it is likely that two free radicals react together to form a relatively stable product, and the chain reaction ends. This third stage is called the **termination stage** (termination) of an autoxidation reaction.[20] With a limited supply of oxygen, when the rate of autoxidation depends on its partial pressure, the main radicals in the system are fatty acid radicals (R•) and the main termination reaction is their recombination. With an adequate oxygen supply, the reaction rate is independent of its partial pressure. This creates higher amounts of peroxyl radicals (ROO•) and the main termination reactions are then recombination of radicals of the fatty acids (R•) with peroxyl radicals and mutual recombination of peroxyl radicals.

Unsaturated fatty acids

Unsaturated monoenoic fatty acids split off hydrogen atoms relatively easily, at least the hydrogen from the methylene group that is adjacent to the double bond. Even less energy is needed to split hydrogen from dienoic and trienoic fatty acids. The primary reaction products of autoxidation are hydroperoxides. The number of double bonds remains unchanged, but the double bond is usually shifted by one carbon atom to either the carboxyl or methyl end; this is particularly easy in dienoic and trienoic fatty acids, because here the free radicals arise between two double bonds and are stabilised by mesomerism. The reaction with oxygen yields a peroxyl radical at one end of the mesomeric system, and the double bond is simultaneously rearranged from the *cis* configuration to the more stable *trans* configuration.

[20]Termination of hydrocarbon radicals is not the only recombination reaction. Other possibilities (depending on the structure of the radicals) are: (i) the termination by disproportionation, where hydrogen is eliminated, which yields an olefin ($R–CH_2–CH_2^{\bullet} \rightarrow R–CH{=}CH_2 + H^{\bullet}$), (ii) termination by transfer (e.g. in reaction with antioxidants), (iii) termination by recombination with a hydroxyl radical, which leads to an alcohol ($R-CH_2-CH_2^{\bullet} + HO^{\bullet} \rightarrow R–CH_2–CH_2–OH$) and (iv) further oxidation of the terminal hydroperoxide ($R-CH_2–CH_2^{\bullet} + O_2 \rightarrow R–CH_2–CH_2–O–O^{\bullet} \rightarrow R–CH_2–CH_2–O–OH$). In the terminal hydroperoxide, the link between oxygen atoms is then cleaved, which gives an alkanal ($R–CH_2–CH_2–O–OH \rightarrow R–CH_2–CH{=}O + H_2O$). Alternatively, the link between carbon atoms can be cleaved, which results in a shorter alkyl radical ($R–CH_2^{\bullet}$). Some of these reactions are discussed in relation to the secondary reactions of hydroperoxides.

Monoenoic acids

Autoxidation of oleic acid is illustrated in Figure 3.28 as an example of autoxidation of monoenoic acids. The C–**H** bond cleavage in the initial stage of the reaction happens in the vicinity of the double bond, which occurs on carbons C-8 or C-11 (the dissociation energy is 322 kJ/mol). The resulting fatty acid radical, which is called allylic radical, may or may not isomerise, therefore reactions of fatty acid radicals with oxygen in the propagation stage of the reaction produce four hydroperoxides (isomeric hydroperoxyoctadecenoic acids). At room temperature, the amounts are approximately the same, but are dominated to a certain extent by 8- and 11-hydroperoxides. These two hydroperoxides that are generated without the double bond shift, are a mixture of *cis*- and *trans*-isomers, while hydroperoxides formed by positional isomerisation of double bonds are *trans*-isomers.

Dienoic acids

The higher reactivity of the methylene group between two double bonds causes the oxidation process to take place almost exclusively at this carbon atom (dissociation energy is 272 kJ/mol). In the case of linoleic acid, the oxidation occurs at the C-11 methylene group and the main oxidation products are hydroperoxides with conjugated double bonds: (10*E*,12*Z*)- and (10*E*,12*E*)-9-hydroperoxyoctadeca-10,12-dienoic acids and also (9*Z*,11*E*)- and (9*E*,11*E*)-13-hydroperoxyoctadeca-9,11-dienoic acids. At room temperature or lower, it is mainly *cis,trans*- and *trans,cis*-hydroperoxides that are formed, while at higher temperatures mainly *trans,trans*-hydroperoxides arise.

11-Hydroperoxyoctadeca-9,12-dienoic acid (*cis*,*cis*-isomer) is formed at a low concentration (without double bond isomerisation). Radicals on carbons C-8 or C-14, adjacent to the double bond, are also formed to a lesser extent. As in the previous cases, these radicals give rise to the corresponding geometric isomers: 8-hydroperoxyoctadeca-9,12-dienoic and 10-hydroperoxyoctadeca-8,12-dienoic acids and 12-hydroperoxyoctadeca-9,13-dienoic and 14-hydroperoxyoctadeca-9,12-dienoic acids. These reactions of linoleic acid are given in Figure 3.29 and Figure 3.30.

Trienoic acids

In the initial stage of the autoxidation reaction, a linolenic acid C–H bond is cleaved preferentially at C-11 and C-14, that is, at the methylene groups located between two double bonds. The main oxidation products of autoxidation are four hydroperoxides with a system of two conjugated double bonds and an isolated third double bond, with hydroperoxyl groups located in positions C-9, C-12, C-13 and C-16. In fact, these hydroperoxides are a mixture of *cis*,*trans*- and *trans*,*trans*-isomers and the isolated double bond has the *cis* configuration (Figure 3.31).

The predominant oxidation products are 9-hydroperoxide and 16-hydroperoxide, as 12-hydroperoxide and 13-hydroperoxide are less stable and tend to transform into cyclic products (similarly to the reaction catalysed by lipoxygenase that produces prostaglandins). As in the case of linoleic acid, many other hydroperoxides are formed as minor products.

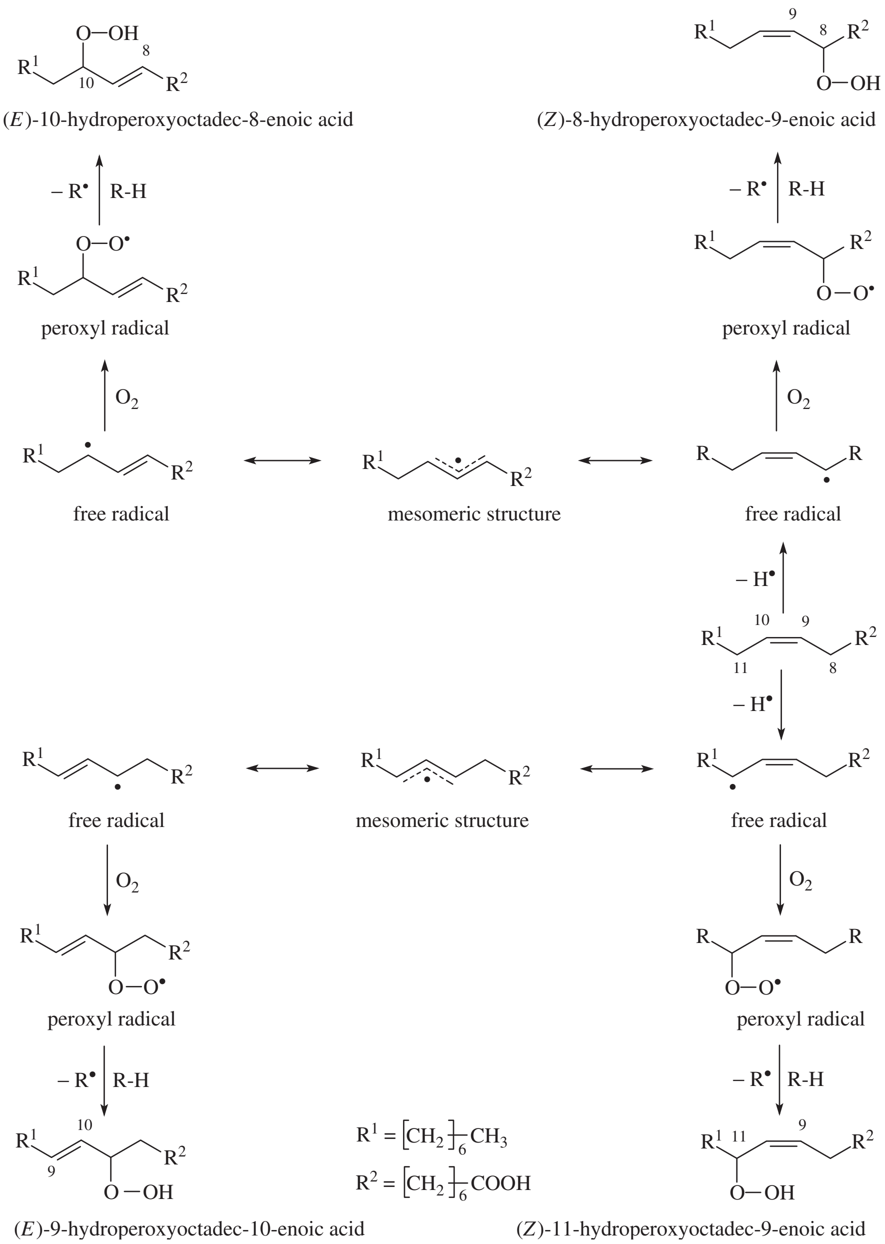

Figure 3.28 Autoxidation of oleic acid.

Saturated acids

Cleavage of the carbon–hydrogen bond in a saturated hydrocarbon chain requires a significant level of activation energy (422 kJ/mol), therefore this reaction does not come into practical consideration with normal temperatures. At higher temperatures however (corresponding to temperatures during baking, frying and roasting), this reaction is possible. In addition to the last carbon atom, all the other carbon atoms are almost equally prone to the creation of free radicals by the C–**H** bond cleavage. The third carbon and, to a lesser extent, the second and fourth carbons, are somewhat more reactive than the other carbon atoms of the hydrocarbon chain. The resulting free radicals bind oxygen through the formation of peroxyl radicals, and the reaction proceeds in a similar way to reactions of unsaturated acid peroxyl radicals, as already shown. Since saturated acids can form free radicals in many different positions along the hydrocarbon chain, the composition of the oxidation products is diverse.

Hydroperoxides

The primary products of autoxidation are sensorially indifferent hydroperoxides of fatty acids, that is products that have no taste and smell in comparison with other autoxidation products, such as aldehydes. Hydroperoxides, especially those of dienoic and trienoic acids, are very unstable compounds that decompose to either a hydrogen radical or a hydroxyl radical. In the former case, this decomposition yields a peroxyl radical, and in the latter

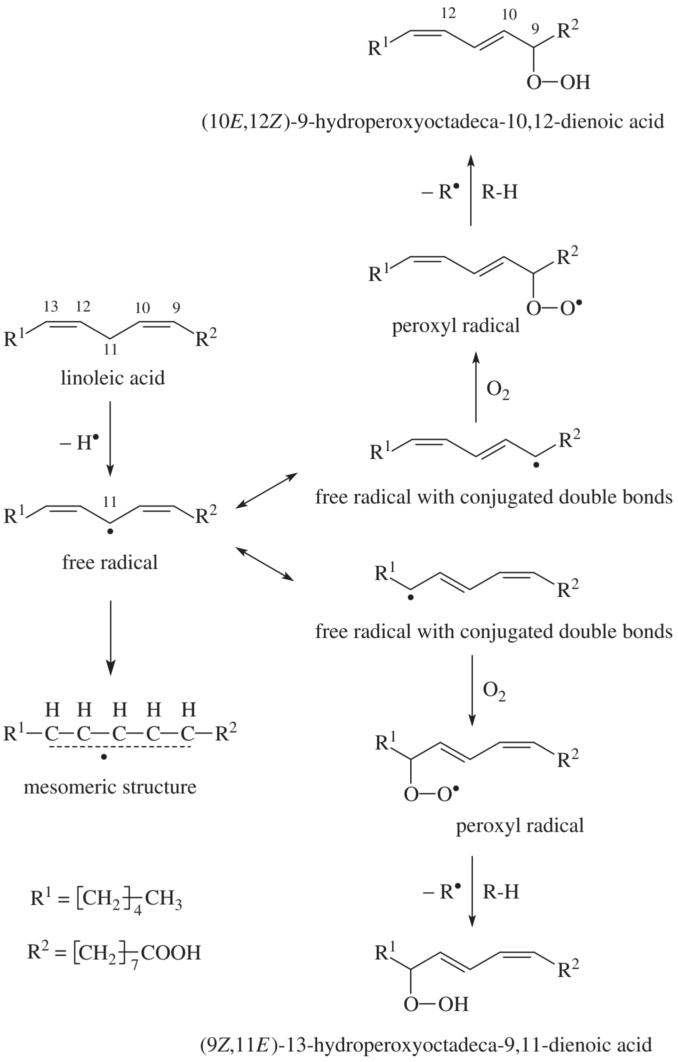

Figure 3.29 Main primary products of linoleic acid autoxidation.

case the reaction produces an **alkoxyl radical** (Figure 3.32). The decomposition of hydroperoxides, especially at higher concentrations, takes place via dimeric intermediates associated by hydrogen bonds (Figure 3.33). Both of these free radicals can initiate the chain radical reaction of fatty acids (Figure 3.32).

According to current knowledge, formation of the alkoxyl radical is favoured, as the O–O bond dissociation energy is about 184 kJ/mol, while the O–H bond dissociation energy is about 377 kJ/mol. During oxidation (and particularly in its advanced stages), these reactions are the major initiation reactions. The reaction of a fatty acid with a peroxyl radical gives fatty acid hydroperoxide, while reaction with an alkoxyl radical produces a hydroxy acid.

The timeline of an autoxidation reaction is shown in Figure 3.34. At the beginning, the reaction is usually initiated by heat or radiation, so the initial reaction rate is low. This reaction stage is called the **induction period**. Hydroperoxides gradually accumulate in the system, which causes formation of other radicals, thus the initiating reaction rate increases with an increasing concentration of hydroperoxides. Therefore, this reaction is called an autocatalytic reaction. If there is sufficient oxygen, the reaction rate increases rapidly until, at some point, the rate of decomposition of hydroperoxides exceeds the rate of their formation, and then the amount of hydroperoxides gradually decreases. During deceleration of the formation of additional hydroperoxides, their decomposition by the above mechanism becomes more important. Decomposition of hydroperoxides does not depend on the presence of oxygen or of unreacted lipids. At higher temperatures, such as during deep fat frying, hydroperoxides do not accumulate in fat, because they decompose at about 150 °C.

Secondary autoxidation products

Hydroperoxides of fatty acids and their radicals can in principle react in three ways in secondary reactions:

- reactions that do not change the number of carbon atoms in the molecule (e.g. the formation of cyclic peroxides and endoperoxides, epoxy acids, hydroxy acids and oxoacids);
- reactions involving decomposition of molecules, producing products with fewer carbon atoms (formation of aldehydes, hydrocarbons or oxoacids);
- polymerisation reaction in which the number of carbons in the molecule increases.

Cyclic peroxides and endoperoxides

Hydroperoxides of polyenoic fatty acids with three or more double bonds in the molecule, which have a system of conjugated double bonds in position β to hydroperoxide group, are very unstable compounds. They tend to form more stable cyclic six-membered peroxides derived from 1,2-dioxane by 1,4-cyclisation, five-membered peroxides derived from 1,2-dioxolane by 1,3-cyclisation and endoperoxides.

As an example, the formation of 1,2-dioxanes from 12-hydroperoxyoctadeca-9,13,15-trienoic acid derived from linolenic acid is shown in Figure 3.35. 1,2-Dioxanes are unstable compounds and decompose to low molecular weight flavour-active products. For example, 10-hydroperoxy-9,12-peroxyoctadeca-13,15-dienoic acid is decomposed into octa-3,5-dien-2-one. The mechanism of formation of 1,2-dioxolanes, cyclic peroxides and cycloendoperoxides from 13-hydroperoxyoctadeca-9,11,15-trienoic acid is shown in Figure 3.36. Peroxohydroperoxides of the 1,2-dioxolane type are considered to be the main precursors of toxic malondialdehyde (see Section 3.8.1.12.1).

Epoxy acids, hydroxy acids and oxoacids

Hydroperoxides, or strictly peroxyl radicals, readily react with unsaturated double bonds of olefins to form epoxide derivatives. The addition of a peroxyl radical to the double bond of an olefin can proceed as an intermolecular reaction (Figure 3.37).

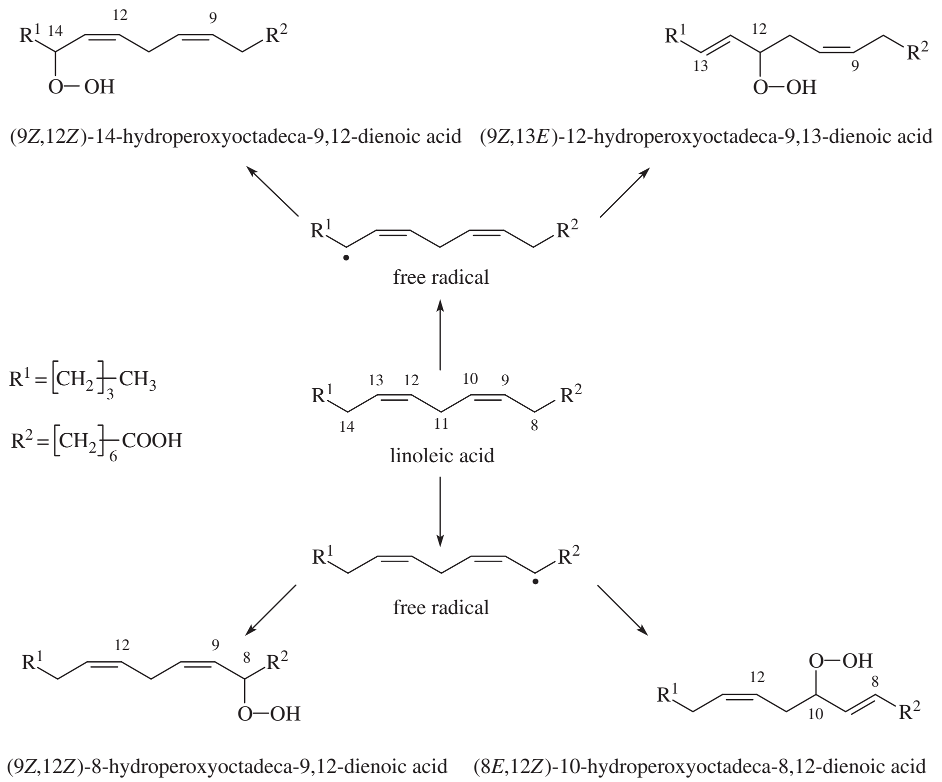

Figure 3.30 Minor primary products of linoleic acid autoxidation.

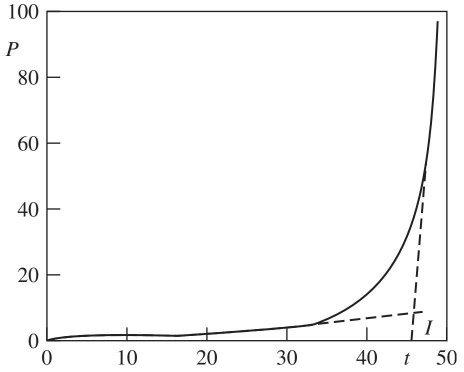

Figure 3.34 Course of autoxidation reaction of sunflower oil at 40 °C: P = amount of fatty acid hydroperoxides in milliequivalents of oxygen per kg (peroxide number), t = duration of the autoxidation in days, I = induction period.

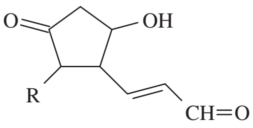
Similarly, epoxides are also formed during the reaction of olefins with hydrogen peroxide. Secondary reactions of oxidised polyenoic acids produce red-coloured cyclopentane derivatives (**3-137**) causing adverse colour changes to stored fish.



3-137, cyclopentanolone derivative formed from oxidised fish lipids

A particularly important reaction of unsaturated fatty acids is an intramolecular reaction (Figure 3.38), occurring when epoxide arises from an alkoxyl radical. The resulting radical of epoxy acid reacts with oxygen to form a hydroperoxyl radical, which is decomposed via hydroperoxide to an alkoxyl radical. This alkoxyl radical provides, by recombination with a hydrogen radical, the corresponding hydroxy acid and elimination of a hydrogen atom yields the corresponding oxoacid. Somewhat more complicated is the intramolecular reaction of hydroperoxides with conjugated double bonds. Conjugated dienes, such as 13-hydroperoxyoctadeca-9,11-dienoic and 9-hydroperoxyoctadeca-10,12-dienoic acids, arise as major autoxidation products of linoleic acid. This reaction is illustrated in Figure 3.39 in the example of 13-hydroperoxyoctadeca-9,11-dienoic acid. Decomposition of this hydroperoxide via alkoxyl radicals creates 13-hydroxyoctadeca-9,11-dienoic- and 13-oxooctadeca-9,11-dienoic acids. Oxidation and other reactions of the alkoxyl radical give rise to two isomeric hydroperoxy acids: 12,13-epoxy-11-hydroperoxyoctadec-9-enoic and 12,13-epoxy-9-hydroperoxyoctadec-10-enoic acids. Decomposition of these epoxyhydroperoxy acids produces, analogously, epoxyhydroxy acids and epoxyoxoacids.

The alkoxyl radicals resulting from the decomposition of hydroperoxides with conjugated double bonds form by 1,4-addition radicals of dihydrofuran derivatives. These radicals are stabilised, in the same way as 1,2-epoxide radicals, by reaction with oxygen and subsequent reactions provide dihydrofuran derivatives. Radicals of dihydrofuran derivatives can also react with oxygen to form a peroxyl radical, which cleaves another fatty acid molecule and is transformed into the corresponding hydroperoxide from which, via an alkoxyl radical, hydroxy acids and oxoacids are formed (Figure 3.40).

Cyclic peroxides (1,2-dioxolane derivatives) provide substituted derivatives of tetrahydrofuran by ring cleavage and rearrangement (Figure 3.41). Dihydrofuran derivatives (so-called 1,4-epoxy compounds) can also be formed from unsaturated 1,2-epoxides by ring opening under acidic conditions and by cyclisation of the free radicals generated (Figure 3.42). This reaction is analogous to the formation of so-called 5,8-epoxides from 5,6-epoxides, which occurs in carotenoid pigments (see Section 9.9.1.2).

Epoxides are highly reactive compounds, especially at higher temperatures. They form dihydroxy derivatives with water, ethers with alcohols, esters with the carboxyl group of fatty acids, chlorohydrins (α-chlorohydroxy compounds) with hydrochloric acid and amino compounds with amines (Figure 3.43). Chlorinated hydroxy acids arise, for example, in polyvinyl chloride (PVC) by reaction of epoxidised soybean oil (used as a stabilizer of PVC) with hydrogen chloride (see Section 11.4.2.2.2).

Common oxidation products are derivatives with a hydroxyl group in the α-position to the oxo group, known as ketols. Ketols are formed in reactions of hydroperoxides with the neighbouring double bonds (Figure 3.44). They have significant reducing properties; their reactivity is close to the reactivity of aldehydes. The hydrolysis product of dihydrofuran derivative

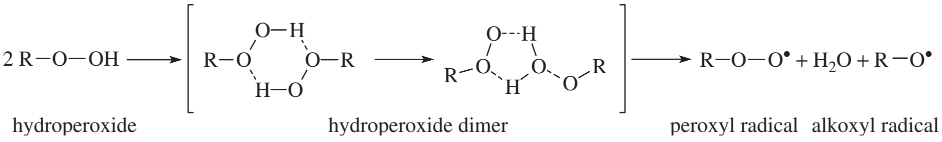


Figure 3.33 Decomposition of hydroperoxides to free radicals.

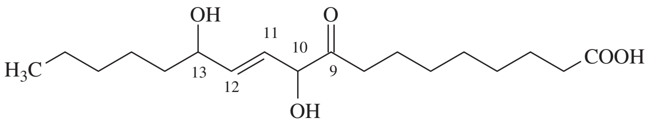
of 9-oxo-10,13-epoxyoctadec-11-enoic acid, which is 10,13-dihydroxy-9-oxooctadec-11-enoic acid, is also a ketol. The structure of this ketol is shown in formula **3-138**.



3-138, (*E*)-10,13-dihydroxy-9-oxooctadec-11-enoic acid

Volatile secondary products

Another important group of reactions are those in which the hydrocarbon chain of the alkoxyl radicals cleaves to form low molecular weight products, mainly volatile and sensory active compounds. The cleavage takes place on both sides of the alkoxyl radicals (Figure 3.45). The composition of reaction products formed from alkoxyl radicals derived from unsaturated fatty acids depends on which carbon, next to the hydroperoxide group, the double bond is located. In addition to non-volatile oxoacids and hydroxy acids, the main volatile sensorially active decomposition products include saturated and unsaturated aldehydes and saturated and unsaturated hydrocarbons. As an example, the cleavage of two major hydroperoxides of linoleic acid, 13-hydroperoxy-9-octadeca-9,11-dienoic (Figure 3.46) and 9-hydroperoxyoctadeca-10,12-dienoic acids (Figure 3.47), are shown. Other hydroperoxides of unsaturated and saturated acids decompose in an analogous manner.

Hydrocarbons give a typical rancid flavour to slightly oxidised oils, while aldehydes carry a typical rancid flavour in the advanced stages of oxidation, and thus there is a close relationship between the aldehyde content and the intensity of the rancid flavour. The nature of the rancid odour changes according to the type of aldehyde. Alkanals and alk-2-enals impart a typical rancid flavour to oils but the sensory effects of alk-2-enals are more intense than those of alkanals. The oxidation of oils with higher linoleic acid contents produces alka-2,4-dienals, which are another important group of volatile oxidation products. In small amounts, they impart a fried flavour to oils, while at slightly higher levels the flavour resembles peanuts, and at even higher levels the flavour becomes unpleasant. Conjugated alkatrienals, forming during the oxidation of linolenic acid in oils, impart an off-flavour to oils, resembling varnish or fish oil. Substances that are less sensorially active than alkanals

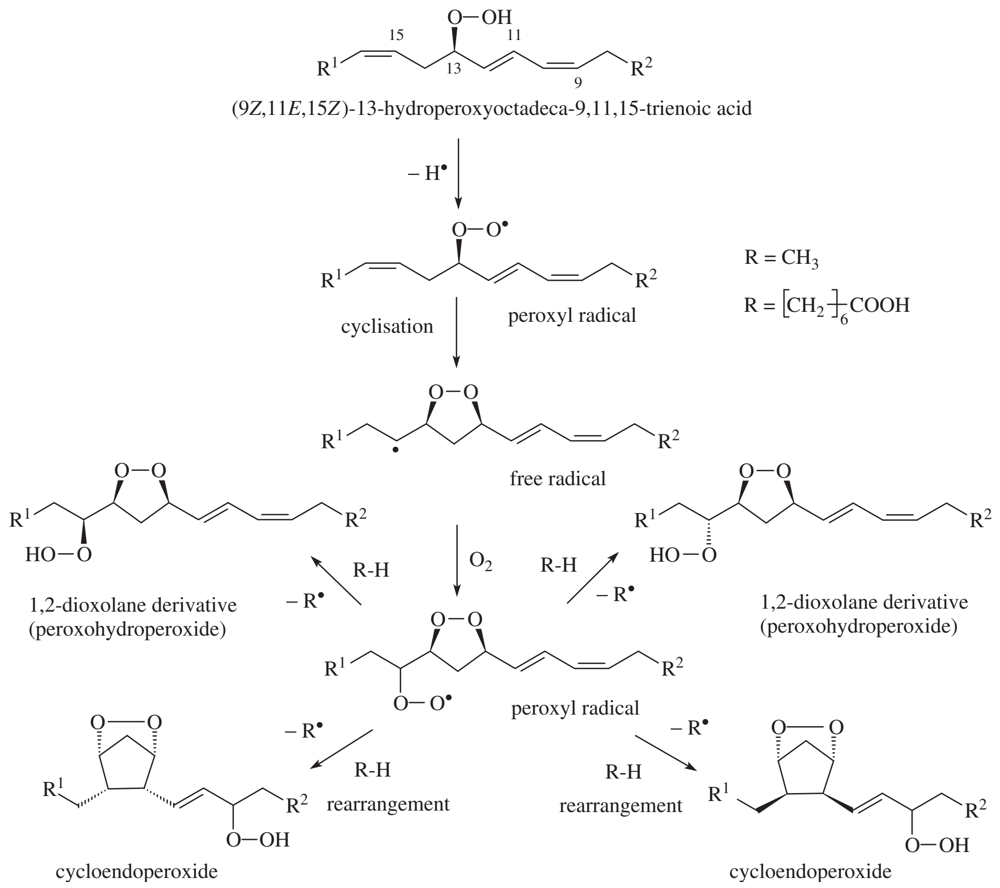


Figure 3.36 Formation of 1,2-dioxolanes from 13-hydroperoxyoctadeca-9,11,15-trienoic acid.

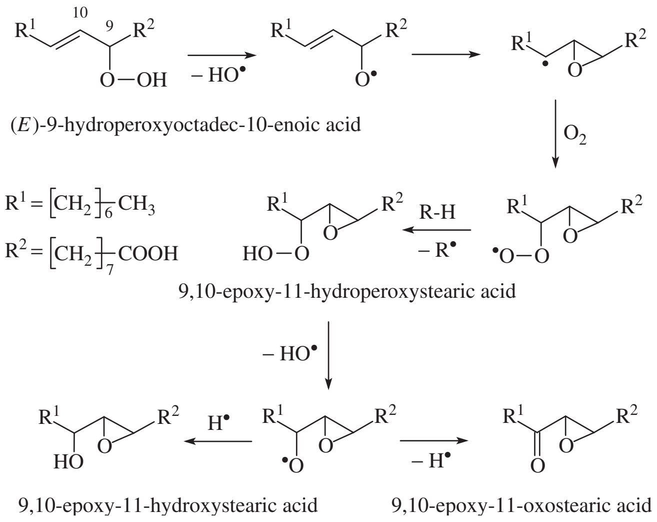

Figure 3.38 Formation of epoxy acids, hydroxyl acids and oxoacids from oleic acid 9-hydroperoxide.

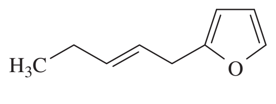
and alkenals, but nevertheless are important reaction products, are alkan-2-ones, the odour of which is reminiscent of moldy cheese. An overview of the hydrocarbons and carbonyl compounds formed by decomposition of hydroperoxides of oleic, linoleic and linolenic acids is given in Sections 8.2.1.1.2 and 8.2.4.1.1.

A specific type of rancidity, known as reversion in the United States, occurs during the oxidation of soybean oil. Reversion is caused by some furan derivatives, such as 2-pentylfuran or (*Z*)- and (*E*)-2-(pent-2-en-1-yl)furan and other decomposition products of hydroperoxides. Pentylfuran arises (Figure 3.48) as a by-product of the decomposition of 9-hydroperoxyoctadeca-10,12-dienoic acid derived from linoleic acid via the terminal radical. The content of linoleic acid in soybean oil is about 51% of the total fatty acids. Similarly, both isomers (*cis* and *trans*) of 2-(pent-2-en-1-yl) furan (**3-139**) arise by decomposition of 9-hydroperoxyoctadeca-10,12,15-trienoic acid formed by autoxidation of linolenic acid.



3-139, (*E*)-2-(pent-2-en-1-yl)furan

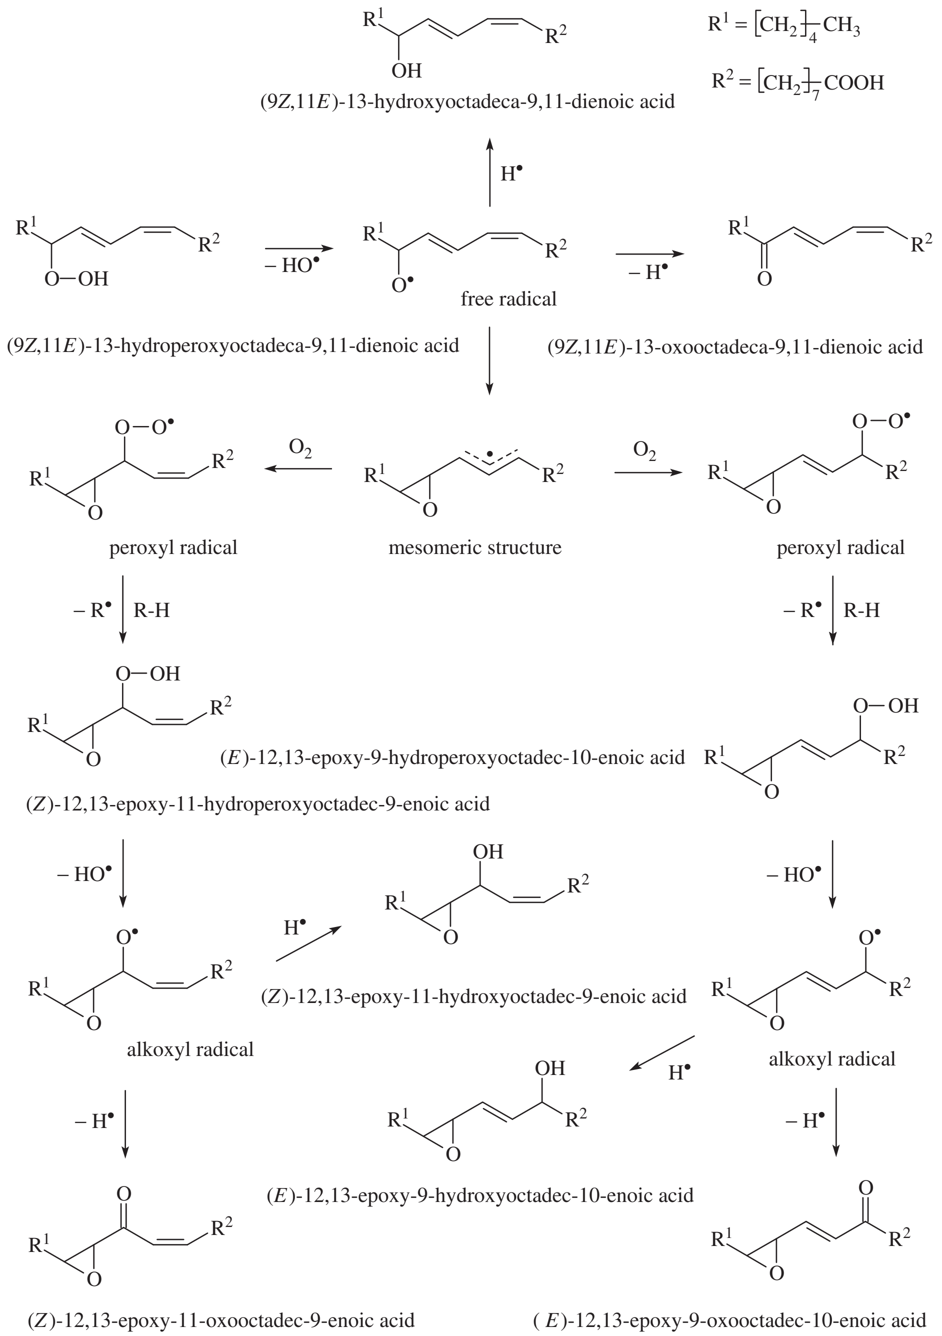


Figure 3.39 Formation of epoxy acids, hydroxy acids and oxoacids from linoleic acid 13-hydroperoxide.

Soybean oils used at present contan 7–10% linolenic acid. A number of other oxidation products of polyenoic fatty acids contribute to the smell of rancid (reverted) soybean oil.

Subsequent reactions of aldehydes

Aldehydes are very reactive compounds that react further in the oxidised fat. Their carbonyl group is oxidised to a carboxyl group and, as a rule, they are further oxidised in the hydrocarbon chain. Common reactions are aldolisation, retroaldolisation and reactions with other food components, such as proteins.

Alkanals

Autoxidation of the hydrocarbon chain and of the carbonyl group of alkanals creates, via unstable peroxy acids and 2-hydroperoxy derivatives, a mixture of products. The important final products are the corresponding fatty acids, formic acid and alkanals containing

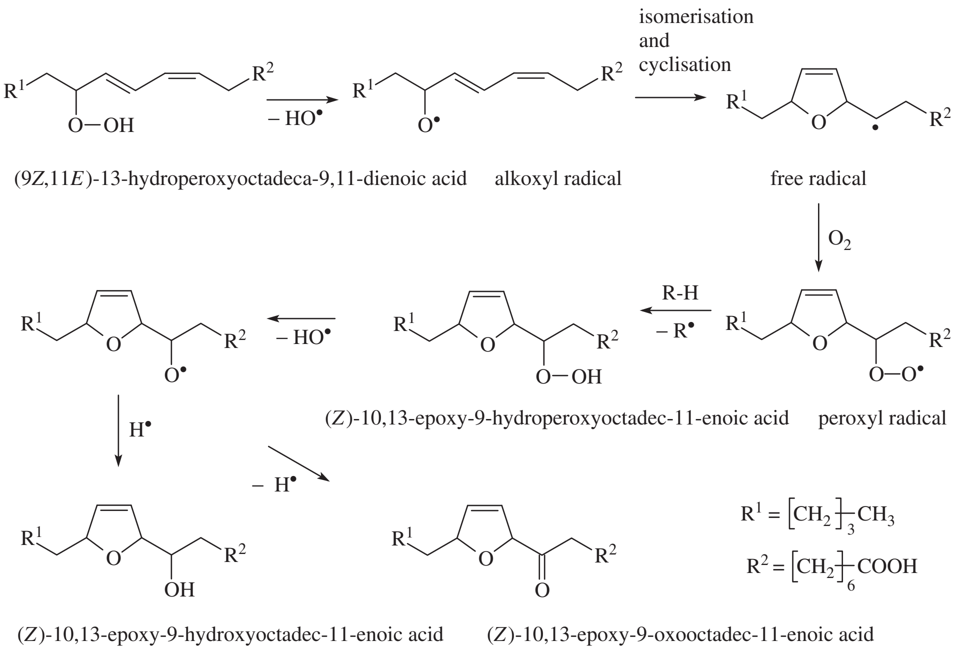

Figure 3.40 Formation of dihydrofuran derivatives from an alkoxyl radical of linoleic acid 13-hydroperoxide.

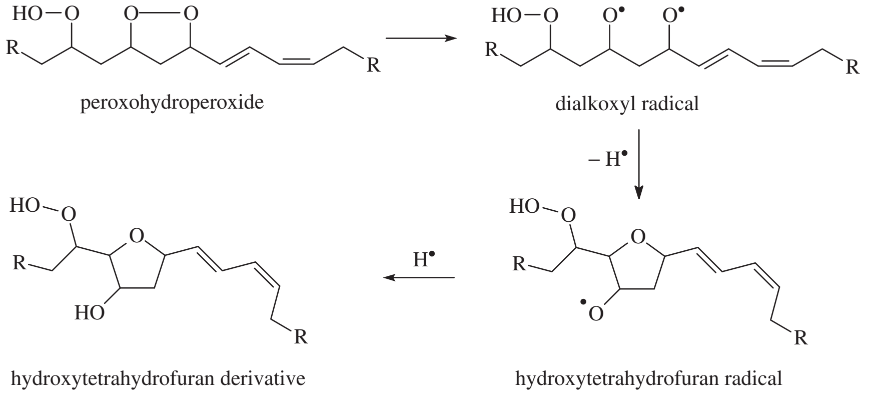

Figure 3.41 Formation of tetrahydrofuran derivatives from 1,2-dioxolanes.

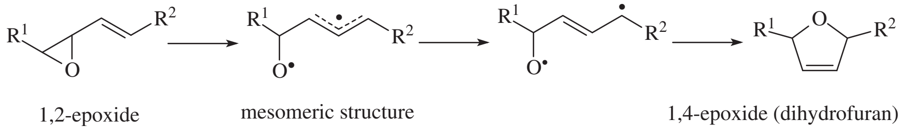

Figure 3.42 Formation of fatty acid 1,4-epoxides from 1,2-epoxides.

fewer carbon atoms per molecule than the parent compound (Figure 3.49). Lower alkanals, such as hexanal, also condense to trimeric 2,4,6-trialkyl-1,3,5-trioxanes (**3-140**).

Alk-2-enals

The continued autoxidation of alk-2-enals leads to a number of products that are formed by similar mechanisms that give rise to products arising from alkanals. An important product is highly reactive malondialdehyde (propanedial, also incorrectly known as malonaldehyde; Figure 3.50). Malondialdehyde exists predominantly in enol form, as a *cis*-isomer in organic solvents and as a *trans*-isomer in water (Figure 3.51).

As with alkanals, the carbonyl group of alk-2-enals is oxidised to a carboxyl group via the corresponding peroxy acid. Retroaldolisation creates acetaldehyde and an aldehyde containing two fewer carbon atoms, whereas aldolisation with acetaldehyde produces alka-2,4-dienals (Figure 3.52).

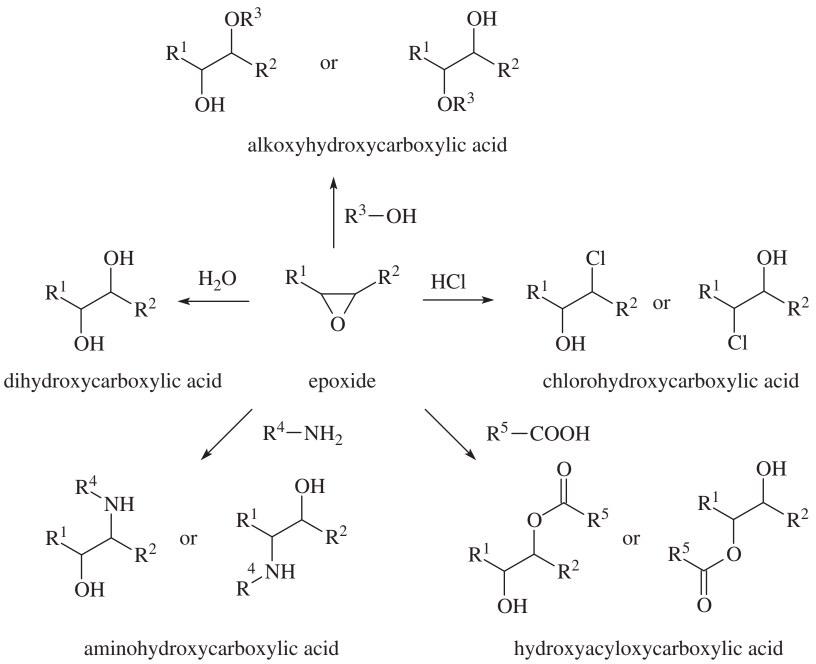

Figure 3.43 Important reactions of fatty acid epoxides.

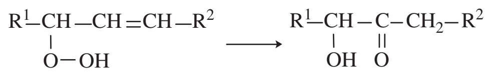

Figure 3.44 Formation of ketols by oxidation of fatty.

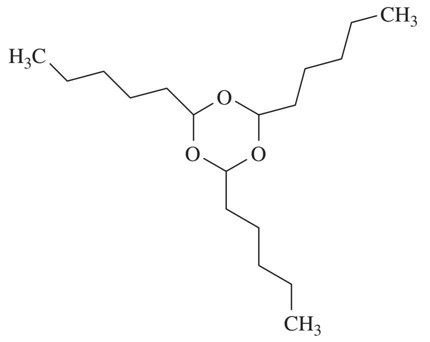

3-140, 2,4,6-tripentyl-1,3,5-trioxane

Alka-2,4-dienals

Autoxidation of alka-2,4-dienals accompanied by retroaldolisation leads temporarily to epoxides and finally to relatively stable end products. Similarly to alk-2-enals, the main reaction products include alkanals, alkenals, dialdehydes (including malondialdehyde) and hydrocarbons. Some secondary reactions of alka-2,4-dienals are shown in Figure 3.53.

Secondary polymeric products

The third group of secondary reactions of oxidised fats are reactions in which the number of carbons in the molecule increases. In specialised areas these reactions are known under the term **oxypolymerisation** (oxidative polymerisation). Oxypolymerisation is one of the consequences of oxidative degradation of lipids. Free radical addition and sometimes cycloaddition reactions can be seen as the main causes of the production of oxidative polymers (oxypolymers) in triacylglycerols, especially if the polyunsaturated fatty acids content is high. Polymers are usually formed by reactions of two free radicals. If both are alkyl radicals, the formed dimers have the oxidised fatty acids bound by a single C–C bond between two carbon atoms. This reaction is described in more detail in Section 3.8.1.6. Alkyl radicals, of course, do not occur in high amounts and react slowly, so reactions between oxygen-containing radicals are more common (Figure 3.54). Most products contain ether bonds of the type C–O–C, although peroxide bonds of the type C–O–O–C can also occur. In theory, diperoxide bonds could also form, but they are unstable and their formation is accompanied by elimination of oxygen. Similarly, two fatty acids may also be linked to one another by two bonds, which yields tetrahydrofuran (**3-141**), tetrahydropyran (**3-142**) or dioxan derivatives (**3-143**). Usually,

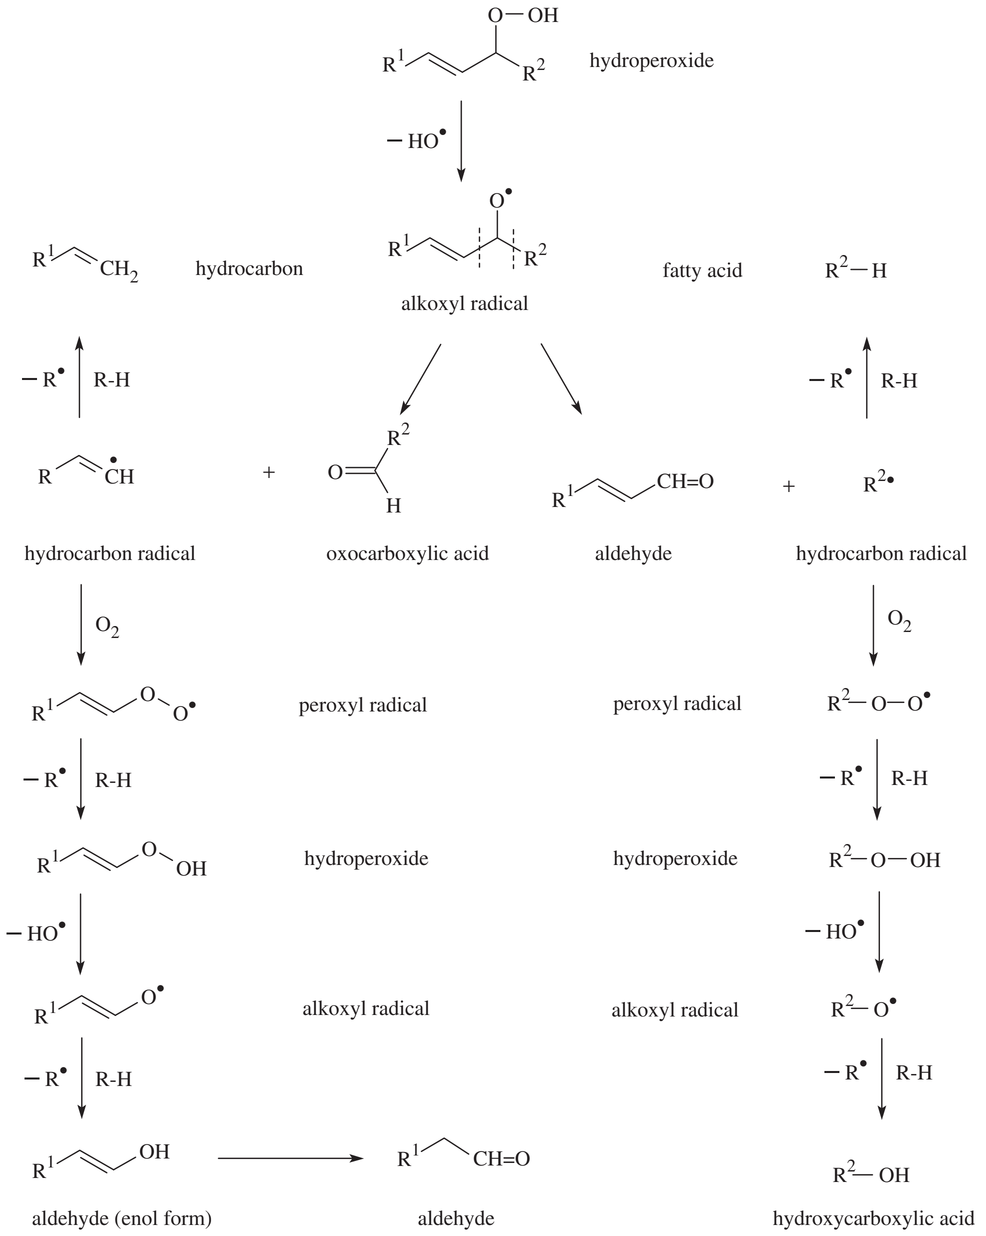

Figure 3.45 Fission of fatty acid hydrocarbon chain during hydroperoxide decomposition.

polymers are described by schematic formulae that indicate the type of link between the chains of original fatty acids (Figure 3.55).

Polymers may arise also by non-radical mechanisms. For example, polymers are formed by reactions of epoxides with hydroxyl groups or by reactions of epoxides with carboxyl groups of free fatty acids (Figure 3.43 and Figure 3.56). Many other types of polymerisation reactions have also been described.

Influence of reaction conditions

The rate of formation and decomposition of hydroperoxides is very dependent on the structure and concentration of reactants and on the reaction conditions, mainly on the temperature, but also on the concentration of oxygen, the surface area exposed to air, water activity, presence of prooxidants or antioxidants and so on.

Structure of acids

An important factor is the presence of reactive double bonds. Saturated fatty acids are practically stable during fat storage at normal temperatures. At temperatures around 20 °C, monoenoic fatty acids (such as oleic acid) are only oxidised very slowly, dienoic fatty acids (such as linoleic acid) are oxidised about ten times faster and trienoic fatty acids (such as linolenic acid) approximately 20 times faster. Arachidonic acid, as an example of tetraenoic fatty acids, is oxidised about 30–40 times faster. At temperatures above

Figure 3.51 Isomerisation of malondialdehyde.

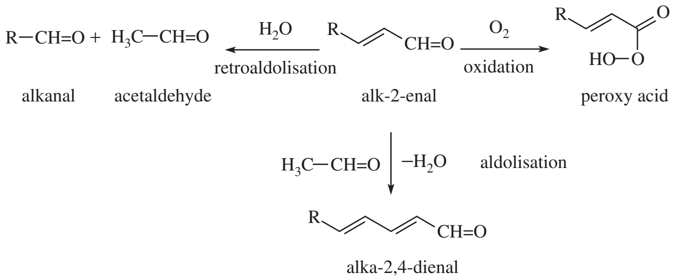

Figure 3.52 Oxidation and (retro)aldolisation of (*E*)-alk-2-enals.

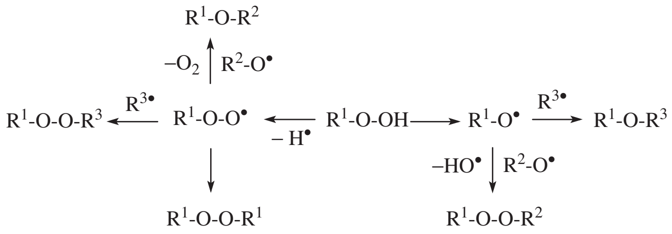

Figure 3.54 Secondary reactions of fatty acid hydroperoxides.

100 °C, all fatty acids are oxidised at about the same rates; *cis* isomers are generally less stable than *trans* isomers, conjugated dienes are less stable than dienes with isolated double bonds and free fatty acids are less stable than fatty acids bound in triacylglycerols.

A fatty acid's inclination to oxidation also depends on the presence of other fatty acids, which is important for natural fats and oils, where fatty acids occur as mixtures of esters. When, for example, higher amounts of linoleic acid hydroperoxides form, their decomposition leads to radicals, which are able to initiate oxidation of monoenoic fatty acids. Vegetable oils that contain less than 10% of polyenoic fatty acids are therefore very stable against oxidation under typical storage conditions. This is the main reason why oilseeds are today bred to have low linoleic acid and linolenic acid contents.

Temperature and oxygen concentration

A rise in temperature accelerates the oxidation process and thus also increases the content of hydroperoxides, but hydroperoxides are very unstable at high temperatures. Particularly unstable are the hydroperoxides of trienoic and other polyenoic fatty acids. With a

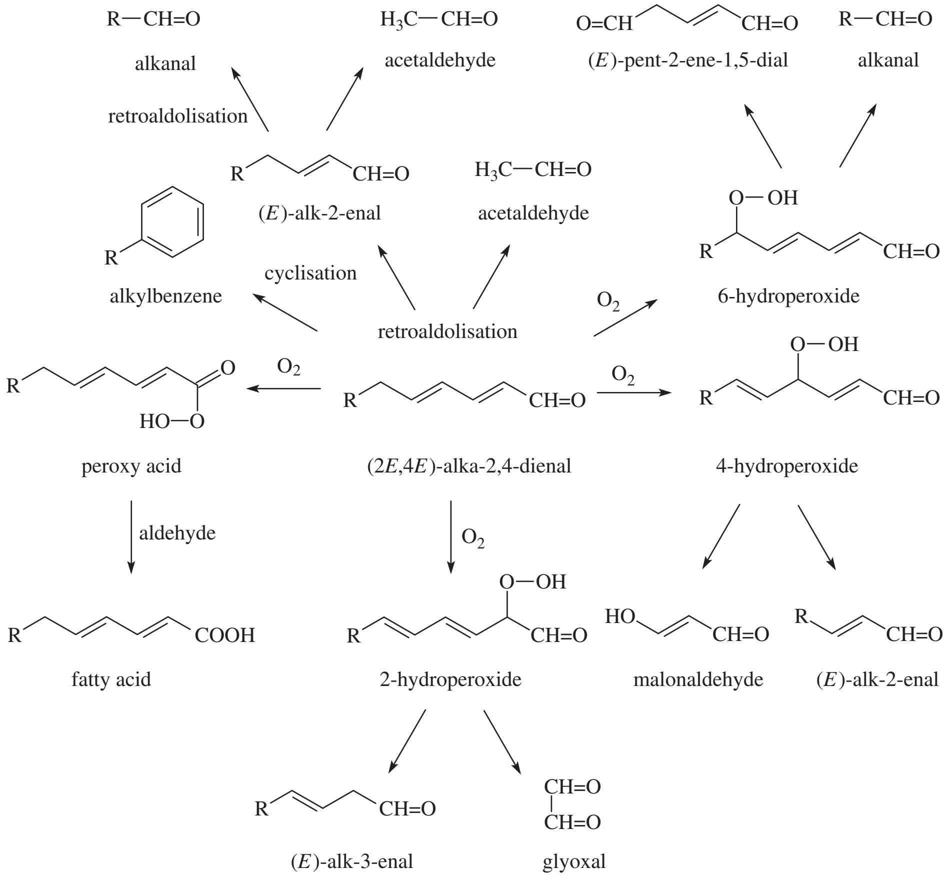

Figure 3.53 Secondary reactions of alka-2,4-dienals.

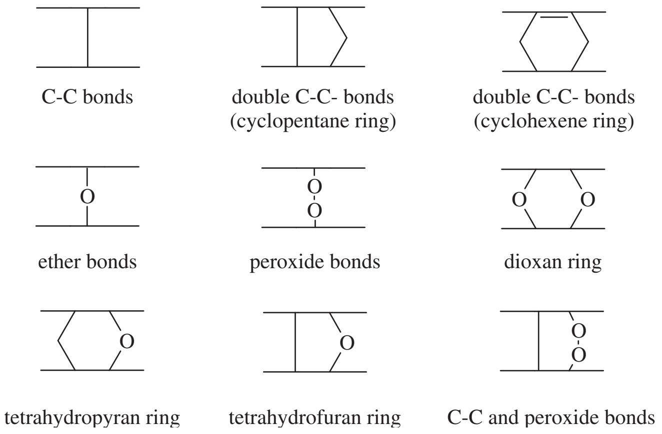

Figure 3.55 Schematic representation of bonds in dimers of oxidised fatty acids.

rise in temperature, the increase of the content of hydroperoxides is therefore soon compensated for by their faster decomposition. The maximum hydroperoxide content is achieved sooner, but it is lower and less distinct.

An important factor is the concentration of oxygen, as only oxygen molecules dissolved in the fat phase can react with free radicals. At higher temperatures, such as during frying, oxygen is consumed within a few minutes and the rate of oxidation is then determined only by the amount of oxygen that penetrates into the fat from the atmosphere by diffusion (diffusion of oxygen is also an important factor in autoxidation of fatty emulsions and dispersions). Under such conditions, the rate of formation of hydroperoxides and the rate of their decomposition are almost comparable, and their content remains approximately constant until the reactive unsaturated acids are oxidised. If a flow of air is introduced into fat, its oxidation is much faster, and the maximum content of hydroperoxides significantly increases.

Water activity

The rate of fat oxidation in foods depends greatly on water activity (see Section 7.9). In dry foods, oxygen can more easily penetrate into the material than in normal foods. The minimum rate of oxidation occurs in foods with water activity values around 0.3. This situation is explained by the decrease in catalytic activity of metals, by quenching free radicals and by formation of antioxidants in the Maillard reaction. In foods with higher water activity, the rate of oxidation is again higher, probably due to increased mobility of metal ions, which catalyse the autoxidation.

Pro-oxidants and antioxidants

Heavy metals with variable valencies have a significnt influence on the oxidation of unsaturated fatty acids and their derivatives, as they can accelerate the reaction, as pro-oxidants. On the other hand, antioxidants will retard the oxidation of fatty acids.

3.8.1.8.3 Oxidation by hydrogen peroxide

It has been shown that lipid hydroperoxides are easily decomposed to form free radicals that accelerate autoxidation reaction. Hydroperoxides can also oxidise unsaturated fatty acids by non-radical mechanisms, as mentioned in the secondary reaction of oxidised lipids. Also, hydrogen peroxide, which arises naturally in

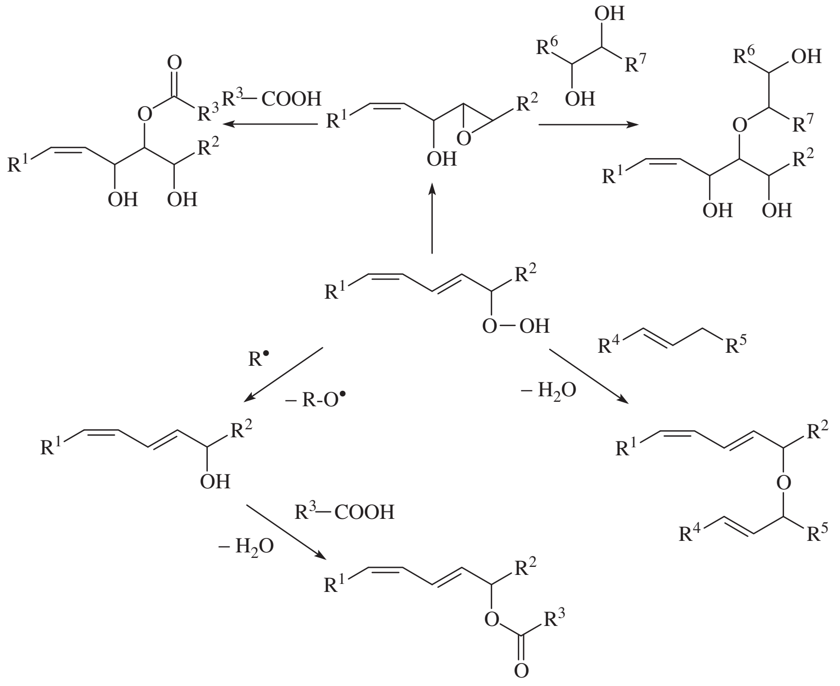

Figure 3.56 Examples of non-radical polymerisation during autoxidation of unsaturated fatty acids.

food processes, can oxidise unsaturated lipids. The primary oxidation product is epoxide, which is immediately hydrolysed to form a fatty acid dihydroxy derivative. For example, the oxidation of oleic acid by hydrogen peroxide yields 9,10-dihydroxystearic acid (Figure 3.57). These reactions are also of great importance in the development of vascular diseases.

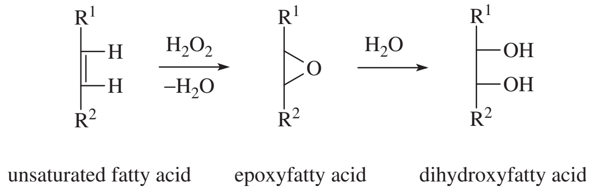

Figure 3.57 Oxidation of unsaturated fatty acids by hydrogen peroxide.

3.8.1.8.4 Oxidation by singlet oxygen

Excitation of ordinary triplet oxygen ($^3O_2$) yields reactive singlet oxygen ($^1O_2$), which can react with the unsaturated double bond of lipids and other unsaturated compounds.[21] Under the conditions eligible for the processing and storage of foods, singlet oxygen forms most often during irradiation in the presence of photosensitisers. With conventional unsaturated fatty acids, singlet oxygen reacts at least 1450 times faster than triplet oxygen. The relative reactivity of linolenate, linolate and oleate are roughly in the proportions 3.5:3:1.

Singlet oxygen adds to the double bond of fatty acids with the formation of unstable peroxide (formerly called moloxide) or a six-membered ring. The resulting intermediates rapidly decompose to form hydroperoxides (Figure 3.58). Analogously, isomeric hydroperoxide forms by reaction with a hydrogen atom of the methylene group at the carboxyl end of the fatty acid molecule. These hydroperoxides differ from hydroperoxides resulting from autoxidation reaction in the ratio of the individual positional isomers, since the primary mechanism of the formation of free radicals is different. For example, oxidation of oleic acid by singlet oxygen creates an equimolar mixture of 9- and 10-hydroperoxide, but isomeric hydroperoxides with the hydroperoxide group in positions C-8 and C-11 do not form. The products arising from linoleic acid by oxidation with singlet oxygen are a mixture that contains 66% of conjugated hydroperoxides (9- and 13-hydroperoxides) and 34% of unconjugated hydroperoxides (10- and 12-hydroperoxides). Linolenic acid oxidation by singlet oxygen produces a mixture containing 75% of conjugated hydroperoxides (9-, 12-, 13- and 16-hydroperoxides) and 25% of unconjugated hydroperoxides (10- and 15-hydroperoxides).

Photosensitisers

Photosensitisers are compounds that catalyse the oxidation of organic substances with oxygen when exposed to visible radiation. They act as carriers of absorbed energy that is transmitted to triplet oxygen and transformed to singlet oxygen.[22] The mechanism of their action is shown in Figure 3.59. The type I reactions, which occur, for example, in phenols, amines and quinones (easily oxidisable or reducible compounds), via direct interactions of a triplet photosensitiser with other molecules (R–H), which involves a transfer of a hydrogen atom or electron that produces free radicals ($R^\bullet$ and $^\bullet SH$). Triplet sensitisers are therefore photochemically activated free radical initiators. Reactions of type II describe the most common method of energy transfer from the excited triplet photosensitisers to triplet oxygen to form singlet oxygen. Less than 1% of triplet oxygen is simultaneously transferred to the superoxide anion (O_2^-) and oxidised form of the sensitiser (S^+).

Of the substances that are present in foods, the most important photosensitisers are chlorophylls, phaeophytins, haem pigments and riboflavin. In vegetable oils, chlorophylls (and their degradation

[21] According to the Pauli principle, each orbital of a molecule can be occupied by only two electrons (so-called paired electrons), which must have opposite spin directions also known as spins ($s_1 = 1/2$ and $s_2 = -1/2$). The spin of a molecule is the sum of the spins of unpaired electrons, which may be parallel or antiparallel. The ground state of most molecules is a singlet as their spin $S = s_1 + s_2 = 0$, the total magnetic moment $\boldsymbol{M} = 2S + 1 = 1$ and the molecule is diamagnetic. Excitation of such molecules occurring in the singlet state leads to a shift of one electron from the bonding orbital to free antibonding orbital with higher energy. Both electrons with opposite (antiparallel) spins, originally located in the same orbital, are now in different orbitals and have a parallel spin ($s_1 = s_2 = 1/2$). The resulting spin of the molecule $S = 1$ and the state of the molecule, which is paramagnetic, is a triplet, since the total magnetic moment $\boldsymbol{M} = 2S + 1 = 3$.

Oxygen is an exception to this general rule. Atmospheric oxygen, O_2, exists in the triplet state ($^3O_2$). It has 12 valence electrons, of which two electrons with higher energy and parallel spin are located in different orbitals. It is actually a biradical (•O–O•). Excitation of triplet oxygen creates singlet oxygen ($^1O_2$), whose electrons are paired, occuring in the same orbital, spins are antiparallel or the electrons occur in different orbitals and also have the opposite spins. These two of a total of five possible excited states of oxygen are known as $^1\Delta$ (delta) singlet oxygen and $^1\sum$ (sigma) singlet oxygen. Energy of $^1\Delta$ singlet oxygen is 93.8 kJ/mol higher and energy of $^1\sum$ singlet oxygen is 157 kJ/mol even higher than the energy of the basic triplet state. The $^1\sum$ singlet oxygen is so reactive that it does not survive relaxation to the ground state, but the $^1\Delta$ singlet oxygen is sufficiently stable (its lifetime is several microseconds) and can therefore react with other molecules also occurring in the singlet state. This singlet oxygen is responsible for most of the reactions of oxygen in the activated state and its reactivity resides in its electrophilic nature. Therefore this excited state is simply called singlet oxygen. It reacts with compounds rich in electrons (such as unsaturated compounds) so that electrons are added to the free molecular orbital. Singlet oxygen arises in chemical reactions, enzymatic reactions, by decomposition of hydroperoxides and in some other ways. In foods, the most important formation pathway is by photochemical reactions with the participation of natural photosensitisers.

[22] Photolytic cleavage of fatty acid molecules in the initial stage of autoxidation with UV exposure is minimal and has no practical significance in comparison with photosensitised oxidation that occurs in the presence of photosensitisers during exposure to visible light. Photosensitisers contain a conjugated system of double bonds that easily absorbs light energy. The photosensitiser absorbs a photon (a quantum of light) and is transferred from the basic singlet state to an unstable singlet excited state. The molecule existing in this state may lose energy obtained in three ways: (i) by internal conversion with the loss of thermal energy (transformation into another excited state), (ii) by light emission (through the process of fluorescence, the state where the emission begins and ends is a singlet state), and, finally, (iii) by conversion into a triplet excited state that is an intermediate in the photosensitised reaction (followed by degradation to a lower energy triplet state and further to the basic singlet state with the emission of light; the process is called phosphorescence, the state where the triplet emission begins and where it ends is a singlet state).

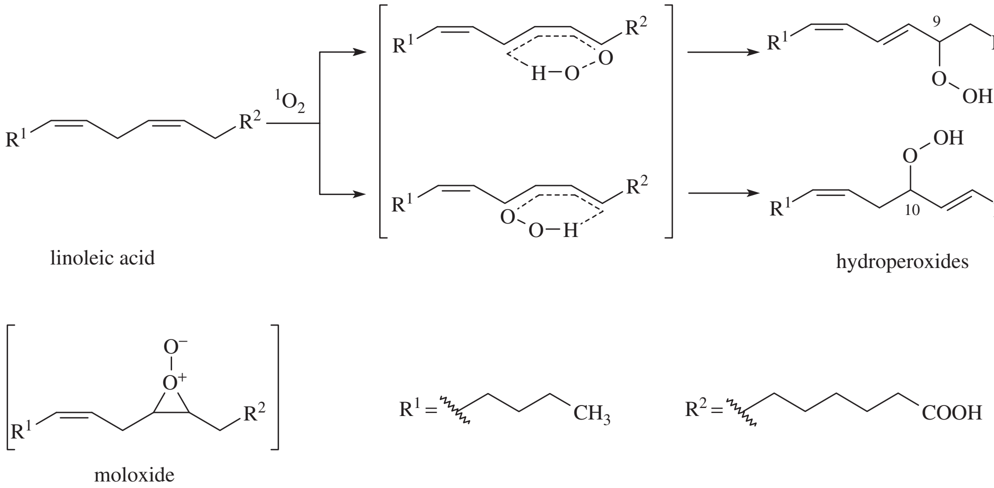

Figure 3.58 Oxidation of unsaturated fatty acids by singlet oxygen.

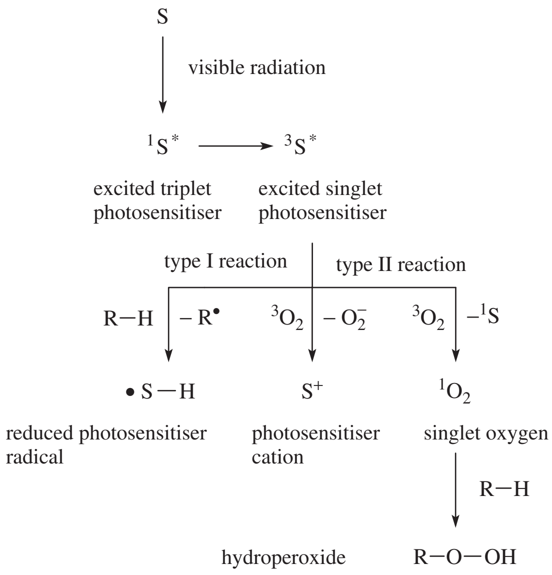

Figure 3.59 Photosensitised oxidation of unsaturated fatty acids.

products, phaeophytins) act mainly as photosensitisers (type II reaction). The concentration of chlorophyll pigments in soybean oil is, for example, 1–1.5 mg/kg; their content in virgin olive oil is higher, around 6 mg/kg. In milk, the main photosensitiser is riboflavin; the main damaged amino acid is methionine. Riboflavin, on absorbing visible light, generates a metastable (triplet) excited state from the initially populated singlet state that may react with triplet molecular oxygen to form singlet oxygen by triplet–triplet annihilation, in the type II photooxidation pathway, or it may react directly with a substrate such as methionine (protein) by accepting hydrogen or electrons and producing radicals through the type I photooxidation mechanism. The significance of the type II reaction in milk has been described in several studies, whereas type I reactions in milk have received less attention. In meat and meat products, myoglobin and oxymyoglobin mainly act as photosensitisers, and the photooxidation product is metmyoglobin.

Other photosensitisers are cofactors of metalloproteins (enzymatic reactions produce, for example, singlet oxygen in some dairy products), some organic compounds such as pyridoxal and its derivatives (see Section 5.10.1), coumarins of the psoralene type (see Section 10.3.2.5.2), polycyclic aromatic hydrocarbons (such as anthracene; see Section 12.2.5), synthetic food colours (e.g. erythrosine; see Section 11.4.1.3) or sulfides, and some metal oxides (such as CdS, ZnS and ZnO).

Scavengers of singlet oxygen

The effects of photosensitisers can be neutralised by substances that serve as scavengers for singlet oxygen. In foods, the most important scavengers are carotenoids, tocopherols and L-ascorbic acid. The mechanism of reactions of carotenoids with singlet oxygen can be simply described by the following reactions:

$$^{1}\text{carotenoid} + {}^{1}O_2 \rightarrow {}^{3}\text{carotenoid} + {}^{3}O_2$$
$$^{1}\text{carotenoid} + {}^{3}S^{*} \rightarrow {}^{3}\text{carotenoid} + S$$
$$^{3}\text{carotenoid} \rightarrow {}^{1}\text{carotenoid}$$

The reaction products of singlet oxygen with carotenoids occurring in the natural singlet state (^{1}carotenoids) are triplet oxygen and carotenoids in the excited triplet state (^{3}carotenoids). Other reaction sequences of carotenoids are described in Section 5.2.6.2.1.

3.8.1.8.5 Enzymatic oxidation

Oxidoreductase enzymes called lipoxygenases (linoleate: O_2 oxidoreductases), formerly known as lipoxidases, are widespread. Multiple forms or isozymes have been detected in both animal and plant species. Lipoxygenases are present in most raw materials and food products, unless they have been heated, as the enzymes are denaturde on heating and lose their activity. Lipoxygenases are non-haem iron-containing dioxygenases involved in the catalysis of the oxidation of polyunsaturated fatty acids containing a (1*Z*,4*Z*)-penta-1,4-diene system of isolated double bonds. They catalyse the oxidation of essential fatty acids to hydroperoxides, but

the other unsaturated fatty acids are not oxidised. Hydroperoxides formed by catalysis of lipoxygenases differ in their optical activity from hydroperoxides formed by autoxidation. Lipoxygenases have different specificity, so they catalyse the formation of hydroperoxide groups only on certain fatty acid carbon atoms and are therefore **regioselective**. Some examples are given in Table 3.46. They are also **stereoselective** as they produce enantiomeric hydroperoxides, while the hydroperoxides arising by autoxidation of fatty acids are racemates. Hydroperoxides of fatty acids produced by the action of lipoxygenases can be further transformed into a variety of biologically active products collectively known as **oxylipins** (oxidised fatty acid derivatives) through the action of several participating enzymes.

The most common substrates for lipoxygenases in plants are linoleic and linolenic acids. Their oxidation, catalysed by lipoxygenases, yields 13- and 9-hydroperoxy fatty acids. Some lipoxygenases mainly catalyse the formation of (13*S*)-hydroperoxides, while less specific lipoxygenases produce a higher proportion of (13*R*)-hydroperoxides. Other lipoxygenases catalyse the formation of optically active 9-hydroperoxides. The 13-hydroperoxides of linoleic and linolenic acids, by the action of hydroperoxide lyases, produce aldehydes with six carbon atoms (Figure 3.60) that possess green (hexanal and hex-3-enal) grassy or beany (nona-3,6-dienal) flavours. Similarly, products with cucumber and melon flavours are formed from 9-hydroperoxides derived from linoleic and linolenic acids (Figure 3.61). For example, isomerisation of (3*Z*,6*Z*)-nona-3,6-dienal yields (2*E*,6*Z*)-nona-2,6-dienal that typically has a flavour resembling fresh cucumbers. Under the action

Table 3.46 Overview of properties of selected plant lipoxygenases.

Plant material	Isoenzyme	Regiospecificity[a]	Occurrence

Potatoes	LOX5	9-Hydroperoxides	Tubers

[a]Ratio of 13- and 9-hydroperoxides.

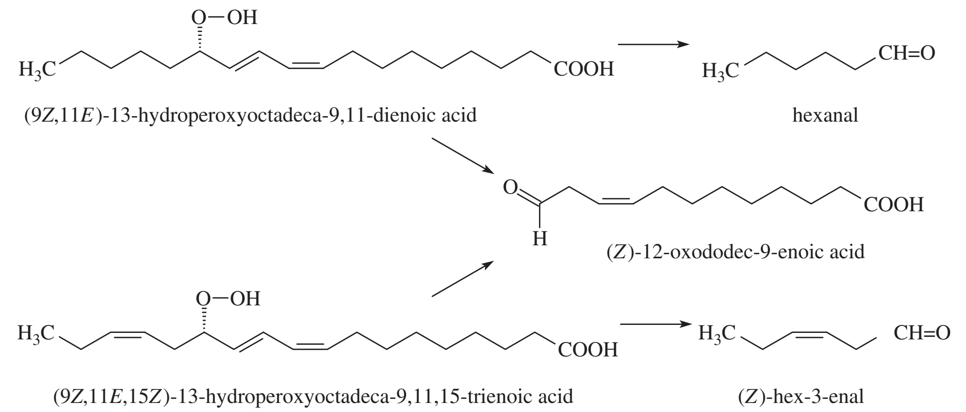

Figure 3.60 Mechanism of action of lyases to 13-hydroperoxides of unsaturated fatty acids.

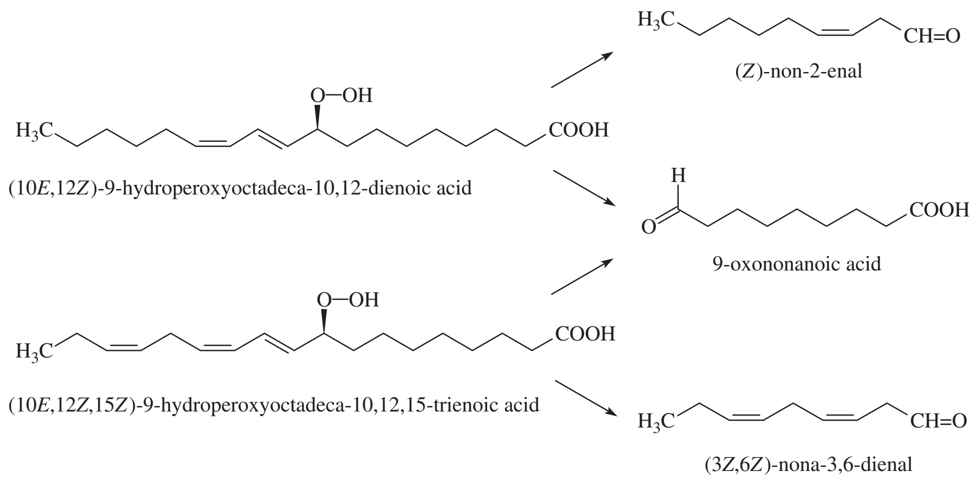

Figure 3.61 Mechanism of action of hydroperoxide lyases to 9-hydroperoxides of fatty acids.

of enal isomerases, *cis*-alkenals are isomerised to *trans*-alkenals or reduced by alcohol dehydrogenases to unsaturated alcohols (Figure 3.62). Both types of reaction products deliver characteristic flavour components to strawberries, bananas, cauliflower, tomatoes and many other fruits and vegetables.

Hydroperoxides of linoleic and linolenic acids also react with sensitive food components, such as carotenes, to form colourless products (lipoxygenase, however, do not directly catalyse the decomposition of carotenes) and induce oxidative changes in sulfur amino acids and proteins. Secondary products of lipid oxidation initiate radical reactions of proteins that lead to a reduction in their nutritional value.

Champignon mushrooms and certain other fungi contain 10-lipoxygenase, which catalyses the formation of unconjugated hydroperoxide, (8*E*,10*S*,12*Z*)-10-hydroperoxyoctadeca-8,12-dienoic acid, from linoleic acid. From this hydroperoxide, lyases produce (*E*)-10-oxodec-8-enoic acid and (*R*)-oct-1-en-3-ol, which is the key component of mushroom aroma (Figure 3.63). Analogously, (8*E*,10*S*,12*Z*,15*Z*)-10-hydroperoxy-8,12,15-octadecatrienoic acid formed by oxidation of linolenic acid yields (3*S*,5*Z*)-octa-1,5-dien-3-ol (Figure 3.63).

Biosynthesis of biologically active oxygenated derivatives of C_{18} fatty acids in plants that are known as **octadecanoids** proceeds by similar mechanisms to the biosynthesis of eicosanoids (such as prostaglandins) in animals. The action of phospholipase A_1, which hydrolyses linolenic acid in the membrane phospholipids and 13-lipoxygenase, which oxidises this acid, yields intermediates such as (9*Z*,11*E*,13*S*,15*Z*)-13-hydroperoxyoctadeca-9,11,15-trienoic acid. This acid then provides, under the action of hydroperoxide dehydratase, (9*Z*,13*S*,15*Z*)-12,13-epoxyoctadeca-9,15-dienoic acid (allene oxide), which yields, with catalysis of allene oxide cyclase, cyclopentanone derivative (10*Z*,15*Z*)-12-oxophyto-10,15-dienoic acid. This acid, through three-stage β-oxidation and reduction by 12-oxophytodienoate reductase, yields the plant

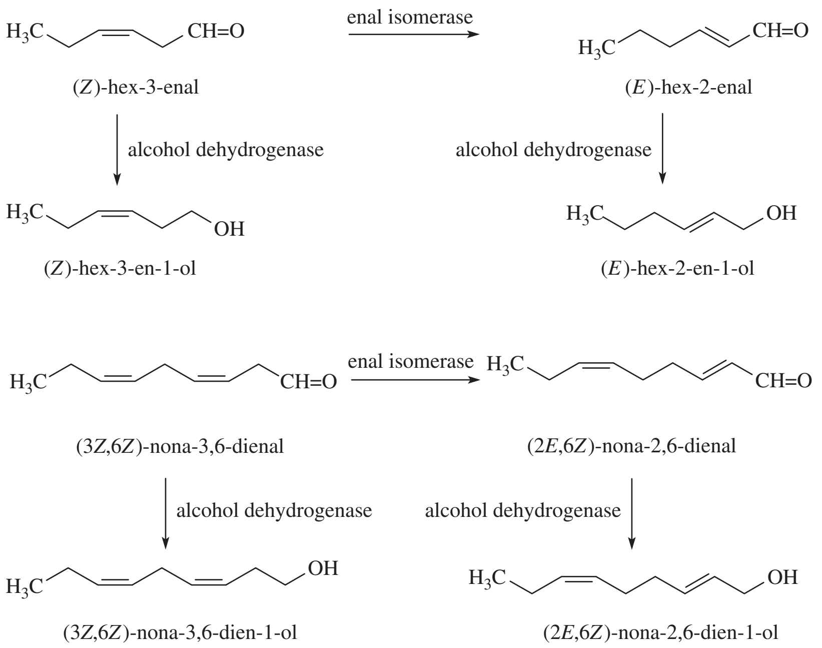

Figure 3.62 Mechanism of action of isomerases and alcohol dehydrogenases to hydroperoxide fission products.

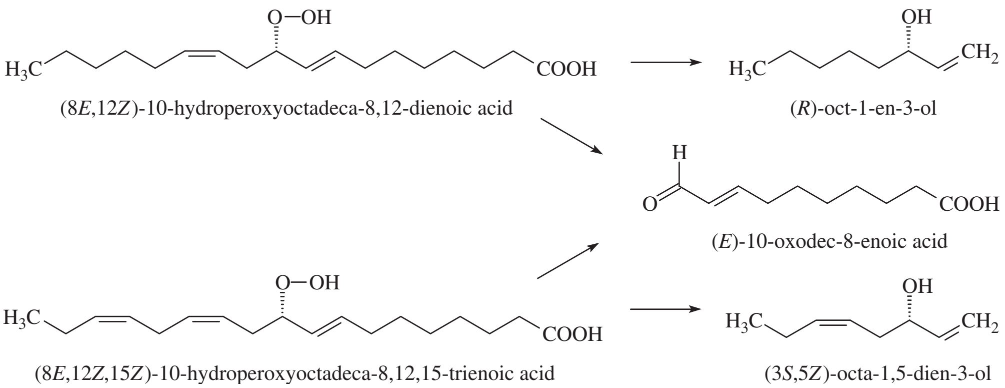

Figure 3.63 Mechanism of action of lyases in mushrooms.

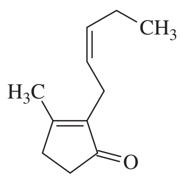
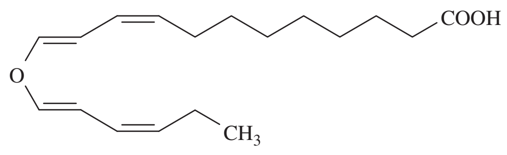
hormone (−)-jasmonic acid (Figure 3.64). Jasmonic acid plays a role in the inhibition of plant growth and leaf senescence. It is also responsible for the formation of potato tubers and bulbs of some root vegetables, such as onion. Esterification of jasmonic acid, catalysed by carboxyl methylesterase, yields methyl jasmonate. Another volatile transformation product of jasmonic acid is a fragrant ketone (*Z*)-3-methyl-2-(pent-2-en-1-ylcyclopent)-2-en-1-one called *cis*-jasmone (**3-144**). On hydroxylation, *O*-glycosylation and conjugation with amino acids some other metabolites are formed. Volatile jasmonoids occur in the essential oil of jasmine (*Jasminum grandiflorum*, Oleaceae) flowers and in many other essential oils, such as bergamot and lemon essential oils. They are also important components of the aroma of black tea. Jasmonoids are used in plant cells in the regulation of important processes such as seed germination, root growth, fruit ripening and aging, activate defence mechanisms in response to injury, environmental stress factors (e.g. salinity, drought and low temperature) and attack by various pathogens.

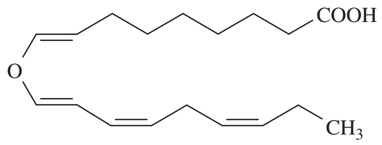


3-144, *cis*-jasmone

Other accompanying enzymes of lipoxygenases are divinylether synthases that catalyse the rearrangement of fatty acid hydroperoxides into divinyl ether fatty acids, which have a role in plant defences towards pathogens. The volatile fission products of these ethers give products with green and grassy flavours. Hydroperoxide generated by 13-lipoxygenases from linolenic acid serves as a precursor of (1*E*,3*Z*,9*Z*,11*E*)-12-hexa-1,3-dien-1-yloxy-9,11-dodecadienoic acid, which is known as etherolenic acid (**3-145**). Similarly, 9-hydroperoxide of linolenic acid is transformed into another divinyl ether fatty acid, (1*E*,3*Z*,6*Z*,8*E*)-9-nona-1,3,6-trien-1-yloxynon-8-enoic acid known as colnelenic acid (**3-146**). Analogously, 13- and 9-hydroperoxides of linoleic acid become precursors of colneleic and etheroleic acids, respectively.



3-145, etherolenic acid



3-146, colnelenic acid

(7*Z*,10*Z*,13*Z*)-Hexadeca-7,10,13-trienoic acid, abundant in many plant species known as 16:3 plants, is a precursor of a range of biological active substances (oxylipins) called **hexadecanoids**.

3.8.1.8.6 *Oxidation catalysed by metals*

Lipid oxidation is catalysed by transition metals that form compounds in many oxidation states, due to the relatively low reactivity of unpaired d electrons. These compounds, which include mainly iron,[23] copper, manganese, nickel, cobalt and chromium, are reduced by adopting one electron. The last three elements are indeed fairly active, but the level of their active forms is so low that these metals are almost of no significance. Other metals, as free ions or some undissociated salts or complexes, act as catalysts directly or indirectly in the initiation, propagation and termination phase of autoxidation reaction.

Initiation reaction

Metals in their higher valency $M^{(n+1)+}$ are initiators of autoxidation reactions. The initiation reaction takes place by electron transfer to form free radicals of hydrocarbons ($R^{\bullet}$), that is, $M^{(n+1)+} + R\text{–}H \rightarrow M^{n+} + R^{\bullet} + H^{+}$, and with ferric ions as $Fe^{3+} + R\text{–}H \rightarrow Fe^{2+} + R^{\bullet} + H^{+}$. The initiation phase is also indirectly catalysed by metals in the lower valency M^{n+} via their transient metal complexes with oxygen. The reaction products are hydrocarbon radicals ($R^{\bullet}$), metals in higher valences, reactive oxygen species such as superoxide radical anion ($O_2^{-\bullet}$) or the protonised form of the superoxide radical ($HO_2^{\bullet}$):

$$M^{n+} + O_2 \rightarrow [M^{(n+1)+} \ldots O_2] \xrightarrow{R-H} R^{\bullet} + [M^{(n+1)+} \ldots {}^{-}O_2H]$$

$$M^{n+} + O_2 \rightarrow [M^{(n+1)+} \ldots O_2] \xrightarrow{R-H} R^{\bullet} + M^{n+} + HO_2^{\bullet}$$

$$M^{n+} + O_2 \rightarrow [M^{(n+1)+} \ldots O_2] \xrightarrow{R-H} RO^{\bullet} + [M^{(n+1)+} \ldots {}^{-}OH]$$

$$M^{n+} + O_2 \rightarrow [M^{(n+1)+} \ldots O_2] \xrightarrow{(M^{n+} \cdots R-H)} HO_2^{\bullet} + [M^{(n+1)+}R^{-}] + M^{n+}$$

$$M^{n+} + O_2 \rightarrow [M^{(n+1)+} \ldots O_2] \rightarrow M^{(n+1)+} + O_2^{-\bullet}$$

The autoxidation reaction is also indirectly catalysed by reactive oxygen species (e.g. $O_2^{-\bullet}$, $HO_2^{\bullet}$ and H_2O_2), which form by the above mentioned and other reactions:

$$O_2^{-\bullet} + H^{+} \rightarrow HO_2^{\bullet}$$

$$O_2^{-\bullet} + H^{+} + HO_2^{\bullet} \rightarrow H_2O_2 + O_2$$

The reaction of superoxide radical $HO_2^{\bullet}$ with unsaturated acids is very slow and, therefore, is not too significant. Superoxide radical anion $O_2^{-\bullet}$ does not react with fatty acids. However, much more reactive are hydroxyl radicals generated by reduction of hydrogen peroxide by metals that directly initiate autoxidation reaction. As well as metals, these radicals are one-electron initiation agents:

$$M^{n+} + H_2O_2 \rightarrow M^{(n+1)+} + HO^{\bullet} + HO^{-}$$

$$R\text{–}H + HO^{\bullet} \rightarrow R^{\bullet} + H_2O$$

Propagation reactions

Some metals (Fe, Cu and Ni) catalyse the decomposition of hydroperoxides to alkoxyl radicals in their lower valency, which results in a change to a higher valency. Metals in the higher valency then catalyse the decomposition of hydroperoxides to peroxyl radicals and switch to a lower valency:

$$R\text{–}O\text{–}OH + M^{n+} \rightarrow R\text{–}O^{\bullet} + HO^{\bullet} + M^{(n+1)+}$$

$$R\text{–}O\text{–}OH + M^{(n+1)+} \rightarrow R\text{–}O\text{–}O^{\bullet} + H^{+} + M^{n+}$$

The resulting alkoxyl and peroxyl radicals increase the autoxidation reaction rates of initiation and propagation phases, since the rate of cleavage of hydroperoxides by metal ions is much faster than the formation of radicals *ab inicio*. Metal ions and non-ionised salts may react in this way (Figure 3.65). Of the metals bound in complexes, some are effective, but some are ineffective. Metals may also become less effective in the presence of fats if micelles are formed. The catalyst for the oxidation of lipids may be bound iron complexes. Iron bound in haem pigments has the same catalytic activity as the ions Fe^{2+} a Fe^{3+}, in aqueous solutions it is even more active, as it catalyses the cleavage of hydroperoxides as follows:

$$R\text{–}O\text{–}OH + Fe^{2+} \rightarrow R\text{–}O^{\bullet} + HO^{-} + Fe^{3+}$$

$$R\text{–}O\text{–}OH + Fe^{3+} \rightarrow R\text{–}O\text{–}O^{\bullet} + H^{+} + Fe^{2+}$$

In addition to these reactions, resulting in direct electron transfer, four other mechanisms have been postulated that may be involved in catalysis of lipid oxidation by haem iron. The first of these mechanisms implies formation of complexes with hypervalent iron (with valency +4), which can oxidise lipids directly. The second mechanism is indirect. Haem iron catalyses the formation of hydroxyl radicals $HO^{\bullet}$, which (as one electron agents) initiate the autoxidation reaction. Hydroxyl radicals are formed by reaction of Fe^{2+} ions bound in haem pigments via $O_2^{\bullet-}$ and hydrogen peroxide (H_2O_2), which is reduced to hydroxyl radicals with the formation of haematin:

$$H_2O_2 + \text{haem} - Fe^{2+} \rightarrow HO^{\bullet} + HO^{-} + \text{haem} - Fe^{3+}$$

The third mechanism of catalysis of lipid autoxidation by haem pigments is a photosensitised reaction and oxidation of lipids by either singlet oxygen or free radicals. The fourth mechanism assumes hydroxyl radical attack, in which haem iron is released in an ionic form, which then catalyses the oxidation of lipids in the same way as non-haem iron.

The redox potentials of other metals, such as Mn, Co and so on, are too low, therefore these metals cannot catalyse the cleavage of hydroperoxides in aqueous systems (e.g. in emulsions), but can

[23] It is not yet quite clear whether, in addition to ferric (Fe^{3+}) and ferrous ions (Fe^{2+}), whether mixed complexes of both ions with oxygen ($Fe^{3+}\text{–}O_2\text{–}Fe^{2+}$) and the so-called hypervalent iron (ions with valences +4 or + 6, for example ferryl cations FeO^{2+} and ferrate anions FeO_4^{2-}), which are the active forms of the enzymes containing haem cofactors (such as peroxidases, catalases and cytochrome P-450) are also involved in the process of the oxidation of lipids.

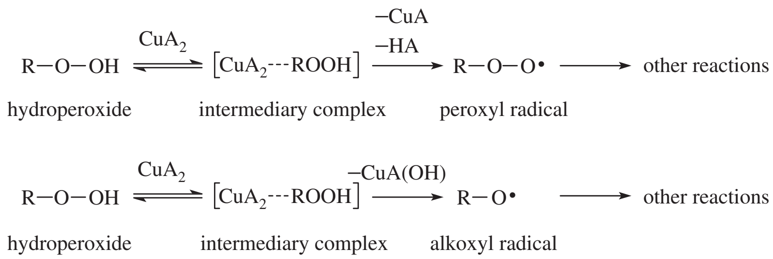


Figure 3.65 Catalytic activities of cuprous salts in autoxidation reactions. CuA_2 = cuprous salt, CuA = cupric salt, HA = fatty acid, CuA(OH) = hydrated cupric salt.

catalyse the decomposition of lipid hydroperoxides in anhydrous fats through the transient complexes formed with hydroperoxides:

$$\text{R–O–OH} + Co^{2+} \rightarrow [\text{R–O–OH} \ldots Co]^{2+}$$
$$\rightarrow \text{R–O}^{\bullet} + Co^{3+} + HO^{-}$$
$$\text{R–O–OH} + Co^{3+} \rightarrow [\text{R–O–OH} \ldots Co]^{3+}$$
$$\rightarrow \text{R–O–O}^{\bullet} + Co^{2+} + H^{+}$$

Inhibition

Since the effects of heavy metals increase the amount of free radicals in the lipid phase, not only do the rates of initiation and propagation reactions increase, but also the rate of termination reaction increases. Heavy metals therefore also change the composition of the reaction products. At high concentrations of free radicals, the termination reaction may dominate and metals then act as the inhibitors of autoxidation. Autoxidation reaction can also be inhibited by metals when they are present at higher concentrations. It is assumed that the reason is the oxidation and reduction of free hydrocarbon radicals to anions and cations by ions of Fe and Cu and the formation of complexes of free radicals. Other complexes are also formed with Co. All these reactions interrupt the radical chain autoxidation reaction. Reactions with Fe ions are given as examples.

$$R^{\bullet} + Fe^{2+} \rightarrow Fe^{3+} + R^{-}$$
$$R^{\bullet} + Fe^{3+} \rightarrow Fe^{2+} + R^{+} \rightarrow \text{products}$$
$$R^{\bullet} + Fe^{3+} \rightarrow [R^{\bullet} \ldots Fe^{3+}]$$

The formation of Co complex can be described by the following equations:

$$R^{\bullet} + CoA_3 \rightarrow \text{R–}CoA_2$$
$$\text{R–O}^{\bullet} + CoA_3 \rightarrow \text{R–O–}CoA_2$$
$$\text{R–O–O}^{\bullet} + CoA_3 \rightarrow \text{R–O–O–}CoA_2$$
$$(CoA_3 = \text{undissociated salt of } Co^{3+} \text{ with fatty acids})$$

Crude oil contains mainly iron and copper at levels up to several milligrams per kilogram, but during degumming and subsequent refining the content of these metals is reduced to negligible amounts. In foods, however, these metals are present in considerable concentrations and can pass into the oil phase, although the original oil may have contained only traces of the metals.

3.8.1.9 Inhibitors of oxidation

The inhibitors of oxidation reaction of fats are substances which reduce the oxidation rate, regardless of the mechanism of their action. These compounds include antioxidants, synergists, chelating agents and compounds decomposing hydroperoxides by non-radical reactions. Also agents stabilising hydroperoxides may reduce the reaction rate because they inhibit the formation of free radicals.

3.8.1.9.1 Antioxidants

Antioxidants (see Section 11.2.2) are substances that can react with free radicals of the autoxidation chain, especially with peroxyl radicals (Figure 3.66). The reaction creates hydroperoxides or other non-radical lipid products. The antioxidant is transformed to the form of a free radical, which, however, is fairly stable, so it is unable to continue in the autoxidation reaction. The role of the antioxidant thus lies in shortening the autoxidation chain and increasing the rate of termination reactions. During the reaction the antioxidant is consumed. When all of the antioxidant has been consumed, the autoxidation reaction proceeds as if no antioxidant was present. Antioxidants therefore cannot completely stop the autoxidation reaction; they just slow this reaction down, ideally to the initial reaction rate.

Figure 3.67 shows the reaction without an antioxidant and the reaction in its presence. It is clear that antioxidants prolong the induction period (slow autoxidation), but do not affect the rate of the subsequent rapid oxidation. The ratio of the length of the induction period of inhibited and uninhibited reactions is called the **protection factor**. It is usually expressed as a percentage of increased stability (extension of the induction period).

In addition to the inhibition reaction, other reactions run in parallel, such as oxidation of free antioxidant radical to peroxyl

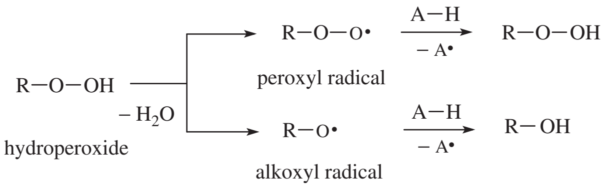

Figure 3.66 Reactions of antioxidants with free radicals formed by autoxidation of fatty acids: A–H = antioxidant, A• = antioxidant radical.

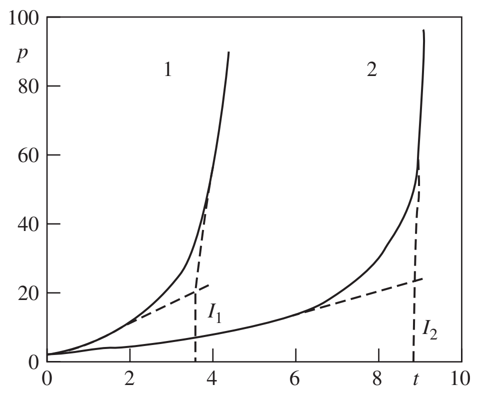

Figure 3.67 Impact of added antioxidant on the course of autoxidation reactions: p = amount of fatty acid hydroperoxides in milliequivalents of active oxygen per kg (peroxide number), t = duration of autoxidation in days, 1 = antioxidant (BHA) concentration = 0%, 2 = 0.02%, I_1 and I_2 = corresponding induction periods, protection factor $PF = (I_2 - I_1)/I_1$.

radical or the reverse reaction with the formation of a free lipid radical, especially at high antioxidant concentrations. The reaction mechanism is given in detail in Section 11.2.2.2.

The most commonly used antioxidants are synthetic phenol derivatives, which contain two (or three) hydroxyl groups in the *ortho*- or *para*-positions. Natural antioxidants are usually substituted in the *ortho*-position, so they are more efficient as antioxidants. Synthetic antioxidants are usually substituted in the *para*-position, so they are less toxic than the corresponding *ortho*-derivatives. Instead of one hydroxyl group, a methoxyl group or at least a branched alkyl substituent may be present. Substitution in a benzene ring by additional alkyl group or two alkyls increases the antioxidant efficiency. Far less frequently used antioxidants, especially for their higher toxicity, are compounds with heterocyclic nitrogen (such as dihydropyridine or dihydroquinoline derivatives). Natural antioxidants, mainly tocopherols (see Section 5.4.1), occur in all natural fats and oils. Other common natural antioxidants include phenolic and numerous other compounds (see Section 11.2.2.4).

3.8.1.9.2 Synergists and sequestrants

Synergists are substances that do not have antioxidant activity themselves, but are able to increase the efficiency of antioxidants. The most common synergists include polyhydric acids, such as citric, tartaric, malic, ascorbic and phosphoric acids. These substances are not very soluble in fats, which limits their activity. Therefore, their lipophilic derivatives, such as esters of ascorbic acid (see 5-106) or phospholipids instead of phosphoric acid, are often used. The mechanism of synergism is not fully elucidated and is probably not uniform. It may be caused to a certain extent by the non-radical acceleration of decomposition of lipid hydroperoxides, partly by the regeneration of antioxidants, and partly by the binding of prooxidants (mainly heavy metals) into inactive complexes. This last mechanism is fairly widespread and the synergist is also a chelating agent or sequestrant, a chemical that promotes sequestration. Numerous substances have the ability to bind heavy metals to complexes, such as pyrocatechol and pyrogallol derivatives, some carbohydrates, acidic phospholipids and lysophospholipids, oxalic acid, phytic acid and other compounds. Some sequestrants are used as food additives, for example ethylenediaminetetraacetic acid (EDTA). Metal ions are inactivated due to formation of insoluble and undissociated salts, but also some soluble complexes may be inactive, while others may act as prooxidants.

3.8.1.9.3 Heterolytic decomposition of hydroperoxides

Lipid hydroperoxides mostly decompose into free radicals, but sometimes they can decompose into ions, for example in the presence of acids and alkalis (Figure 3.68), or by reactions with transition metals.

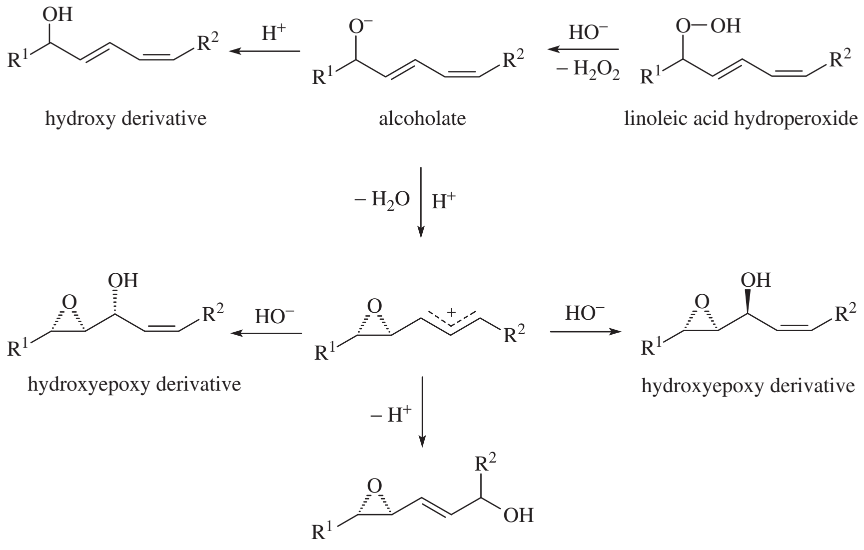

Figure 3.68 Heterolytic decomposition of hydroperoxides in acid and alkaline media.

3.8.1.10 Oxidation and quality of lipids

3.8.1.10.1 Rancidity during storage

Oxidation reactions that proceed during storage of fats reduce their sensory quality. Such processes are known as rancidity. Rancidity is not just caused by oxidation of fatty acids, but also by other reactions. Therefore, several types of rancidity can be distinguished:

- **hydrolytic rancidity**
- **oxidative rancidity**
- **ketonic rancidity**
- **flavour reversion.**

Hydrolytic rancidity

Fatty acids released during hydrolysis of fats do not bring about fat rancidity, because they are sensorially imperceptible in small amounts. The exceptions are fats containing bound fatty acids with shorter carbon chain (4–10 carbons). Butyric acid is released from butter and imparts a nasty, very pungent odour. Acids with 6–10 carbon atoms are also present to a larege extent in coconut or palm kernel oils, as well as in milk fats. Native enzymes or enzymes released by molds give the product a typical soapy off-taste.

Oxidative rancidity

Hydroperoxides resulting in fat oxidation do not affect the sensory quality of fats and oils, but their decomposition products produce distinctive odours that depend on the concentration of the secondary products and their composition. These reactions are described in detail in other sections. A certain range of oxidation reactions, both enzymatic and non-enzymatic, is often desirable, because it leads to the formation of characteristic flavour active products in many foods (such as fruits, vegetables and fried foods).

Ketonic rancidity

Ketonic or perfume rancidity typically occurs in butter, where it is undesirable. Fatty acids with 6–12 carbon atoms released from triacylglycerols by hydrolysis with lipases of microorganisms (e.g. of fungi of the genera *Penicillium* and *Aspergillus*) are enzymatically degraded largely by β-oxidation[24] to 3-oxoacids. Their decarboxylation yields alkan-2-ones, known as methylketones, which can be reduced to the corresponding alkan-2-ols (Figure 3.69). The most common methylketones (see Section 8.2.4.1.2) are pentan-2-one, hexan-2-one, heptan-2-one, octan-2-one and nonane-2-one that have specific perfume odours. Pentane-2-one and hexane-2-one posses fruit odour reminiscent of bananas, heptan-2-one has a floral and herbal odour, octane-2-one has a flowery odour and nonan-2-one exhibits a floral and oily odour. The odour itself is not unpleasant, and in mold cheeses it is even desirable, but is unusual and atypical in edible fats.

Flavour reversion

Flavour reversion is characteristic of soybean oil, and sometimes also occurs in other oils containing linolenic acid, for example rapeseed oil. It manifests itself when the oil still contains fairly low amounts of fatty acid hydroperoxides. Smells resembling grass and beans are due to flavour reversion, and are caused by different compounds resulting from the decomposition of hydroperoxides, including various derivatives of furan. Oil, in which this defect is apparent, can have this smell removed during refining, but the defect re-appears after a certain amount of time (hence the name

[24] Acyl-CoA synthetase synthesises, in the presence of HS-CoA, acyl-CoA from a saturated fatty acid. Acyl-CoA is transformed by acyl-CoA dehydrogenase into 2,3-dehydroacyl-CoA, and isomerism leads to *trans*-2-enoyl-CoA, enoyl-CoA hydratase yields (*S*)-3-hydroxyacyl-CoA, which is transformed into 3-oxoacyl-CoA by 3-hydroxyacyl dehydrogenase; the latter compound is hydrolysed by 3-ketoacyl-CoA thiolase to HS-CoA and 3-oxoacid. This acid eliminates carbon dioxide and yields methylketone, with catalysis of decarboxylase. Reductase can reduce methylketone to a secondary alcohol.

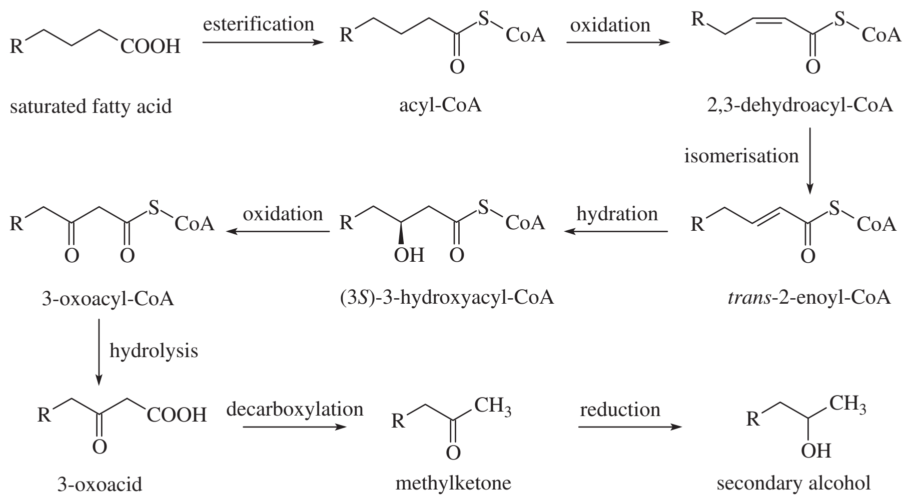

Figure 3.69 Formation of alkan-2-ones in ketone rancidity.

flavour reversion). Flavour reversion is especially off-putting to consumers in the United States as they require utterly tasteless cooking oil. Substances causing flavour reversion are thus actually present in small quantities that many other consumers do not mind, provided they ever notice the flavour change.

3.8.1.10.2 Changes during frying

During frying, the oil or fat is preheated to temperatures around 150–200 °C. The frying process is commonly carried out in:

- a thin layer of fat
- a layer of fat more than 50 mm deep (usually between 100 and 200 mm) where the fried food is submerged in fat or floats on fat.

The second approach is more common today and is called **deep frying** or **deep fat frying**. After inserting the food, water evaporates upon contact with hot fat, which cools the fat. During the deep frying process, which usually takes a few minutes, the temperature again increases by a few tens of degrees. In the processes taking place in the fat exposed to high temperature in the presence of air and moisture, several types of reactions can be distinguished:

- Hydrolytic processes induced by hot water vapour (released from the fried food) action on the hot fat are often the main processes occurring during frying; they lead to the hydrolysis of fatty acids, which are largely adsorbed on fried food or escape into the air.
- Oxidation processes that are very fast at frying temperatures; dissolved oxygen in fat is consumed, so that further oxidation is slow and depends on the rate at which oxygen diffuses from the air; the rate of diffusion, however, significantly increases if oil starts to foam, as foaming increases the interface between fat and air.
- Processes causing both polymerisation reactions between free radicals and reactions of carboxyl groups of free fatty acids with hydroxyl and epoxy groups of oxidised fatty acids of fat.
- Pyrolytic processes such as dehydration of oxidation products or their reactions with proteins and other components of fried foods; they yield significant sensorially active substances; pyrolytic reactions include the decomposition of glycerol (released by hydrolytic processes) to acrolein (see Section 8.2.4.1.1).

Under conditions employed in deep frying, a complex series of reactions takes place resulting in a loss of quality of both the frying oil and the fried food. The levels of polar compounds, polymers, free fatty acids, oxidised fatty acids and the smoke point of the fat have become the most generally accepted indicators for quality evaluation of frying fats and are included in some of the current official regulations. In general, if the content of polar compounds generated by oxidative and hydrolytic reactions exceeds 25% and the amount of polymers exceeds 10% of the fat weight, it is recommended that the used fat be replaced with fresh fat.

3.8.1.11 Effects of oxidised lipids on human health

Oxidised lipids have only a low acute toxicity; therefore their effect on human health is often underestimated. The toxicity of fats used for frying has not been firmly established, therefore the limits for their use (25% of polar compounds and 10% of polymers) indicate that in reality the functional properties are deteriorating and the flavour of the fried food will get worse. Adversely reflected in terms of chronic toxicity are cyclic dimers and particularly cyclohexene derivatives. A higher content of hydroperoxides causes symptoms of vitamin E and essential fatty acid deficiency, which results in increased permeability of the skin to water. It is also difficult to enzymatically hydrolyse (digest) oxidised lipids. Recently it has been shown that a higher intake of oxidised fats increases their levels in blood serum, and oxidised fatty acids or free radicals arising from oxidised fatty acids then react with certain proteins in blood serum and in the walls of blood vessels and form atherosclerotic deposits. Oxidised sterols are particularly active in this respect. Similar deposits are formed, for example, in the nerve tissue and some other important organs. Oxidation products of lipids, especially the reactive acrolein, (*E*)-4-hydroxyalk-2-enals and malondialdehyde, also react with proteins and nucleic acids, where any alterations may facilitate development of malignant tumours. For these reasons, an increased intake of natural antioxidants, mainly tocopherols and carotenes, is recommended, which leads to an increased intake of easily oxidisable polyenoic fatty acids.

3.8.1.12 Oxidation of food constituents and other reaction of oxidised lipids

Oxidation products of lipids (hydroperoxides, free alkoxyl and peroxyl radicals, epoxides and aldehydes) react with a number of food constituents during the processing and storage of food. These reactions often lead to a reduction in the nutritional value of foods (such as reactions with proteins and vitamins) and a deterioration of their organoleptic properties (e.g. reactions with flavour active substances).

3.8.1.12.1 Reactions with proteins and deoxyribonucleic acids

Reactions of proteins with lipid hydroperoxides and other oxidised lipids give rise to different types of lipoproteins, in which lipids and proteins are bound by physical bonds (as in natural lipoproteins), but also by covalent bonds. Reactions with hydroperoxides, free radicals, epoxides and aldehydes lead to the fission of some protein bonds, formation of protein radicals and oligomers, cross links between protein chains and some sensitive functional groups of amino acids are oxidised (see Section 2.5.1.1).

Cysteine and methionine are particularly sensitive to oxidation, as are histidine, arginine, tryptophan and phenylalanine. In foods, oxidation mainly takes place in sulfur-containing amino acids (cysteine, cystine and methionine). Cysteine can be oxidised to cystine or even to cysteic acid, but the oxidation by hydroperoxides in foods does not go so far. Methionine is oxidised to

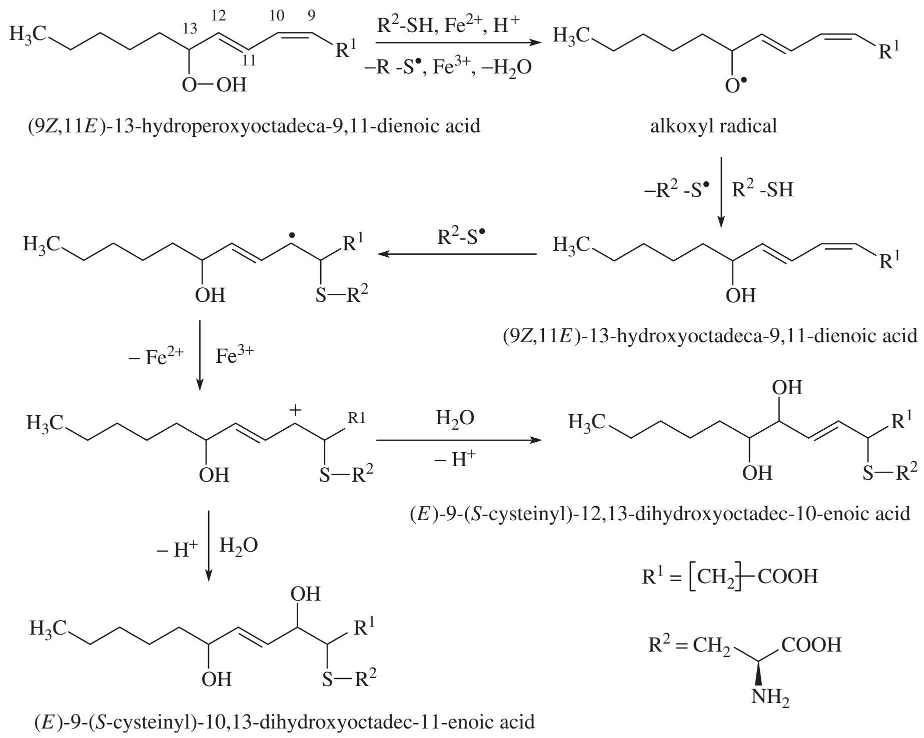

Figure 3.70 Reaction of cysteine with 13-hydroperoxyoctadeca-9,11-dienoic acid.

methionine sulfoxide, but not to methionine sulfone. Figure 3.70 gives as an example of a simplified reaction of cysteine with 13-hydroperoxyoctadeca-9,11-dienoic acid, which is formed by oxidation of linoleic acid. Further reactions of sulfur-containing amino acids are presented in the section dealing with the reactions of amino acids (see Section 2.5.1.1). Also sensitive to oxidation are thiols, sulfides, oligosulfides and inorganic sulfides. Selenium compounds are oxidised in the same way as sulfides. Furthermore, selenites can be oxidised to selenates.

The reaction of hydroperoxides with primary amino groups probably produces an imine, according to the mechanism indicated in Figure 3.71. Imines are also formed as reaction products of protein-bound amino acids with carbonyl compounds resulting as secondary products of lipid oxidation. In particular, 2-alkenals (α,β-unsaturated aldehydes), such as acrylamide, (*E*)-4-hydroxyhex-2-enal, (*E*)-4-hydroxynon-2-enal and (*E*)-4,5-epoxydec-2-enal and malondialdehyde, are very reactive compounds that accumulate in forms covalently bound to proteins and nucleosides *in vivo* and can also be found in foods. The covalent products of these aldehydes, known by the acronym **ALE** (advanced lipoxidation end products) are used as markers of oxidative stress in the organism. Analogous reaction products of proteins with reactive products arising from sugars, known as AGEs, are described in Section 4.7.5.6. Dietary ALEs derived from acrolein and other alk-2-enals are found in the greatest amounts in heat-treated dairy and meat products.

Of all the 2-alkenals, acrolein is by far the strongest electrophile and, therefore, shows the highest reactivity with nucleophiles, such as the sulfhydryl group of cysteine, ε-amino group of lysine and imidazole group of histidine. Acrolein is present

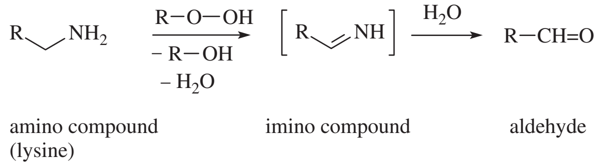

Figure 3.71 Reaction of hydroperoxides with amines or basic amino acids.

in foods mainly as a decomposition product of methionine (see Figure 2.61), arachidonic acid (see Figure 3.72), glycerol (see Section 8.2.4.1.1), hydroxyacetone (acetol, Figure 4.60) and spermine (see Section 10.3.2.10.3). With the amino group of amino acids, acrolein undergoes nucleophilic addition at the double bond (C-3) to form a derivative with retention of the aldehyde group, resulting in the formation of the Michael addition-type acrolein–amino acid adducts. It has been shown that acrolein modifies lysine and histidine residues of human serum albumin and some proteinases. Although it has been proposed that, upon reaction with amino groups, acrolein forms β-substituted propanals (R–NH–CH_2–CH_2–CH=O) and imine (R–NH–CH_2–CH_2–CH=N–R), an aduct of acrolein (two molecules) with lysine, 2-amino-6-(3-formyl-1,2,5,6-tetrahydropiperidino) hexanoic acid, also known as N^{ε}-(3-formyl-3,4-dehydropiperidino) lysine or FDP-lysine (**3-147**), has recently been identified as the major product.

(*E*)-4-Hydroxyalk-2-enals arising from lipid peroxidation in biological membranes *in vivo* and in foods have been proven

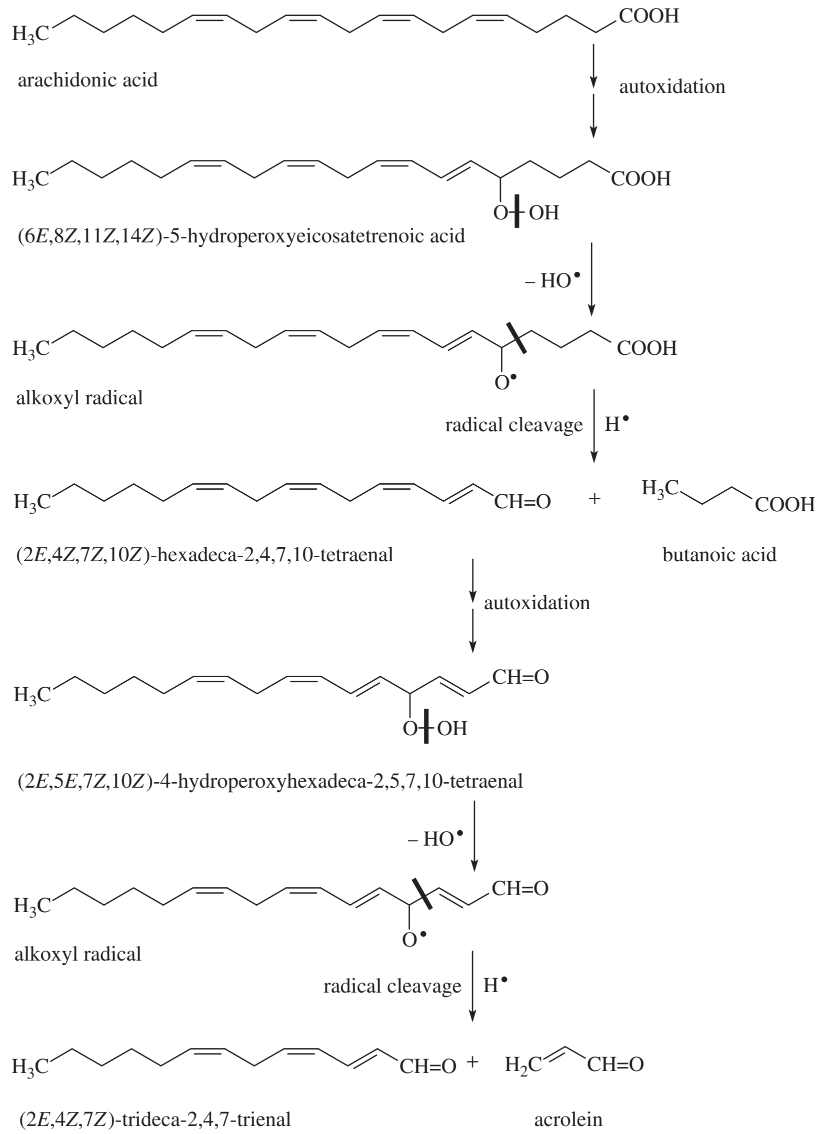

Figure 3.72 Formation of acrolein from arachidonic acid.

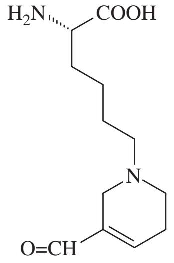

3-147, 2-amino-6-(3-formyl-1,2,5,6-tetrahydropiperidino)hexanoic acid

to be involved in carcinogenesis. The most important compound is (*E*)-4-hydroxynon-2-enal, which arises from the ω-6 fatty acids (linoleic or arachidonic acids) (Figure 3.73). Linolenic acid analogously yields (*E*)-4-hydroxyhex-2-enal. 4-Hydroxynon-2-enal has also been found in many animal tissues, where it is produced in significant quantities during oxidative stress. In foods, it is formed in various meat products, such as frankfurter suasages (0.08–0.62 mg/kg), and in cooking oils used repeatedly in catering and in households. For example, the thermally oxidised soybean oil after intermittent heating at 185 °C for 1 h contained 2.3 mg/kg of 4-hydroxynon-2-enal. 4-Hydroxynon-2-enal has various beneficial effects (such as stimulation of guanylate cyclase and phospholipase C) at low concentrations (below 0.1 mM), whereas at higher concentrations (1–20 mM) it inhibits protein and DNA syntheses, activates phospholipase A2 and is associated with many diseases, such as chronic inflammation, neurodegenerative diseases, atherosclerosis, diabetes and various types of cancer. Detoxification and elimination of 4-hydroxynon-2-enal is provided by several enzymes, including glutathione *S*-alkyltransferase, also known as *S*-hydroxyalkyl glutathione lyase (which catalyses the conjugation of aldehyde to glutathione with the formation of polar products) and aldehyde dehydrogenase (which reduces

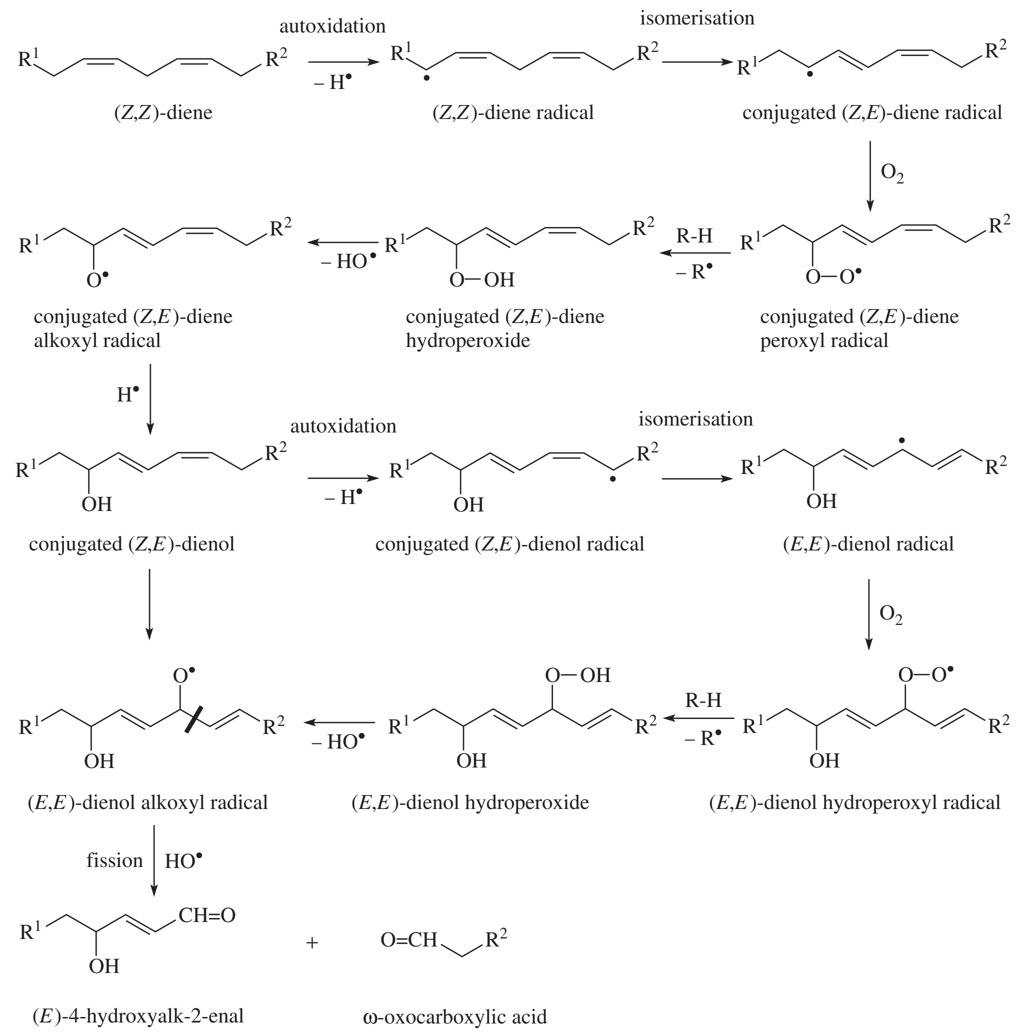

Figure 3.73 Expected mechanisms of formation of (*E*)-4-hydroxyalk-2-enals from ω-6 fatty acids.

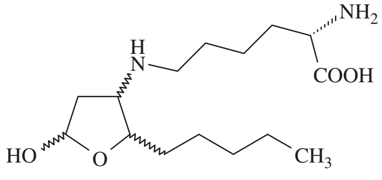
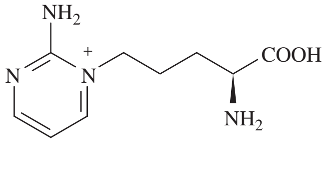
aldehyde to alcohol). An example of a product of 4-hydroxynon-2-enal with lysine is 3-(N^{ε}-lysino)-4-hydroxynonan-1-ol, known as HNE-lysine (**3-148**), while a 2-aminopyrimidine derivative, HNE-arginine (**3-149**), results from a reaction with arginine. Analogous products arise in reactions of 4-hydroxynon-2-enal with cysteine and histidine.



3-148, HNE-lysine



3-149, HNE-arginine

Considerable attention has also been paid to malondialdehyde, but the mechanisms of its formation from fatty acids are not yet fully understood. As shown in Figure 3.51 and Figure 3.53, malondialdehyde arises as a secondary oxidative product by cleavage of alk-2-enals and alka-2,4-dienals. Its precursors are thus, under certain conditions (acidic pH, singlet oxygen), dienoic fatty acids, such as linoleic acid. Biochemically, the most important sources of malondialdehyde, however, are probably cyclic peroxides of fatty acids with three or more double bonds and similar structures (hydroperoxybisepidioxides, hydroperoxybiscycloendoperoxides and dihydroperoxides) (Figure 3.36). Malondialdehyde in tissues may also arise from certain precursors of prostaglandins. For example, (9*Z*,13*E*,15*Z*)-12-hydroperoxy-9,13,15-octadecatrienoic acid (12-hydroperoxylinolenic acid) formed by oxidation of linolenic acid can cyclise to a derivative of 1,2-oxolane, oxidation of which yields a cyclic peroxohydroperoxide as a major product. Cleavage of bonds on both sides of peroxohydroperoxides gives malondialdehyde (Figure 3.74). This aldehyde readily reacts with functional groups

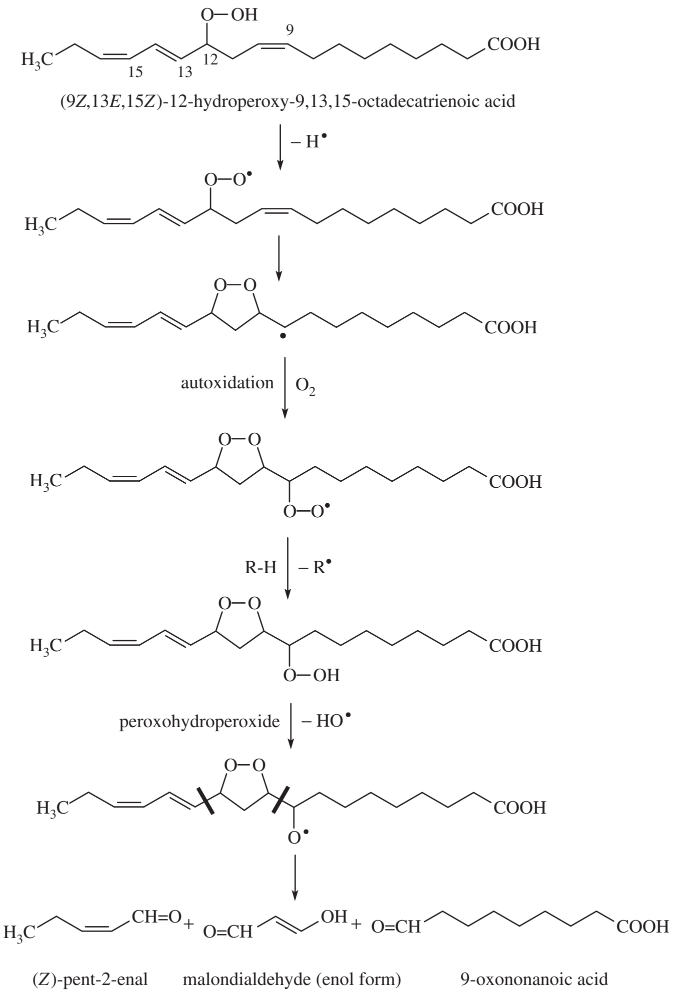


Figure 3.74 Formation of malondialdehyde from linolenic acid peroxohydroperoxide.

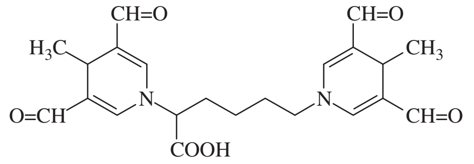
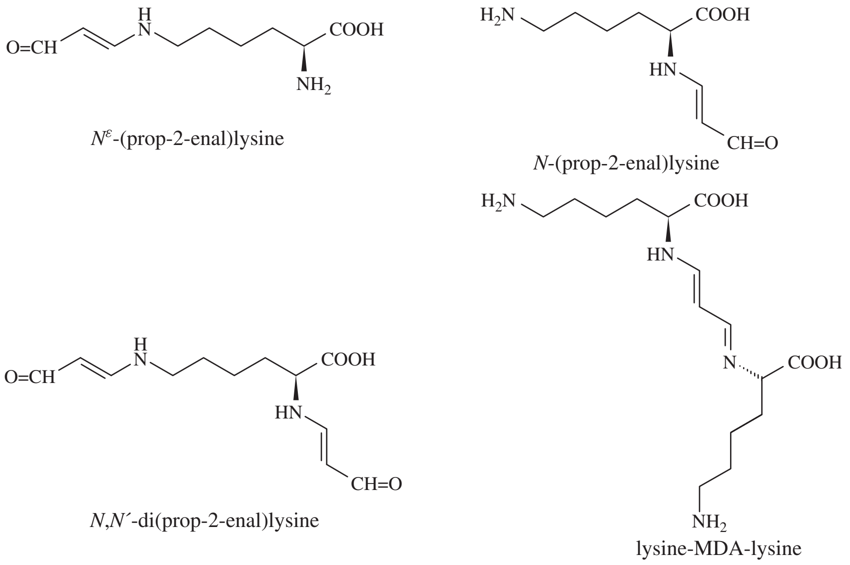
present in proteins, nucleic acids and phospholipids, especially amino groups.

Reaction of a malondialdehyde (MDA) carbonyl group with amino groups leads to the formation of imines, but formation of these structures is of no nutritional concern, because they are hydrolysed at the acidic pH of the stomach. *N*-Prop-2-enals, which are absorbed from the gut, are also formed in neutral or acidic aqueous media, but most of the absorbed material is not metabolised. A third type of reaction products are unavailable 4-substituted 1,4-dihydropyridine-3,5-dicarbaldehydes, which arise in reactions of malondialdehyde with amino compounds, such as lysine, in the presence of alkanals. Examples of malondialdehyde reaction products with lysine are N^{ε}-(prop-2-enal)lysine, so-called MDA-lysine, N^{α}-(prop-2-enal)lysine, *N*,*N*′-di(prop-2-enal)lysine (**3-150**) and conjugated cross-link in proteins termed lysine-MDA-lysine. An example of the reaction product of lysine with malondialdehyde and acetaldehyde is *N*,*N*′-di(4-methyl-1,4-dihydropyridine-3,5-dicarbaldehyde)lysine, which, for example, arises in the reaction of bovine serum albumin with malondialdehyde and acetaldehyde (**3-151**).

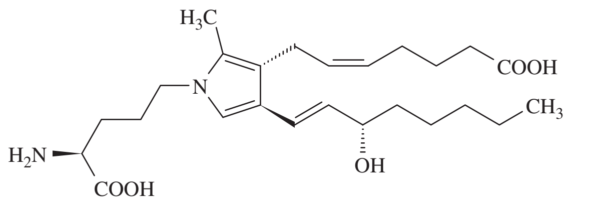


3-151, *N*,*N*′-di(4-methyl-1,4-dihydropyridine-3,5-dicarbaldehyde)lysine

ALEs can also be formed from prostaglandin H_2 (PGH_2), which rearranges non-enzymatically into levuglandin E_2. Levuglandin E_2 condenses with the ε-amino group of protein-bound lysine to form a pyrrole derivative levuglandin E_2-lysine (**3-152**), which has been identified in the blood plasma.



3-150, malondialdehyde conjugates with lysine



3-152, levuglandin E_2-lysine

Alk-2-enals also react to form adducts with 2′-deoxyguanosine (the corresponding base guanine) and other bases in DNA. If the damaged DNA is not repaired, these adducts may be mutagenic. The proposed reaction mechanism involves a Michael addition of the N^2-amino group of deoxyguanosine at the C-3 position of the alk-2-enals. The Michael product then cyclises at the *N*-1 of deoxyguanosine to form two pairs of diastereomers. The simplest alk-2-enal, acrolein, reacts with 2′-deoxyguanosine in DNA to form 1,N^2-propanodeoxyguanosine adducts: (6*R*/*S*)-3-(2′-deoxyribos-1′-yl)-5,6,7,8-tetrahydro-6-hydroxypyrimido[1,2-*a*]purine-10(3H)/ones (Figure 3.75) and also (8*R*/*S*)-3-(2′-deoxyribos-1′-yl)-5,6,7,8-tetrahydro-8-hydroxypyrimido[1,2-*a*]purine-10(3H)/ones. Other alk-2-enals, such as (*E*)-4-hydroxyhex-2-enal and (*E*)-4-hydroxynon-2-enal, react with deoxyguanosine analogously. Malondialdehyde possibly reacts with deoxyguanosine in a different way (via adenine adduct) to form a variety of adducts, the most abundant of which is pyrimido[1,2-*a*]purin-10(3*H*)-one, which is known as M_1G (Figure 3.75). The M_1G adduct is mutagenic and has been detected in human liver cells and other products.

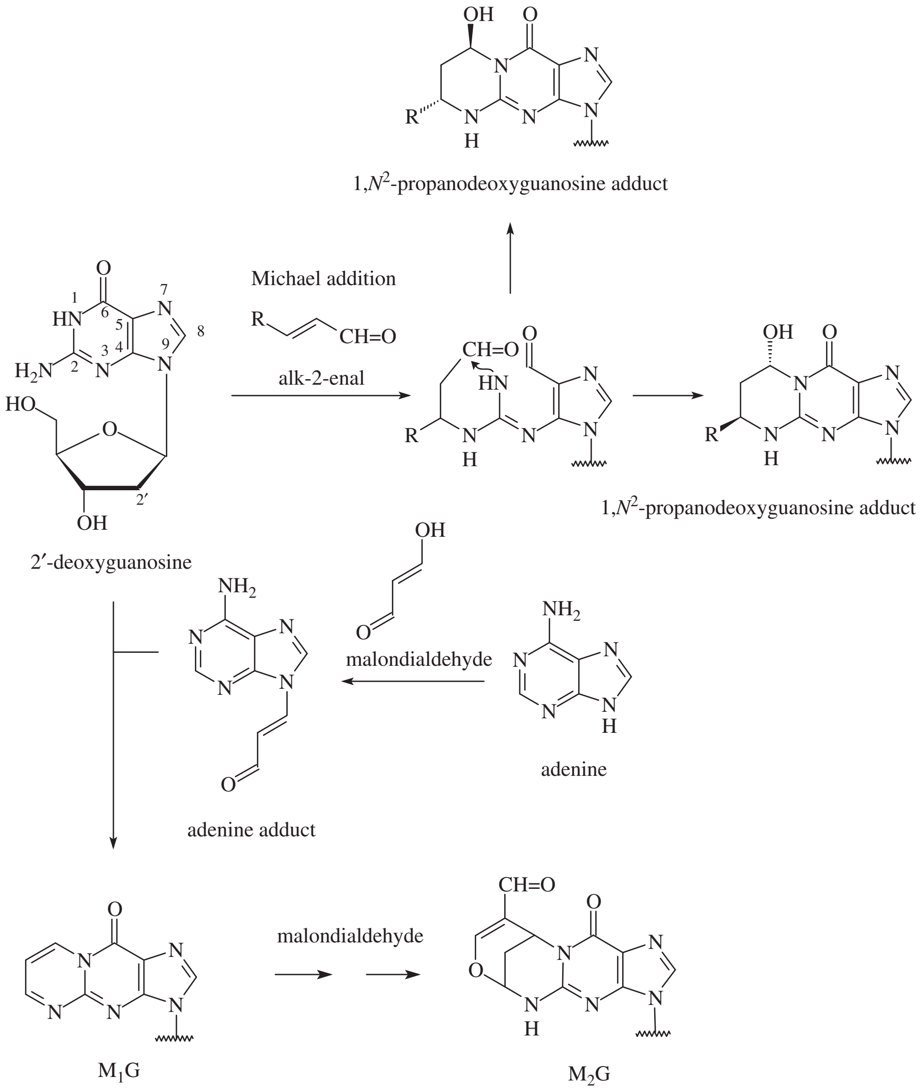


Figure 3.75 Formation of 2′-deoxyguanine adducts with alk-2-enals and malondialdehyde: R = H (acrolein), R = $CH(OH)CH_2CH_3$ (4-hydroxyhex-2-enal, R = $CH(OH)[CH_2]_4CH_3$ (4-hydroxynon-2-enal).

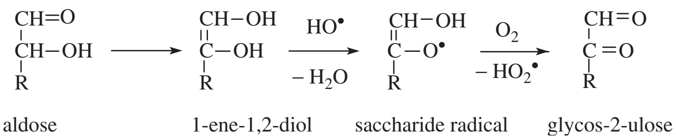

Figure 3.76 Oxidation of monosaccharides to glycosuloses.

3.8.1.12.2 Reactions with saccharides

Oxidation of saccharides is usually initiated by one-electron oxidising agents, such as transition metal ions (especially Fe^{3+} and Cu^{2+}) and free radicals (mainly the hydroxyl radical $HO^{\bullet}$ and alkoxyl radical $RO^{\bullet}$). The primary products of oxidation by free radicals (Figure 3.76), which takes place after the isomerisation to 1-ene-1,2-diols, are α-dicarbonyl compounds containing the original number of carbon atoms, known as glycos-2-uloses. Glycos-2-uloses are further oxidised and decomposed. Radicals formed as intermediates and α-dicarbonyl compounds react further with proteins in the Maillard reaction.

3.8.1.12.3 Reactions with vitamins

Vitamins that have a role as antioxidants (vitamin E, ascorbic acid and provitamins A) are easily oxidisable substances that react with free radicals or act as singlet oxygen scavengers. The reaction of tocopherols (T–OH) with hydroperoxyl radicals ($ROO^{\bullet}$) is also a part of the protective mechanisms in biomembranes of living tissues:

$$R\text{–}O\text{–}O^{\bullet} + T\text{–}OH \rightarrow R\text{–}O\text{–}OH + T\text{–}O^{\bullet}$$
$$(R\text{–}O\text{–}OH = \text{hydroperoxide}, T\text{–}O^{\bullet} = \text{tocopheryl radical})$$

At the phase interface, tocopheryl radicals are then reduced back to tocopherols by ascorbic acid (H_2A), which is oxidised to ascorbyl radical ($HA^{\bullet}$):

$$H_2A + T\text{–}O^{\bullet} \rightarrow HA^{\bullet} + T\text{–}OH$$

Another one-electron oxidation of ascorbyl radical produces dehydroascorbic acid (A), which is reduced back to ascorbic acid by dehydroascorbate reductase:

$$2HA^{\bullet} + NADH + H^{+} \rightarrow 2H_2A + NAD^{+}$$

Other vitamins are also oxidised. In folacin, for example, the links C-9 and N-10 are cleaved (see Section 5.12.2); vitamins D undergo photodegradation in the presence of photosensitisers (see Section 5.3.6).

3.8.1.12.4 Reactions with other compounds

Other significant reactions are reactions of oxidised lipids with phenolic compounds, many of which are used as antioxidants (see Section 11.2.2).

3.8.1.13 Oxidation in biological systems

Triplet oxygen is reduced to water during oxygenic photosynthesis in plants and in analogous reactions in the respiratory chain of animals[25]:

$$^3O_2 + 4\,e^- + 4H^+ \rightarrow 2\,H_2O$$

At the same time, toxic forms of oxygen, free radicals and covalent compounds, form as byproducts (through one, two and three-electron reduction), which oxidise lipids of biological membranes, then subsequently DNA, proteins and other biomolecules (Figure 3.77). Fortunately, organisms are also equipped with detoxifying mechanisms, which include:

- enzymes whose cofactors are Mn, Zn, Cu, Se and Fe
- vitamins (vitamin E, provitamins A and vitamin C).

3.8.1.13.1 Singlet oxygen

Singlet oxygen, which originates in photosensitised reactions (Figure 3.59), is very effectively scavenged by carotenes, tocopherols (vitamin E) and ascorbic acid (vitamin C) in living organisms as well as in edible oils and fats.

3.8.1.13.2 Superoxide anion

Superoxide anion O_2^- has one unpaired electron; therefore it is a free radical, $O_2^{-\bullet}$. This superoxide radical arises by one-electron reduction of triplet oxygen. In plants, this reaction is catalysed by

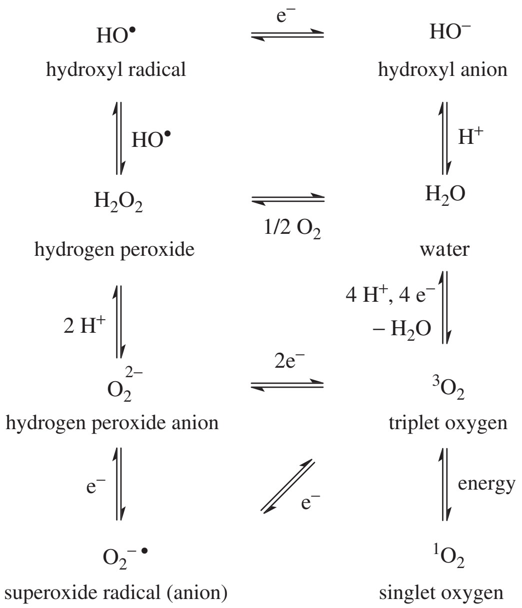

Figure 3.77 Metabolism of oxygen.

[25]During oxygenic photosynthesis, the reaction $A + H_2O + \text{energy} \rightarrow AH_2 + \frac{1}{2}O_2$ takes place, where A is the acceptor (carbon dioxide) and AH_2 the monose unit ($H_2C{=}O$). The oxidation of nutrients in the respiratory chain proceeds according to the equation: $AH_2 + \frac{1}{2}O_2 \rightarrow A + H_2O + \text{energy}$ (e.g. the oxidation of sugars in the citric acid cycle and oxidation of fatty acids by β-oxidation).

NADPH oxidase, in animals superoxide radical is a byproduct of other oxidases):

$$^3O_2 + e^- \rightarrow O_2^{-\bullet}$$

The superoxide anion is removed by the activity of superoxide dismutase. The mitochondrial enzyme contains Mn as a cofactor; the cytosolic enzyme has Zn and Cu as cofactors. A donor of two hydrogen atoms may be, for example, ascorbic acid ($H_2A + O_2^{-\bullet} + H^+ \rightarrow HA^\bullet + H_2O_2$):

$$O_2^{-\bullet} + e^- \rightarrow O_2^{2-}$$
$$O_2^{2-} + 2H^+ \rightarrow H_2O_2$$

Spontaneously, without the involvement of any enzymes, one-electron reduction or dismutation (the so-called Haber–Weiss reaction) takes place:

$$O_2^{-\bullet} + H_2O_2 \rightarrow HO^\bullet + HO^- + {}^3O_2$$
$$O_2^{-\bullet} + Fe^{3+} \rightarrow {}^3O_2 + Fe^{2+}$$

3.8.1.13.3 Hydrogen peroxide

Hydrogen peroxide is the result of two-electron reduction of triplet oxygen:

$$^3O_2 + 2e^- + 2H^+ \rightarrow H_2O_2$$

It is mainly decomposed by microsomal catalase ($H_2O_2 : H_2O_2$ oxidoreductase), which contains Fe (haematin) as a cofactor or by cytoplasmic or mitochondrial GSH peroxidase (H_2O_2 : donor oxidoreductase) containing Se as a cofactor:

$$2H_2O_2 \rightarrow 2H_2O + {}^3O_2$$
$$2G\text{–}SH + H_2O_2 \rightarrow G\text{–}S\text{–}S\text{–}G + 2H_2O$$

Otherwise, a single electron reduction takes place, which proceeds as in the Haber–Weiss reaction or Fenton reaction, which yields a highly reactive hydroxyl radical ($HO^\bullet$):

$$H_2O_2 + e^- \rightarrow HO^\bullet + HO^-$$
$$H_2O_2 + Fe^{2+} \rightarrow HO^\bullet + HO^- + Fe^{3+}$$

3.8.1.13.4 Hydroxyl radical

The most dangerous toxic form of oxygen is the hydroxyl radical, which is generated by two-electron reduction of triplet oxygen:

$$^3O_2 + 3e^- + 3H^+ \rightarrow HO^\bullet + H_2O$$

Hydroxyl radicals damage the mitochondrial (chromoplastic), microsomal (peroxysomal) and endoplasmic reticulum membranes. The damage associated with many degenerative processes (diseases) includes certain forms of cancer and occurs even during the normal aging of organisms. Hydroxyl radicals operate mainly at the place of formation, where they attack unsaturated fatty acid (RH) bound in the membrane phospholipids. Unsaturated fatty acids yield hydroperoxides (R–O–OH) through the previously described mechanisms:

$$R\text{–}H + HO^\bullet \rightarrow R^\bullet + H_2O$$
$$R^\bullet + O_2 \rightarrow R\text{–}O\text{–}O^\bullet$$
$$R\text{–}O\text{–}O^\bullet + R\text{–}H \rightarrow R\text{–}O\text{–}OH + R^\bullet$$

The protective mechanism of organisms lies in the reduction of hydroperoxyl radicals by vitamin E (tocopherols, TH):

$$R\text{–}O\text{–}O^\bullet + T\text{–}H \rightarrow R\text{–}O\text{–}OH + T^\bullet$$

Tocopheryl radicals $T^\bullet$ are stabilised by a number of reactions. They can be reduced back to tocopherols by ascorbic acid (H_2A), which is oxidised to dehydroascorbic acid (A):

$$2T^\bullet + H_2A \rightarrow 2T\text{–}H + A$$

Hydroperoxides are removed from bonds in damaged phospholipid by activated phospholipase A_2 and free hydroperoxide becomes a substrate for peroxidases. Otherwise, the oxidation of fatty acids results in the accumulation of lipid hydroperoxides and their secondary metabolites such as (*E*)-4-hydroxynon-2-enal and malondialdehyde, which react with proteins and DNA (see Section 3.8.1.12.1).

Proteins and deoxyribonucleic acids

The main agents damaging proteins are hydroxyl radicals ($HO^\bullet$), singlet oxygen ($^1O_2$) and superoxide radicals ($HO_2^\bullet$). Reactions are analogous to those in foods and can result in loss of enzymatic activity, cell cytolysis and cell death. Damaged proteins in biomembranes are often associated with oxidised lipids.

The main oxidising agent of DNA is the hydroxyl radical ($HO^\bullet$), which oxidises the purine and pyrimidine bases and deoxyribosyl residues. The main oxidation products are 5-(hydroxymethyl)uracil (**3-153**) and 8-hydroxyguanine (**3-154**), which is formed by reaction of guanine with singlet oxygen. In the presence of transition metals, the main compound that is attacked is adenine. The reaction product is adenine-N^1-oxide (**3-155**).

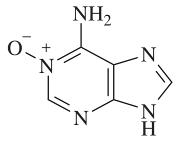
3-154, 8-hydroxyguanine



3-155, adenine-N^1-oxide

3.8.1.14 Degradation reactions

At high temperatures, pyrolytic reactions of lipids can yield fatty acid anhydrides, and fatty acids may eliminate carbon dioxide by decarboxylation. These reactions take place during food processing only at trace levels.

3.8.2 Reactions of homolipids

3.8.2.1 Reactions of waxes

Waxes do not have specific chemical properties and their reactivities are similar to other fatty acid esters. The only difference is that, due to their higher molecular weight and high melting points, waxes react more slowly. Their most important chemical reaction is hydrolysis to the parent components, primary alcohols and fatty acids.

3.8.2.2 Reactions of fats and oils

3.8.2.2.1 Hydrolysis and saponification

Hydrolysis of fats and oils (lipolysis) in foods is primarily caused by the action of lipases. The sources of lipases can be crude oils (lipase from vegetable seeds, beans or fruit pulps) or microorganisms. Some lipases show substrate specificity according to the length of the acyl group and regiospecificity (*sn*-non-specific and *sn*-1,3-specific lipases). Lipolysis in food technology may proceeds on purpose, for example, during ripening of certain cheeses, with specific types of molds added during the cheesemaking process (surface-ripened Camembert or blue chesses such as Roquefort and Gorgonzola with molds growing in the curd), and in cured and fermented dried sausages (by *Lactobacillus* bacteria and other bacteria added as starter cultures or by natural microflora). Examples are given in Table 3.47.

Hydrolysis products are dependent on the specificity of lipase. In the case of pancreatic lipase, the final products are fatty acids and 2-monoacylglycerols, in the case of *sn*-non-specific lipases from oil seeds, di- and monoacylglycerols, glycerol and free fatty acids gradually form upon hydrolysis of crude vegetable oils. A necessary condition for the enzymatic hydrolysis process is the presence of water. The solubility of water in refined oils is around 0.1% at 20 °C, and may be higher in crude oils due to the presence of heterolipids. These water contents are sufficient for hydrolysis. Analogously, hydrolysis takes place in the fat cells of oilseeds with increased water content. Enzymatic hydrolysis is used, for example, to obtain essential fatty acids containing C_{20}–C_{22} fatty acids, when high temperatures cannot be used.

Partial hydrolysis of fats actually occurs at high temperatures during deep frying of foods, when the released water causes hydrolysis of the ester bonds. The released fatty acids distil off from the oil bath to the surroundings. Particularly prone to this behaviour are fats containing medium-chain fatty acids, such as coconut or palm kernel oil and milk fat.

Fatty acids in oleochemistry (as well as fatty acids for food use) are obtained through autocatalysed hydrolysis (Figure 3.78) at high temperatures, where the byproduct is glycerol. Temperatures above 200 °C are particularly necessary in order to increase the solubility of water in the fat. The solubility of water in fat generally depends on temperature and the length of the acyl group. For example, water solubility at 93 and 205 °C in coconut oil is 3.5 and 12%, while in beef tallow it is only 1 and 5%, respectively. The reaction proceeds in a two-phase system of oil–water, where the lipid phase is a dispersion medium. Glycerol is soluble in water and is extracted from the fat phase into the aqueous phase; therefore the reaction equilibrium is shifted in favour of hydrolysis. Using a continuous counter flow arrangement, a degree of hydrolysis of up to 98–99% can be achieved.

Saponification of lipid ester bonds is based on the reaction of aqueous solutions of alkali metal hydroxides and the formation of soaps (alkali metal salts of fatty acids) and glycerol as a byproduct. Intermediates of saponification of triacylglycerols are di- and monoacylglycerols.

A partial saponification of acylglycerols also occurs during deacidification (neutralisation) of raw oils by alkaline agents, which

is a side-reaction that leads to some loss of oil. A partial saponification also takes place during ester exchange, when sodium hydroxide is used as a catalyst. Saponification of fat blends is used deliberately to produce sodium soaps, toilet soaps (from a mixture of coconut oil and beef tallow) and detergent soap powders (usually from beef tallow only).

3.8.2.2.2 Interesterification reactions

In oleochemistry, a characteristic reaction of fatty acids is esterification, but the characteristic reaction of their esters, especially natural fats, is an interesterification reaction. Interesterification is a set of reactions where the original ester reacts with a fatty acid, an alcohol or another ester.[26] The following reactions are seen:

- **acidolysis**
- **alcoholysis**
- **ester interchange (transesterification)**.

This set of reactions is catalysed either by enzymes or acidobasic catalysts and is characterised by migration of acyls between the molecules of alcohols or in the glycerol molecule. When using acid–base catalysts, acyl migration is statistically random. There is a growing interest in using enzymes (lipases or phospholipases) in technological applications, where it is possible to perform selective interesterification reactions catalysed by specific enzymes.

In the presence of water, lipases catalyse the hydrolysis of lipids to fatty acid partial esters and, in the final stage, to glycerol. Hydrolysis is the opposite reaction of the esterification reaction catalysed by lipases, where the resulting water has to be removed.[27] Esterification is used industrially for the preparation of fatty acid esters. In the absence of water, lipases (as well as other hydrolases) also catalyse the interesterification reaction. When immobilised lipases became available commercially, this reaction found applications on an industrial scale. The basic advantage of the use of lipases, compared with acidobasic catalysts, is their specificity, particularly if particular *sn*-1,3-lipases are employed.

Acidolysis

Acidolysis is a reaction of triacylglycerols with carboxylic acid, which leads, under acid catalysis, to the exchange of acyl residues. The reaction is in dynamic equilibrium and if the equilibrium is not shifted by removing reaction components, the product contains all components, including the starting reactants (Figure 3.79). Of all the interesterification reactions, acidolysis currently has the least practical significance.

The reaction of C_{16} and C_{18} higher fatty acids with triacylglycerols of coconut oil results in the release of C_8–C_{14} fatty acids, which can be continuously distilled from the reaction mixture as the product. The reaction can be autocatalysed at higher temperatures or an acidic catalyst (such as 4-toluenesulfonic acid) as well as basic catalysts (such as zinc, calcium or magnesium oxides) may be used. These procedures are now obsolete and fatty acids (for food purposes, for the production of triacylglycerols containing caprylic and capric acids only) are now obtained by hydrolysis and subsequent rectification.

[26]Sometimes, the term transesterification is used instead of alcoholysis, particularly instead of methanolysis. It is also possible to come across the term re-esterification, which is also used in several senses. Oleochemistry uses this term for interesterification and esterification of fatty acids with glycerol.

[27]Water activity must be about 0.3, when no changes in the tertiary structure of the enzyme causing loss of activity occur. At this value, complexes of enzyme–substrate and enzyme–fatty acid may be formed and the latter complexes are cleaved by water.

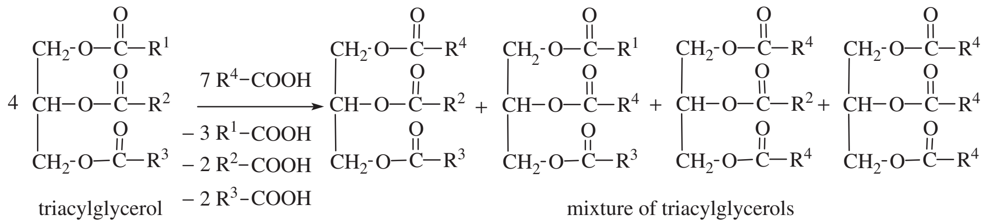

Figure 3.79 Acidolysis of triacylglycerols.

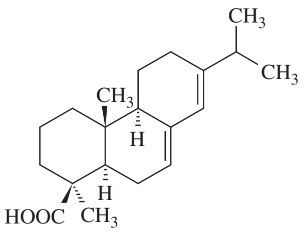
Acidolysis of fatty acids with diterpene abietic acid (**3-156**), the main component of the so-called resin acids (see Section 8.2.14) is used, for example, to produce varnishes, where the exchange of fatty acids for phthalic acid yields glyptals (polymers containing the ester functional group with properties of natural resins).



3-156, abietic acid

An important application of enzymatic acidolysis, specifically using *sn*-1,3-lipase, is the synthesis of structured triacylglycerols containing palmitic or stearic acid in the *sn*-1 and *sn*-3 positions and oleic acid in the *sn*-2 position. These triacylglycerols are components of cocoa butter (Figure 3.80). The synthesis is a consequence of a fraction of palm oil containing 1,2-dipalmitoyl-2-oleoyl-*sn*-glycerol. Acidolysis with stearic acid gives a mixture of 1-palmitoyl-2-oleyl-3-stearoyl-*sn*-glycerol and 1,3-distearoyl-2-oleoyl-*sn*-glycerol. The third major triacylglycerol contained in cocoa butter is obtained by acidolysis of trioleoylglycerol (triolein) with stearic acid. Combination of both procedures gives a mixture of structured triacylglycerols, the so-called CBE fat (cocoa butter equivalent), which serves as a substitute for cocoa butter.

Enzymatically catalysed acidolysis using specific *sn*-1,3-lipases is used for the preparation of dietetically important structured triacylglycerols of the MUM-type (Figure 3.81) that contain unsaturated (U) essential fatty acids in the outer *sn*-1,3 positions and medium-chain (M) fatty acids (caprylic or capric) in the *sn*-2 position.

Alcoholysis

The reaction of triacylglycerols with alcohol is called alcoholysis. It can be catalysed by acids (sulfuric acid or 4-toluenesulfonic acid), and then an interesterification reaction, which is a parallel reaction to esterification of free fatty acids occurring in the fat. Alcoholysis is kinetically similar to esterification. The base catalysed reaction employs methoxides, hydroxides and carbonates of alkali metals. The most commonly used catalysts are sodium methoxide, sodium hydroxide or potassium hydroxide. Industrially produced alcoholysis products are methyl, ethyl or propyl esters (Figure 3.82) of fatty acids. Analogous to hydrolysis, mixing of fat (oil) with alcohol gives a two-phase system

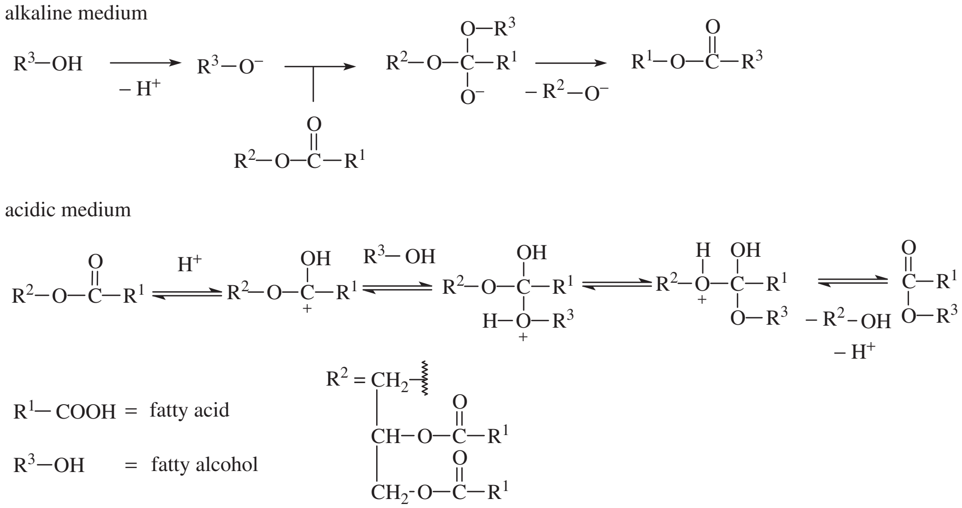

Figure 3.82 Mechanism of alcoholysis of triacylglycerols.

consisting of the alcohol (glycerol) phase and ester phase. The ester phase is a homogeneous reaction phase in which glycerol dissolves, to a limited extent, and passes into the alcohol phase. It is therefore possible to achieve a significant shift in the reaction equilibrium; the degree of conversion is 98–99%.

Vegetable oils (such as rapeseed, soybean and palm oils) or animal fats (beef tallow) are used for the production of so-called biodiesel, which is typically made by alcoholysis of oils and fats with methanol, ethanol or propan-1-ol. With the growth in the hydrocarbon chain length of the alcohol, the lipophilicity increases so that the two-phase system does not form in the reaction with propan-1-ol, and glycerol does not separate. Therefore, the industrially important esters, such as propyl or butyl esters as well as esters of secondary alcohols, can be only prepared by direct esterification of fatty acids with the appropriate alcohol. Methyl and especially ethyl esters can also be obtained by enzyme-catalysed alcoholysis using non-specific lipases.

Glycerolysis

Glycerolysis is a particular example of alcoholysis, being a reaction in which fat (triacylglycerols) reacts with glycerol (Figure 3.83) to give a mixture of monoacylglycerols and diacylglycerols. Glycerolysis takes place at high temperatures (at temperatures 200–250 °C the solubility of glycerol in fat increases to 220–400 moles per one mole of fat) in the presence of an alkaline catalyst (usually either potassium hydroxide, calcium oxide or sodium methoxide). The excess of glycerol is chosen to correspond to its solubility at a given temperature, for example 220–400 moles/mole of triacylglycerols; nevertheless the reaction mixture contains less than 55–60% of monoacylglycerols that are used as emulsifiers. This mixture can be used as such, but for more demanding applications the reaction mixture is subjected to molecular distillation, which gives the product (emulsifier) containing up to 95% of monoacylglycerols (Table 3.48). These emulsifiers also contain varying fatty acids compositions. The composition of the emulsifier is usually close to the fatty acid composition of beef tallow, even though they are usually made from plant oils. The process of glycerolysis has

Table 3.48 Composition of monoacylglycerol emulsifiers.

Component (%)	Emulsifier[a]	Distilled emulsifier[b]
Monoacylglycerols	50–55	90–95
Diacylglycerols	30–35	2–5
Triacylglycerols	<5	0.2–1.0
Free fatty acids	1.0	1.0–2.0
Glycerol	<8	0.2–1.0

[a] The emulsifier composition corresponds to the composition of the fat phase after glycerolysis.
[b] Molecularly distilled emulsifier.

industrial importance, because emulsifiers produced in this way are used in the food, cosmetics and pharmaceutical industries. Emulsifiers based on monoacylglycerols can also be produced by direct esterification of fatty acids with glycerol, but this method is only rarely used.

Glycerolysis can also be catalysed by specific *sn*-1,3-lipases (Figure 3.84). A mixture of di- and monoacylglycerols is obtained in the first stage; further glycerolysis gives products with a reduced diacylglycerols content, which in practice is a mixture of 1- and 2-monoacylglycerols. Isolated 2-monoacylglycerols can also be used for the synthesis of structured triacylglycerols.

A special case of alcoholysis is the use of sugars, usually saccharose and sugar alcohols. Direct esterification of sucrose is very difficult, because it leads to dehydration and caramelisation (see Section 4.7.6). Alcoholysis may, depending on the initial fatty acid ester, give different products. The reaction of saccharose with a mixture of triacylglycerols gives a mixture of saccharose esters with mono-, di-, triacylglycerols and glycerol. As saccharose has a total of eight hydroxyl groups, compounds ranging from saccharose mono to octa fatty acid esters can be produced. This reaction mixture is known by the name **sugar esters**. Sugar esters are mixed non-ionic surfactants (see Section 11.5.2.1.5) widely used as emulsifiers in

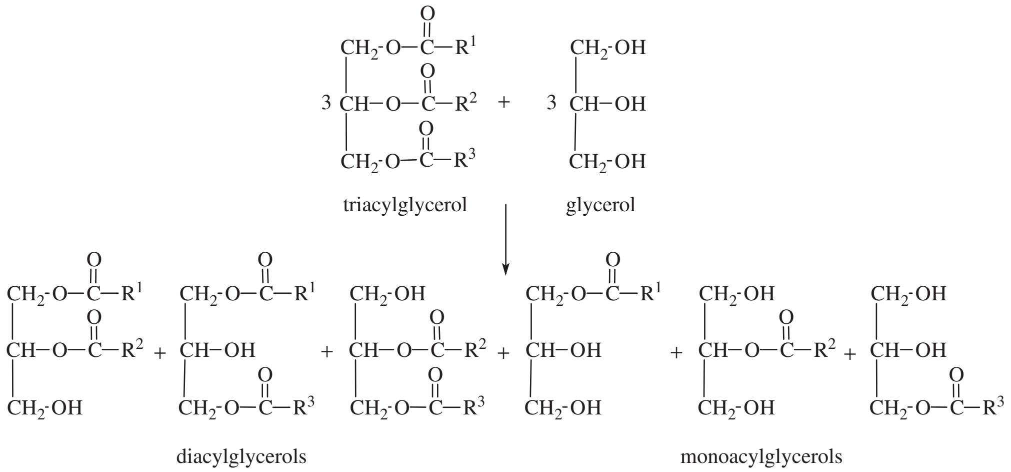

Figure 3.83 Glycerolysis of triacylglycerols.

$$\mathrm{TAG + G} \xrightleftharpoons{sn\text{-}1,3\text{-specific lipase}} \mathrm{1,2\text{-}DAG + 2,3\text{-}DAG + 2\text{-}MAG} \xrightleftharpoons{sn\text{-}1,3\text{-specific lipase}} \mathrm{1(3)\text{-}MAG + 2\text{-}MAG}$$

Figure 3.84 Glycerolysis of triacylglycerols by specific lipases.

foods and beverages, in detergents, in industrial cleaners, in agricultural chemicals and as excipients in pharmaceuticals. Products consisting of sucrose monoesters, and to a small extent sucrose diesters, are manufactured by a transesterification reaction of sucrose and fatty acid methyl esters in *N*,*N*-dimethylformamide or dimethylsulfoxide.

The maximum degree of esterification gives a mixture in which hexa, hepta and octa sucrose esters prevail. The product Olestra is a lipid-like substance that was developed as a non-energy (non-absorbable) fat substitute, since ester bonds are not hydrolysed by enzymes of the digestive tract. However, it was found that Olestra has some adverse gastrointestinal effects and depletes blood levels of many valuable fat-soluble substances, including carotenoids.

Ester interchange

The ester interchange (or transesterification) is catalysed by alkaline catalysts. For food uses, sodium hydroxide or sodium methoxide are usually used. The choice of catalyst is closely related to reaction temperature. Sodium methoxide is effective in the temperature range of 50–70 °C and the maximum transesterification temperature is 120 °C, while sodium hydroxide is effective above 160 °C. The maximum temperature for the catalyst must be chosen so that in the aprotic environment the condensation reaction of esters is avoided. The reaction is rapid and in the homogeneous phase proceeds to equilibrium according to the diagram in Figure 3.85. The equilibrium composition of the reaction mixture that is achieved will not be affected by changes in composition of the reaction mixture components, as a new equilibrium is always reached. This is why this transesterification is called uncontrolled transesterification. In the resulting equilibrium mixture, the distribution of fatty acids in triacylglycerols is random, very different from the fatty acid distribution in natural triacylglycerols, where the genetic information is generally encoded in DNA. Therefore, this transesterification is often also known as **randomisation**.

The composition of the randomised reaction mixture of triacylglycerols can be calculated by the number of triacylglycerols present. The number of triacylglycerols (taking into consideration positional isomers) is equal to $(n^3 + n^2)/2$ and the number of triacylglycerols without positional isomers is $(n^3 + 3n^2 + 2n)/6$. When 5 (6) acyls are present in fats, which is typical in triacylglycerol mixtures, the total number of triacylglycerols after randomisation is 75 (126) and 35 (56), respectively.

The only way to affect the shift in the reaction equilibrium during randomisation is the so-called controlled transesterification, where the reaction temperature is chosen so that triacylglycerols with the highest melting points crystallise, which changes the original composition of the reaction mixture of triacylglycerols and a new equilibrium is created in the liquid phase. This procedure, which can be repeated, is a combination of randomisation with fractional crystallisation of triacylglycerols. At temperatures of crystallisation of triglycerides, at which sodium methoxide is not effective, a eutectic alloy of sodium with potassium has to be used. The actual catalysts are then sodium and potassium mono- and diacylglycerolate anions that form in the reaction of alkali metals with the mono- and diacylglycerols that are present in small amounts in natural fats.

In base-catalysed transesterification, some side reactions take place. For example, the reaction of water with sodium methoxide creates sodium hydroxide that can cleave the ester bonds to form soaps. Oxidation of tocopherols and other antioxidants in alkaline media also occurs, which reduces the oxidative stability of transesterified fat.

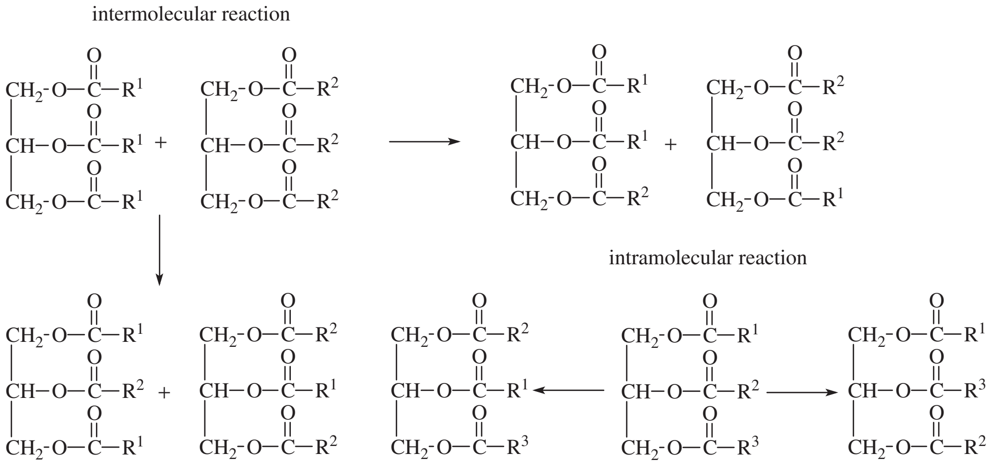

Figure 3.85 Ester interchange in triacylglycerols.

As it is now undesirable to produce fats (fat blends) containing *trans*-isomers of C_{18} fatty acids, which implies the complete elimination of the partial catalytic hydrogenation technology of oils and fats, uncontrolled transesterification has become the only method of modification of triacylglycerols leading to the production of fats of suitable consistency. **Structural fat** is in this case prepared by an alkali-catalysed uncontrolled transesterification of at least two different fats. One possibility is the preparation of structural fat based on fully hydrogenated vegetable fats, the first of which is the source of medium chain fatty acids (coconut or palm kernel oil), and the second is the source of long chain fatty acids (such as fully hydrogenated rapeseed oil). The ratio of the two fats is chosen so that the content of triacylglycerols containing saturated fatty acids has no adverse effect on the texture of the resulting fat blend. This means that the acyls of saturated fatty acids substitute acyls of *trans*-C_{18} fatty acids in the original partially hydrogenated vegetable oils. The total content of *trans*-isomers in fat blends based on transesterified fats does not usually exceed 1% of the total fatty acid content.

Enzymatically catalysed transesterification

The mechanism of acyl exchange during enzymatic transesterification of triacylglycerols is explained by the formation of the complexes enzyme–enzyme–acylglycerol and enzyme–fatty acid (Figure 3.86). A substantial change in the use of lipases acting as transesterification catalysts is their substrate (group) specificity (depending on the acyl length) and especially the regiospecificity of *sn*-1,3-specific lipases. As a result of their *sn*-1,3-regiospecifity, the randomisation of acyls occurs only in the *sn*-1 and *sn*-2 positions of triacylglycerol molecules (Figure 3.87) and a substantial portion of unsaturated fatty acids remains in the *sn*-2 position, which is considered from a nutritional point of view as an asset. Structural fats derived from enzyme catalysis have different physical properties, including texture, unlike the structural fats obtained by base-catalysed randomisation.

Enzymatic transesterification of triacylglycerols does not lead to the oxidation of tocopherols. The actual catalyst is sensitive to the presence of hydroperoxides and aldehydes, which may cause changes in the enzyme structure. This also leads to a gradual loss of its activity.

3.8.2.2.3 Pyrolytic reactions

Heating fat to high temperatures causes its pyrolysis in parallel with oxidation, polymerisation, oxypolymerisation and some other reactions. The presence of water leads to hydrolysis of fatty acids bound in triacylglycerols, and diacylglycerols, monoacylglycerols, glycerol and free fatty acids are formed as products. Free fatty acids and other products are also formed during pyrolysis of triacylglycerols in the absence of water (Figure 3.88). Another important product of pyrolysis is acrolein, that is produced in anhydrous fats, for example during deep frying, and which irritates eyes and mucous membranes of operating personnel. Acrolein is also produced directly by dehydration of glycerol.

$$TAG^1 + E \rightleftarrows TAG^1 \cdot E \rightleftarrows DAG^1 + FFA^1 \cdot E$$

$$TAG^2 + E \rightleftarrows TAG^2 \cdot E \rightleftarrows DAG^2 + FFA^2 \cdot E$$

$$DAG^1 + FFA^2 \cdot E \rightleftarrows TAG^3 \cdot E \rightleftarrows TAG^3 + E$$

$$DAG^2 + FFA^1 \cdot E \rightleftarrows TAG^4 \cdot E \rightleftarrows TAG^4 + E$$

$$TAG^3 + E \rightleftarrows$$

$$TAG^4 + E \rightleftarrows$$

$$FFA^1 \cdot E + H_2O \rightleftarrows FFA^1 + E$$

3.8.3 Reactions of heterolipids

Reactions of heterolipids are generally similar to those of other lipids, but reactions of bound phosphoric acid are specific to heterolipids. Phospholipids are hydrolysed by various phospholipases; an overview of which is given in Table 3.47 and the mechanism of their action is shown in Figure 3.89. Phosphatidylcholine is a demanded product and its concentration in lecithin can be increased by enzymatically controlled interesterification after adding choline. Phosphatidylcholine can also be produced directly from diacylglycerols or phosphatidic acids using immobilised enzymes.

Phospholipids can form salts, for example with metal ions, due to the presence of one free hydroxyl group of the bound phosphoric acid in phosphatidylethanolamine, phosphatidylserine and phosphatidylinositol and two free hydroxyl groups in phosphatidic acid. Mostly, calcium and magnesium ions are involved in these reactions, but the resulting complexes have hydrophobic character, as in metal soaps. Cations of heavy metals (copper, manganese and iron) bound in phospholipids catalyse autoxidation significantly less than free metal ions, phospholipids can thus become synergists of antioxidants.

Unsaturated fatty acids bound in phospholipids can be oxidised by oxygen, similarly to fatty acids in triacylglycerols. Phospholipid hydroperoxides may react with amino groups of other phospholipids and other amino compounds to form dark brown macromolecular products similar to melanoidins (see Section 4.7.5.7) formed in the Maillard reaction. Therefore, phospholipids act as synergists (among other mechanisms) of

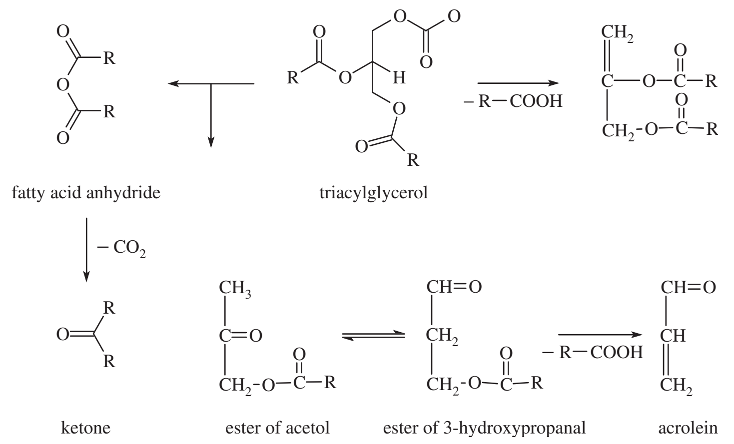

Figure 3.88 Formation of acrolein in triacylglycerol thermolysis.

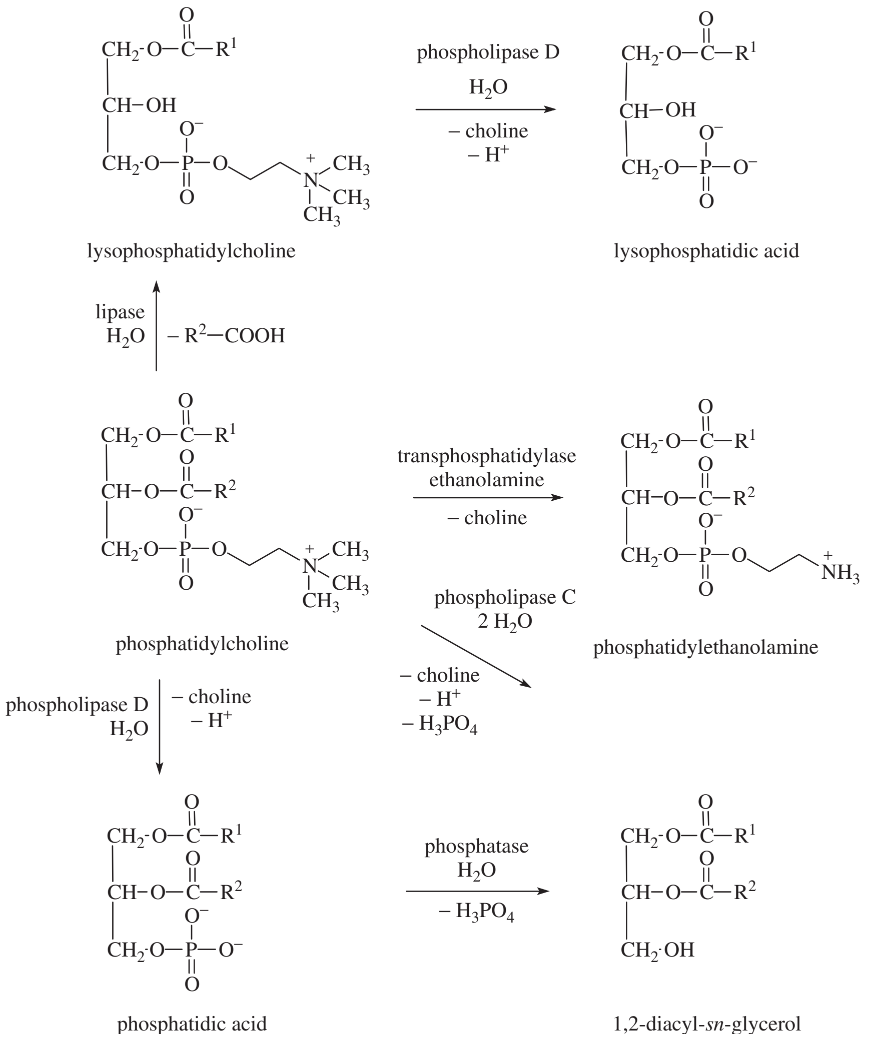

Figure 3.89 Degradation of phospholipids catalysed by phospholipases.

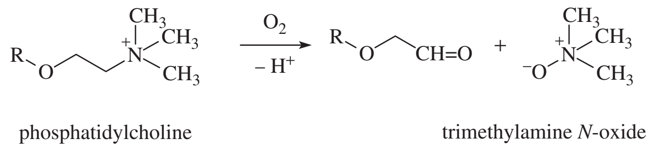

Figure 3.90 Oxidation of bound choline (R = residue of phospholipid molecule).

phenolic antioxidants. In addition to the chains of unsaturated fatty acids bound in phosphatidylcholine, the bound choline is also oxidised to trimethylamine *N*-oxide (Figure 3.90), which is further degraded to dimethylamine.

An important group of reactions of phospholipids containing free amino groups are nonenzymatic browning reactions of the amino groups with reducing sugars or with dehydroascorbic acid. The reaction mechanism is similar to the reaction of sugars with other amines. Phosphatidylethanolamine and phosphatidylserine are more reactive than phosphatidylcholine.

3.8.4 Reactions of steroids

Important reactions of free steroids include esterification, where esters and glycosides of steroid compounds are easily hydrolysed. These reactions in food raw materials are catalysed by sterol esterases and glycosidases, respectively. Other important reactions of steroids include elimination and substitution reactions and oxidation. Hydrogenation of steroids is of industrial importance.

3.8.4.1 Elimination and substitution reactions

When sterols are oxidised at moderate temperatures (≤100 °C), their reaction products are mainly derived from hydroperoxides, but at temperatures close to 200 °C and above, thermal reactions such as dehydration and condensation become important. The secondary hydroxyl groups are eliminated as water molecules, and new double bonds of Δ^5 sterols arise preferentially at the Δ^3 position, which results in the formation of sterol dienes with conjugated double bonds. For example, stigmasta-3,5-diene is produced by dehydration of β-sitosterol. The level of stigmasta-3,5-diene in virgin olive oils is very low (<0.1 mg/kg), but its concentrations in refined olive oils (pomace and olive oil mixtures) may reach ≤120 mg/kg. Refined oils also contain significant amounts of other steroidal hydrocarbons, including campesta-3,5-diene and stigmasta-3,5,22-triene in addition to stigmasta-3,5-diene. The relative amounts of these steroidal hydrocarbons can be used to detect refined seed oils.

The elimination of water may also proceed intermolecularly, which yields disteryl ethers (Figure 3.91). Disteryl ethers are formed in low concentration (a few milligrams per kilogram) by dehydration of sterols during the conventional bleaching of fats and oils with acid-activated bleaching earths. Disteryl ethers are the main steryl dimers characterised in foods; other dimers may be formed by direct sterol ring linkages.

In the production of acid hydrolysates of proteins using hydrochloric acid, the residual sterols and their esters occurring in the starting materials yield small amounts of 3-chloro derivatives by replacement of the C-3 hydroxyl group with chlorine. Possible intermediates in the formation of 3-chlorosterols may be 3,5-dienes derived from sterols (Figure 3.91).

3.8.4.2 Addition reactions

Double bonds of sterols can be hydrogenated similarly to double bonds of unsaturated fatty acids bound in triacylglycerols. Hydrogenation of oils and fats results in changes to the structure of steroids, especially in the molecules of 4,4-dimethylsterols and

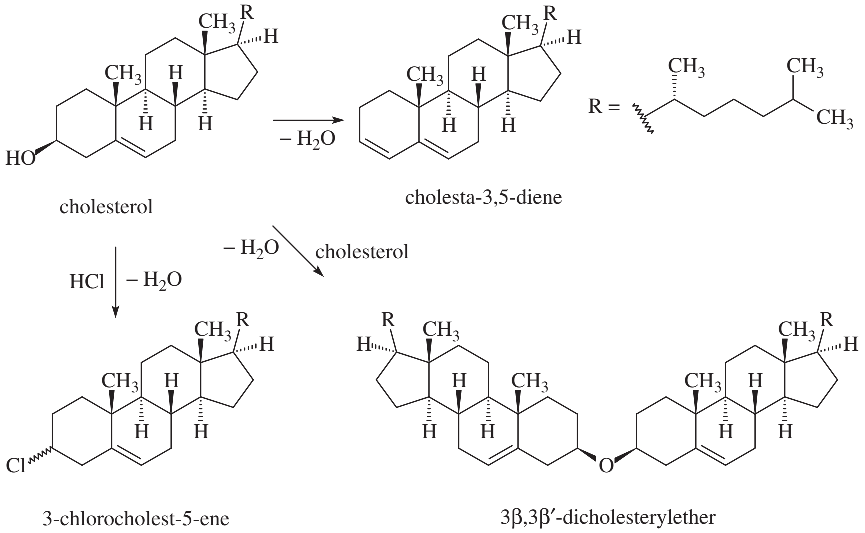

Figure 3.91 Dehydration and other reactions of sterols during heating.

4-methylsterols and to a lesser extent in sterols (4-demethylsterols). Possible reactions are as follows:

- isomerisation of double bonds in the side chain, which gives arise to the geometric and positional isomers of the original steroids;
- hydrogenation of double bonds in the side chain, which leads to steroids with saturated side chains;
- opening of the cyclopropane ring;
- hydrogenation of all double bonds.

The predominant reaction is isomerisation of the double bond in position C-24 (C-28) to position C-24 (C-25) leading to thermodynamically stable isomers. The 4,4-dimethylsterol 24-methylenecycloartanol (**3-105**) yields a mixture of isomers consisting of, among other compounds, cyclosadol (**3-106**) and cyclobranol (**3-107**). Similar isomerisation proceeds in 4-methylsterols such as obtusifoliol (**3-110**) and others (Figure 3.92). The formation of geometric and positional isomers of 4-methylsterols (such as citrastadienol, 3-111) and sterols (such as Δ^5-avenasterol, **3-121**) with ethylidene group in the side chain at C-24 is shown in Figure 3.93. Hydrogenation of double bonds in the side chain yields saturated derivatives. For example, 24-methylenecycloartanol (**3-105**) is transformed to 24-methylcycloartanol and stigmasterol (**3-120**) yields β-sitosterol (**3-119**).

The opening of the cyclopropane ring during hydrogenation occurs in cycloartenol and 24-methylenecycloartanol. The hydrogenation of cycloartenol produces lanosta-9(11),24-dienol (known as parkeol) and lanosterol (lanosta-8,24-dienol). 24-Methylenecycloartanol yields 24-methylenelanost-9(11)-enol and 24-methylenelanost-8-enol. Changes of some steroids in hydrogenated sunflower and soybean oils are documented in Table 3.49.

For food purposes, phytosterols are isolated from tall oil, a byproduct of wood pulp manufacture from coniferous trees. Crude tall oil contains 5–10% of phytosterols that are selectively hydrogenated at the double bond in position C-5 yielding the corresponding **stanols**, the main component of which is sitostanol. It has been shown that if phytosterols (or their fatty acid esters) are consumed at higher levels (e.g. in margarines) they inhibit absorption of exogenous and endogenous cholesterol in the gastrointestinal tract and lower total and LDL cholesterol concentrations, while the usual levels of consumed phytosterols do not significantly affect cholesterol absorption.

3.8.4.3 Oxidation

In vivo (in the biosynthesis of bile acids and some hormones) and also during heat processing and storage of foods, sterols are oxidised in the nuclei and side chain to form various oxygenated derivatives known by the general term **oxysterols**. Some of these compounds are synthesised *in vivo* from cholesterol, but they can also be formed in food during processing procedures and storage. For example,

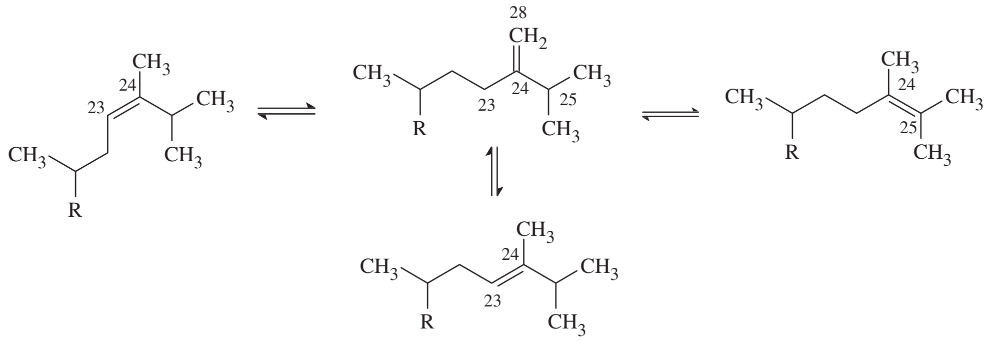

Figure 3.92 Isomerisation of steroids with a methylene group in the side chain (R = steroid residue).

Phytosterol	Amount of oxidation product (mg/kg)[a]				
	7α-hydroxy-	7β-hydroxy-	7-oxo-	5α,6α- and 5β,6β-epoxy-	5α,6β-dihydroxy-
Sitosterol	4.7	9.7	13.5	5.4	2.8
Campesterol	1.4	1.8	9.2	3.6	1.6

[a] Total amount of phytosterol oxidation products is 53.7 mg/kg.

oxidation of cholesterol by oxygen yields (via a C-7 radical) 7α- and 7β-hydroperoxides. Analogous to the secondary oxidation reactions of fatty acids, hydroperoxides of sterols are transformed into the corresponding 5,6-epoxides (5α,6α-epoxides and 5β,6β-epoxides) and their hydrolysis gives 3,5,6-triols. Alkoxyl radicals formed by decomposition of hydroperoxides give rise to the major cholesterol oxidation products that include epimeric 7-hydroxy derivatives and the 7-oxo derivative, which is further transformed into 3,5-diene-7-one by dehydration (Figure 3.94). In addition to 7-hydroperoxides of cholesterol, epimeric 22-hydroperoxides, 20,25-dihydroperoxides, 5α,6β-dihydroxy derivatives and 2,4,6-trienes have also been identified as oxidation products with triplet oxygen. Oxidation of cholesterol with singlet oxygen produces epimeric 5-hydroperoxides that rearrange to 7-hydroperoxides via the corresponding hydroperoxyl radicals. Phytosterols and steryl esters are oxidised similarly. Plant sterols also undergo oxidative processesses comparable to those involved in cholesterol oxidation.

Sterol oxidation products are found in stored oils and especially in oils used for deep frying, therefore these products are also present in fried potato chips (Table 3.50), fried potato crisps and other fried products. Sterol oxidation products are also found in lipids of dried foods, such as dried milk or eggs.

After absorption, oxysterols react with blood plasma lipoproteins to form complexes that can initiate formation of atherosclerotic deposits in the vascular wall. However, the important oxidation reaction from the physiological point of view is the transformation of provitamins D (ergosterol and 7-dehydrocholesterol) into vitamins D_2 and D_3, respectively.

Reactions of triterpene alcohols are probably related to reactions of sterols, but they have not yet been adequately explored.

4

Saccharides

4.1 Introduction

The term **saccharide** comes from the Greek word 'zahari', meaning sugar. The term is frequently used in chemistry to describe polyhydroxyaldehydes H–[CHOH]$_n$–CH=O and polyhydroxyketones H–[CHOH]$_n$–C(=O)–[CHOH]$_m$–H, which contain three or more aliphatic carbon atoms in the molecule. This term also includes derived substances that are formed from these three carbon compounds by condensation reactions with the formation of acetal bonds, and includes monosaccharides, oligosaccharides and polysaccharides, as well as substances derived from saccharides through the reduction of the carbonyl group, the oxidation of one or more terminal groups or the replacement of one or more hydroxy group(s) by a hydrogen atom, an amino group, a thiol group or similar heteroatomic groups. The term **carbohydrate** is actually a descriptor of what these molecules are theoretically composed of. It was applied originally to monosaccharides, in recognition of the fact that they are carbon hydrates in a ratio of one carbon molecule to one water molecule, so that their empirical composition can be expressed as $C_n(H_2O)_n$. However, the term is now used generically in a wider sense, and also includes derivatives of these compounds. The term carbohydrate is most common in biochemistry, medicine and nutrition. The former name, 'glycides', is now used less frequently and is not recommended for use in chemistry.

Depending on the number of carbon atoms in the molecule, saccharides are divided to **trioses**, **tetroses**, **pentoses**, **hexoses** and higher sugars. Compounds with aldehyde functional group are called **aldoses** (e.g. aldopentoses and aldohexoses) and compounds with a ketone function are called **ketoses** (such as ketohexoses).

Depending on the number of sugar units bound in the molecule, saccharides are divided into:

- **monosaccharides**
- **oligosaccharides**
- **polysaccharides** also known as **glycans**
- **complex** or **conjugated saccharides**.

Monosaccharides consist of only one sugar unit. Oligosaccharides consist of between two and ten of the same or different monosaccharides connected to each other by glycosidic (semiacetal) bonds. Monosaccharides and oligosaccharides are sometimes referred to collectively by the name sugars, as they share many common properties and often have a sweet taste. Polysaccharides are composed of more than ten of the same or different monosaccharides; commonly they consist of multiple molecules of monosaccharides, which are often precisely determined. Complex carbohydrates also contain compounds other than saccharides, such as, for example, peptides, proteins and lipids.

Saccharides arise naturally in cells of photoautotrophic organisms (green plants and photosynthetic bacteria) by assimilation of carbon dioxide in the air in the presence of water and energy, and by use of natural light (photosynthesis) converted by photosystems into chemical energy. Heterotrophic organisms obtain the necessary saccharides from autotrophic organisms or from non-saccharide carbon substrates, such as certain amino acids, hydroxy acids, glycerol and other substances (the metabolic pathway is called gluconeogenesis), or they transform saccharides into different structures. Saccharides are common components of all cells. The level of saccharides in animal tissues is only a few percent, but in plant tissues they commonly represent 85–90% of dry matter.

Saccharides have various functions in cells:

- They are used primarily as an energy source (e.g. polysaccharides, oligosaccharides and monosaccharides), 1 g glucose provides 17 kJ (4 kcal), the energy yield of sugar alcohols is only 10 kJ/g (2.4 kcal/g) and are therefore main (primary) nutrients together with proteins and lipids.
- They are the basic building units of many cells, and protect cells against the effects of various external factors (e.g. some oligosaccharides, polysaccharides and complex saccharides).

The Chemistry of Food, First Edition. Jan Velíšek.
© 2014 John Wiley & Sons, Ltd. Published 2014 by John Wiley & Sons, Ltd. Companion Website: www.wiley.com/go/velisek/foodchemistry.

- They are biologically active substances (e.g. oligosaccharides in milk) or components of many biologically active substances such as glycoproteins, some coenzymes, hormones and vitamins.

Saccharides are highly reactive substances that are transformed into many different products, even without the participation of other reaction partners, during food storage and processing. The most common and important reactions of carbohydrates are their reactions with amino compounds that are known as non-enzymatic browning reactions, which also involve reactions of carbohydrates in the absence of amino compounds. Reactions of carbohydrates with amino compounds (proteins, amino acids) are the Maillard reactions. The products of these reactions are important flavour-active compounds and are yellow, brown or black pigments in many foods and compounds with beneficial properties (e.g. antioxidants), but can also be substances with antinutritional or even toxic effects.

This chapter on saccharides is divided into two main parts. The first part describes major monosaccharides, and their functional derivatives, oligosaccharides and polysaccharides. Their structure and nomenclature, occurrence in major food commodities, properties and importance in human physiology and nutrition, recommended intake and use in food technology are all described. The second part is devoted to reactions of saccharides that lead to the formation of products that influence odour, taste and colour of foods, and to reactions taking place during storage and thermal processing of food raw materials and foods.

4.2 Monosaccharides

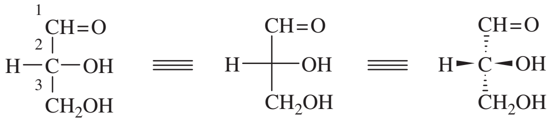
4.2.1 Structure and nomenclature

Monosaccharides, aldoses and ketoses, are divided – according to the number of carbons in the chain – into trioses, tetroses, pentoses, hexoses and higher sugars, and into aldotrioses, ketotrioses and so on. The carbon chain of monosaccharides present in foods is usually linear, but branched-chain monosaccharides also exist.

Monosaccharides occur as substances with a free carbonyl group (acyclic compounds) and as cyclic **hemiacetals**, also called **lactols**. Trioses are exclusively acyclic substances, tetroses and higher monosaccharides exist predominantly in five- and six-membered and, exceptionally, also in seven-membered cyclic structures. They can therefore be regarded as substances derived from oxolane (tetrahydrofuran), oxane (tetrahydropyran) or oxepane, and are thus actually heterocyclic compounds. Acyclic forms, which exist in constitutional equilibrium with cyclic forms, occur in zigzag conformers, as well as alditols (see Section 4.3.1.1.1).

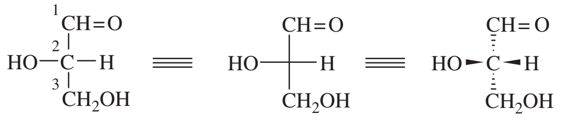
4.2.1.1 Aldoses

The simplest aldose is aldotriose, known as glyceraldehyde, which contains the aldehyde group in position C-1 and a chiral carbon atom in position C-2. It exists therefore in two ($2^1 = 2$; generally 2^n, where n is the number of chiral carbon atoms) configuration isomers, as D-glyceraldehyde (**4-1**) and L-glyceraldehyde



4-1, D-glyceraldehyde (D-*glycero*-triose)

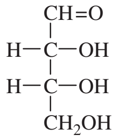
(**4-2**). Solutions of D-glyceraldehyde rotate the plane of polarised light to the right (clockwise) and D-glyceraldehyde is therefore (+)-glyceraldehyde or (+)-D-glyceraldehyde or d-glyceraldehyde (is dextrorotary). L-Glyceraldehyde solutions rotate the plane of polarised light to the left (counter clockwise) therefore L-glyceraldehyde is (−)-glyceraldehyde or (−)-L-glyceraldehyde or l-glyceraldehyde (is laevorotary).



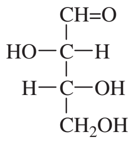
4-2, L-glyceraldehyde (L-*glycero*-triose)

Isomers are called **optical isomers**, **antipodes** or **enantiomers**. Their equimolar mixture is optically inactive and is called a **racemate**. Symbols (affixes) *R* and *S* are used only rarely for labeling configurations of saccharides. D-Glyceraldehyde is thus (*R*)-glyceraldehyde and L-glyceraldehyde is (*S*)-glyceraldehyde. The former name for glyceraldehyde was glycerose. In biochemistry, the simplest two carbon sugar glycolaldehyde (biose) and the simplest one carbon sugar formaldehyde (monose) are also classified as saccharides (aldoses).

The prefixes D- and L- are also used with other monosaccharides. The formal insertion of clusters of atoms H–C–OH (or the mirror image of HO–C–H) between the first and second carbons of a D-glyceraldehyde molecule gives two optically active aldotetroses called D-erythrose (**4-3**) and D-threose (**4-4**). L-Glyceraldehyde can yield L-erythrose (**4-5**) and L-threose (**4-6**) in the same way. The total number of **configuration isomers** (**stereoisomers**) is $2^2 = 4$. The pairs of saccharides D-erythrose with L-erythrose as well as D-threose with L-threose are **enantiomeric** substances (asymmetric carbons have the opposite configuration; one substance is a mirror image of the other). The pair from D-erythrose with D-threose as well as the pair from L-erythrose with L-threose are **diastereoisomeric** substances that differ in configuration at one chiral centre, while the configuration at the second chiral centre is identical.

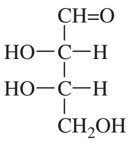


4-3, D-erythrose
(D-*erythro*-tetrose)

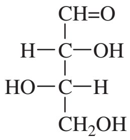


4-4, D-threose
(D-*threo*-tetrose)

In a similar way, a total of eight optically active linear aldopentoses (four pentoses of the D-series and four pentoses of the L-series) and a total of 16 linear aldohexoses

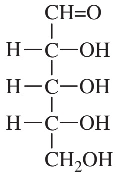


4-5, L-erythrose
(L-*erythro*-tetrose)

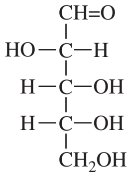


4-6, L-threose
(L-*threo*-tetrose)

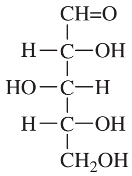
(eight hexoses of the D-series and eight hexoses of the L-series) can be derived. Structures of D-aldopentoses and D-aldohexoses in Fischer projections are given in formulae **4-7** to **4-10** and **4-11** to **4-18**.



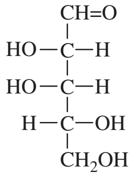
4-7, D-ribose
(D-*ribo*-pentose)



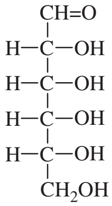
4-8, D-arabinose
(D-*arabino*-pentose)



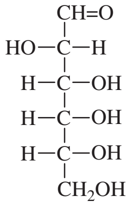
4-9, D-xylose
(D-*xylo*-pentose)



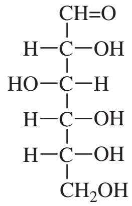
4-10, D-lyxose
(D-*lyxo*-pentose)



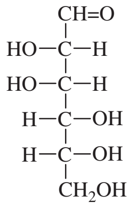
4-11, D-allose
(D-*allo*-hexose)



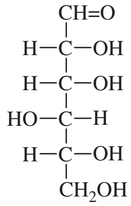
4-12, D-altrose
(D-*altro*-hexose)



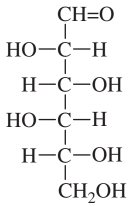
4-13, D-glucose
(D-*gluco*-hexose)



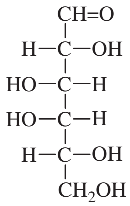
4-14, D-mannose
(D-*manno*-hexose)



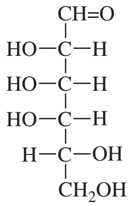
4-15, D-gulose
(D-*gulo*-hexose)



4-16, D-idose
(D-*ido*-hexose)



4-17, D-galactose
(D-*galacto*-hexose)

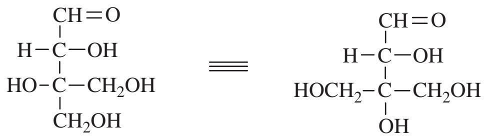


4-18, D-talose
(D-*talo*-hexose)

The affiliation of an aldose to the D- or L-series is determined by the conformity of the configuration of the chiral carbon atom with the highest sequence number in the molecule (such as carbon C-3 in aldotetroses, carbon C-4 in aldopentoses and carbon C-5 in aldohexoses), with the configuration of the chiral carbon atom of either D-glyceraldehyde or L-glyceraldehyde. Whether the aldose belongs to the D- or L-series of sugars is independent of the configuration of the other carbon atoms. For example, (+)-D-glucose configuration at carbons C-5, C-4 and C-2 is D (*R* configuration) and the carbon C-3 has an L configuration (*S* configuration). The change in configuration at the other chiral atom provides a different aldose of the same series (e.g. changing the configuration at C-4 of D-glucose gives D-idose). The change in configuration of all chiral atoms, in the case of the D-isomer, gives the corresponding L-isomer. For example, D-glucose is transformed into L-glucose and vice versa. Aldoses, which differ only in configuration at C-2 are called **epimers**. Examples of epimers are D-glucose and D-mannose.

Removing the suffix '-se' from the trivial names of trioses, tetroses, pentoses and hexoses gives the configuration prefixes *glycero*-, *erythro*-, *threo*-, *ribo*-, *arabino*-, *xylo*-, *lyxo*-, *allo*-, *altro*-, *gluco*-, *manno*-, *gulo*-, *ido*-, *galacto*- and *talo*-, which are, together with the configuration symbols D and L, the basis of systematic carbohydrate nomenclature. The systematic name of D-glyceraldehyde is then D-*glycero*-triose, D-erythrose is D-*erythro*-tetrose, D-ribose is D-*ribo*-pentose and D-glucose is D-*gluco*-hexose. For practical reasons, however, the preferred names are trivial names, if the saccharide structure is expressed uniquely.

In addition to sugars with straight chains, branched chain sugars also exist in nature, for example as components of pectin and other polysaccharides. Again, their preferred names are the trivial names. Aldopentose D-apiose with one chiral carbon atom has the systematic name 3-*C*-hydroxymethyl-D-*glycero*-tetrose (**4-19**).



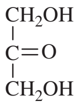
4-19, D-apiose

The abbreviated notations of monosaccharides are formed as they are for amino acids. An abbreviation of the monosaccharide name consists of the first three letters of the trivial name. An exception, however, is glucose, for which the abbreviation Glc is used as the symbol Glu is reserved for glutamic acid.

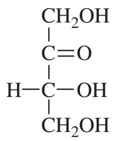
4.2.1.2 Ketoses

The simplest ketose (ketotriose) is optically inactive 1,3-dihydroxyacetone, also known as 1,3-dihydroxypropan-2-one or glycerone (**4-20**). Similar to aldotetroses and higher aldoses derived from glyceraldehyde, one D-ketotetrose (**4-21**), two D-ketopentoses (**4-22**, **4-23**), four D-ketohexoses (**4-24** to **4-27**), and the same number of ketoses of the L-series, can be derived from 1,3-dihydroxyacetone. Trivial names are used for ketohexoses, but for higher ketoses systematic names are preferred. Ketoses with more than four chiral centres are formally divided into two parts so that the four chiral carbon atoms have the lowest serial numbers. The name starts from the centre with the highest number. Ketose **4-28**, for example, is called D-*manno*-hept-2-ulose, D-*altro*-hept-2-ulose is called trivially sedoheptulose,

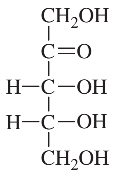
sugar **4-29** is D-*glycero*-D-manno-oct-2-ulose and sugar **4-30** is D-*erythro*-L-*gluco*-non-2-ulose. A branched ketohexose with the trivial name dendroketose (**4-31**) has the systematic name D-4-deoxy-4-*C*-hydroxymethyl-D-*glycero*-pent-2-ulose.



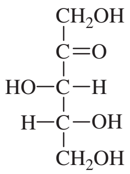
4-20, 1,3-dihydroxyacetone



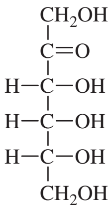
4-21, D-erythrulose (D-*glycero*-tetrulose)



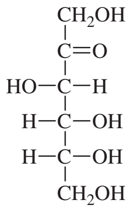
4-22, D-ribulose (D-*erythro*-pent-2-ulose)



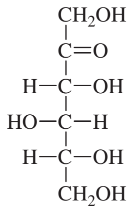
4-23, D-xylulose (D-*threo*-pent-2-ulose)



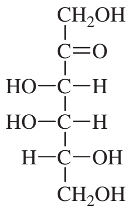
4-24, D-psicose (D-*ribo*-hex-2-ulose)



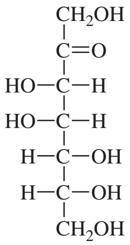
4-25, D-fructose (D-*arabino*-hex-2-ulose)



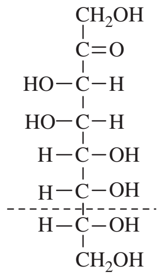
4-26, D-sorbose (D-*xylo*-hex-2-ulose)



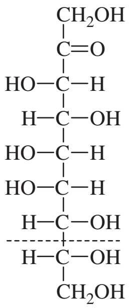
4-27, D-tagatose (D-*lyxo*-hex-2-ulose)



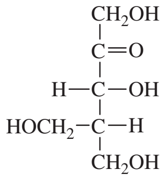
4-28, D-*manno*-hept-2-ulose



4-29, D-*glycero*-D-*manno*-oct-2-ulose



4-30, D-*erythro*-L-*gluco*-non-2-ulose



4-31, D-dendroketose

4.2.1.3 Cyclic structures

Aldehydes and ketones react with alcohols to form unstable hemiacetals. A reaction of hemiacetal with another molecule of alcohol yields stable acetals (see Figure 8.22). In contrast, saccharides spontaneously yield only stable cyclic hemiacetal by intramolecular addition of one hydroxyl group (primary or secondary hydroxyl group) to the carbonyl group. These cyclic forms of aldoses and ketoses are generally called **lactols**. Six membered or five membered (and exceptionally seven membered) rings are mainly formed. Structures with five membered rings are called **furanoses**, the six membered rings are **pyranoses**, and the seven membered rings are **septanoses**.

On the carbon of the carbonyl group (C-1 carbon of aldoses and C-2 carbon of ketoses), a new chiral centre arises due to the ring formation. The carbon of the carbonyl group is called an **anomeric carbon**, the newly formed hydroxyl group at the anomeric carbon is an **anomeric hydroxyl group** (hemiacetal group) and the corresponding pairs of isomers are **anomers**. To mark the configuration of substituents on the anomeric carbon, configuration prefixes α and β, indicating the relative configuration to the chiral carbon atom with the highest number (which determines the affiliation of the sugar to the D- or L-series) are used. The α anomer has the same configuration while the β anomer has the opposite configuration. Both anomers, which are special types of diastereoisomers, differ in their optical rotations.

The formation of cyclic structures from acyclic structures and the relationship between different types of formulae (Fisher, Tollens, Haworth and Mills projection formulae) are shown in Figure 4.1 for the example of D-glucose. In the Fischer representation of a monosaccharide, the carbon chain is written vertically, with the lowest numbered carbon atom at the top and the neighbouring carbon atoms below. The H and OH groups projects to the right or the left. A monosaccharide is assigned to the D or the L series according to the configuration at the highest-numbered centre of chirality. A sugar that belongs to the D series has the highest-numbered hydroxy group projected to the right in the Fischer projection. If a cyclic form of a sugar is to be represented by the Tollens formula in the Fischer projection, a long bond can be drawn between the oxygen involved in ring formation and the (anomeric) carbon atom to which it is linked. Cyclic forms of D-glucose and D-fructose can be represented by formulae **4-32** to **4-39**. Conventionally, the formula in the Haworth projection is drawn so that the planar heterocyclic ring lies perpendicular to the picture plane and the oxygen atom is behind the plane. Axial and equatorial positions are not distinguished; instead, substituents are positioned above or below the ring atom to which they are connected and they are directed above or below the plane, if they lie in the Fischer projection on the left or the right side of the formula. The ring part directed to the front of the plane is usually drawn in bold. Formulae can rotate or flip in space if necessary. In some cases, formulae can be clarified by use of the Mills depiction, in which the main hemiacetal ring is drawn in the plane of the paper; dashed bonds denote substituents below this plane, and thickened bonds those above.

4.2.1.3.1 Mutarotation

In the crystalline state, reducing monosaccharides exist exclusively in cyclic structures (α- or β-anomers). In solutions, a balance between the α- and β-anomers and acyclic forms is established as the individual forms interconvert over time. This process, schematically shown in Figure 4.2, is called **mutarotation**. The mechanism of mutarotation assumes cleavage of the saccharide cyclic forms to neutral acyclic saccharide or its ion that have free carbonyl groups. The equilibrium composition of the mixture (the amount of pyranoses, furanoses or septanoses) depends on the type of sugar, solvent, pH (the reaction generally involves acid–base catalysis) and temperature.

Crystalline D-glucose, existing as an anhydrous substance or monohydrate, is α-D-glucopyranose. In weakly acidic and neutral aqueous solutions at ambient temperature, the establishment of

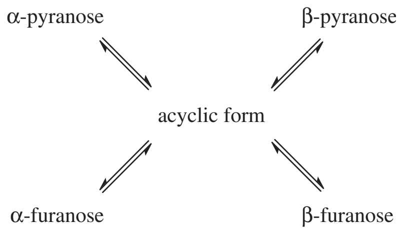

Figure 4.2 Mutarotation of monosaccharides.

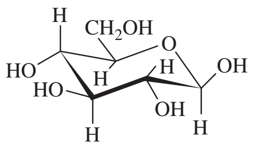
equilibrium takes for about 4 h and in weakly alkaline solutions the equilibrium is established immediately. The equilibrium aqueous solution at 20 °C contains about 33% of α-D-glucopyranose and 67% of β-D-glucopyranose; the solution at 40 °C contains 36% of the α-anomer and 64% of the β-anomer. Furanose forms of glucose are present at levels of up to 1%. The composition of the equilibrium solutions of ordinary aldoses and fructose are given in Table 4.1. In aqueous solutions (at 20 °C), the acyclic form of D-glucose is present at levels of 0.02–0.06%. Aqueous solutions of other aldohexoses and ketohexoses contain similar amounts of acyclic forms. Solutions of pentoses contain higher levels of acyclic forms than hexoses (e.g. D-ribose, 8.5%). Trioses are found exclusively in the acyclic forms. In enzymatically active plant and animal material, the mutarotation of saccharides containing bound glucose and galactose is catalysed by mutarotase (aldose 1-epimerase).

4.2.1.3.2 Conformation

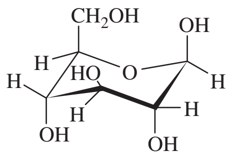
Pyranoses

Cyclic forms of saccharides are planar structures. The thermodynamically most favourable and therefore most common conformations of pyranoses are chair (C) conformations. Boat (B), skew (S) and half-chair (H) conformations are rarely found.

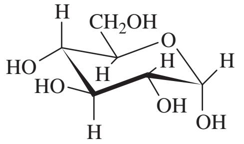
Each pyranose anomer can exist in two chair structures, $^4C_1$ and $^1C_4$. Numbers 1 and 4 correspond to atoms C-1 and C-4, which are above (expressed as superscript) or structures below (expressed as subscript) of the reference plane defined by carbons C-2, C-3, C-5 and the oxygen atom. As an example, structures of both chair conformers of β-D-glucopyranose and α-D-glucopyranose are given in formulas **4-40** to **4-43**.



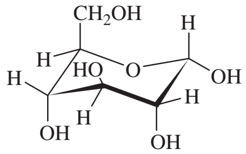
4-40, β-D-glucopyranose-$^4C_1$



4-41, β-D-glucopyranose-$^1C_4$



4-42, α-D-glucopyranose-$^4C_1$



4-43, α-D-glucopyranose-$^1C_4$

In solutions, conformers $^4C_1$ and $^1C_4$ of saccharides are in equilibrium in which the predominant conformer has a larger number of substituents (hydroxyl or hydroxymethyl groups) in the equatorial positions, because (except for the substituent on the anomeric carbon atom) bulky axial substituents are thermodynamically unfavourable. Predominantly **1,3-*syn*-axial** interactions of hydroxyl and hydroxymethyl groups take place, such as, for example, interactions of the hydroxyl group in position C-4 and the hydroxymethyl group in conformer **4-41**. The hydroxymethyl group as well as the anomeric hydroxyl of aldohexoses are always equatorial, which means that D-aldohexoses prefer the conformation $^4C_1$. From the conformational point of view, the most stable aldohexose is the $^4C_1$ conformer of β-D-glucopyranose because all five bulky substituents are in equatorial positions (Table 4.2). An aqueous solution of glucose, however, contains only about 64% of this anomer and the rest is α-anomer. The reason is that the stability of the axial hemiacetal hydroxyl group of α-D-glucopyranose-$^4C_1$ (**4-42**) is increased due to the **anomeric effect** manifested by the interaction with the oxygen atom of the pyranose ring, through electrostatic repelling of their non-bonding electrons. If the hydroxyl group is in the equatorial position (β-anomer), the angle between the dipole moments is small and electrostatic repulsive forces are large. If the hydroxyl group is in the axial position, the repulsive forces are smaller. The axial position is therefore preferable.

Table 4.1 Cyclic forms of some hexoses in aqueous solutions at 40 °C.

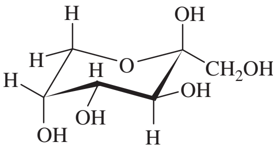
	Furanose (%)		Pyranose (%)			Furanose (%)		Pyranose (%)	
Saccharide	α	β	α	β	Saccharide	α	β	α	β
D-Ribose	6	18	20	56	D-Gulose	<1	<1	21	79
D-Allose	5	7	18	70	D-Idose	16	16	31	37
D-Altrose	20	13	28	39	D-Galactose	<1	<1	27	73
D-Glucose	<1	<1	36	64	D-Talose	<1	<1	58	42
D-Mannose	<1	<1	67	33	D-Fructose	<1	25	8	67

Table 4.2 Position of substituents (e = equatorial, a = axial) in $^4C_1$ conformers of aldohexoses.

	Hydroxyl group				Hydroxyl group		
Saccharide	C-2	C-3	C-4	Saccharide	C-2	C-3	C-4
D-Allose	e	a	e	D-Gulose	e	a	a
D-Altrose	a	a	e	D-Idose	a	a	a
D-Glucose	e	e	e	D-Galactose	e	e	a
D-Mannose	a	e	e	D-Talose	a	e	a

The 1,3-diaxial interaction between a C-1 hydroxyl group and the axial protons at C-3 and C-5 also operates in favour of β-anomers. The resulting effect is that about 36% of D-glucose in equilibrium is present in the form of the α-anomer (at 20 °C). The conformation of glucose molecules explains the almost universal role of glucose in living systems as a structural unit of many biopolymers and an intermediate in a number of important reactions.

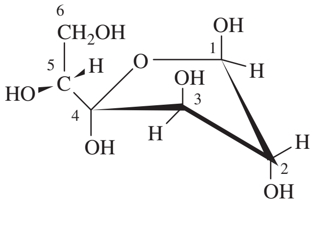
D-Fructose is found primarily as β-pyranose in conformation $^1C_4$ in which the hydroxyl groups at C-3 and C-4 are in the equatorial positions and the hydroxyl group at C-5 is in the axial position (**4-44**).



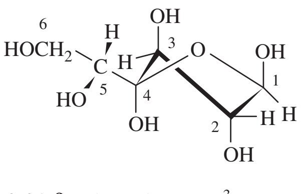
4-44, β-D-fructopyranose-$^1C_4$

Furanoses

Furanose conformers differ from each other in their energy only slightly and can interconvert between the different conformations very quickly. The most frequently occurring are envelope (E) and twist (T) conformations. Both of these basic conformations have almost equal energy. In fact, there are ten E conformations and ten T conformations that interconvert. The interconversion between the many conformers is called **pseudorotation**. Formulae **4-45** and **4-46** are examples of E and T conformers of β-D-glucofuranose. The type of conformer and levels of anomers in furanose solutions and in foods depends on the intramolecular non-bonding interactions.



4-45, β-D-glucofuranose-E_2



4-46, β-D-fructofuranose-$^3T_2$

4.2.2 Occurrence

Monosaccharides are common components of almost all foods, but their content is highly variable, as is the representation of individual sugars. The most common monosaccharides in foods are hexoses and pentoses.

Monosaccharides are present in relatively large quantities in fruits, where their content increases during ripening. However, this varies greatly depending on the type of fruit, the level of maturity, the conditions of post-harvest storage, processing and so on. In apples, for example, only traces of starch are present at the time of harvest, and during post-harvest ripening, this starch is completely degraded. A partial decomposition of hemicelluloses and pectin also occur, and the monosaccharides content rises.

D-Glucose (**4-13**), also known as dextrose, grape sugar or starch sugar, is, together with D-fructose (**4-25**), known as laevulose or fruit sugar, the main monosaccharide of most foods. In the blood of animals, it occurs at concentrations of about 1 g/kg, in diabetic patients (*diabetes mellitus*) it may occur in the urine, in extreme cases at concentrations up to 10%. Free D-mannose (**4-14**), D-galactose (**4-17**) and other hexoses and their derivatives are found in the small quantities in a variety of foods. Pentoses in foods are generally present in smaller amounts than hexoses. The main pentoses are D-ribose (**4-7**), L-arabinose (**4-8**) and D-xylose (**4-9**), which is otherwise known as wood sugar.

Saccharides are deliberately added to a variety of food products to improve their organoleptic properties (taste, texture). Monosaccharides are usually added as invert sugar and in the form of glucose or fructose syrups.

4.2.2.1 Meat and meat products

Glycogen (also known as animal starch) occurs in the muscles of warm-blooded animals in concentrations ranging from 0.02 to 1% (0.3% in fish), depending on age and other factors, and is rapidly degraded post-mortem. In the matured flesh, only monosaccharides and their phosphoric acid esters occur. They are commonly present at levels of 0.1–0.15%, of which glucose 6-phosphate constitutes about 0.1% and about a fifth of this amount represents (0.02%) glucose 1-phosphate and fructose 1,6-bisphosphate. The rest is mainly glucose (0.009–0.09%), fructose and ribose. Ribose arises primarily as a hydrolysis product of free nucleotides (NAD, NADP, ATP and the corresponding nucleosides). A certain proportion of ribose is present in the form of ribitol in riboflavin (vitamin B_2) and other flavins.

4.2.2.2 Milk and dairy products

Monosaccharides, particularly glucose, are present in milk in insignificant quantities. The main sugar is disaccharide lactose, while other related oligosaccharides occur in milk in smaller amounts.

4.2.2.3 Eggs

The amount of saccharides in eggs (in dry matter) is about 10 g/kg. About 9 g/kg of sugars are present in egg white and 1 g/kg in

Table 4.3 Basic composition of honey.

Constituent	Average content (%)	Range	Constituent	Average content (%)	Range
Water	17.2	13.4-22.9	Fructose	38.2	27.3-44.3
Proteins (enzymes)	0.4	0.1-0.6	Saccharose	1.3	0.3-7.6
Minerals	0.17	0.02-1.03	Maltose	7.3	2.7-16.0
Glucose	31.3	22.0-40.8	Higher sugars	1.5	0.1-8.5

the yolk. Protein-bound saccharides in the form of glycoproteins occur in the egg white at a level of about 5 g/kg, and in the yolk at about 0.2 g/kg. The rest are free sugars, especially monosaccharides, but free oligosaccharides and polysaccharides do not occur in the egg white. About 98% of free monosaccharides are glucose, while mannose, galactose, arabinose, xylose, ribose and 2-deoxyribose (2-deoxy-D-*erythro*-pentose) are present at concentrations of 2–20 mg/kg. In the protein-bound carbohydrates, galactose, mannose, glucosamine, galactosamine and lactaminic acid predominate.

4.2.2.4 Honey

The main sugar components of honey are glucose, fructose and maltose (Table 4.3). To a lesser extent there are also a number of various oligosaccharides present, whose composition is given later in Table 4.12.

4.2.2.5 Cereals and cereal products

Mono-, di-, tri- and higher oligosaccharides resulting from the degradation of starch are present in low concentrations in cereals. Wheat flour contains 100–900 mg/kg glucose and 200–800 mg/kg fructose. The maltose content is 500–1000 mg/kg, saccharose and raffinose occur in amounts of 1000–4000 mg/kg and 500–1700 mg/kg, respectively, and the amounts of other oligosaccharides ranges from 0.4 to 1.6%. The sugars content in cereal products is highly variable as it primarily depends on the degree of starch hydrolysis or the amount of added saccharides.

4.2.2.6 Fruits and vegetables

The main sugars in fruits are glucose (about 0.5–32%) and fructose (about 0.4–24%), and other monosaccharides are present to a lesser extent (Table 4.4). Ripe grapes, for example, contain glucose and fructose in roughly the same amounts (about 8%), but fructose dominates in overripe grapes. The sugar content in wine musts is 120–250 g/l (expressed as glucose). In addition to glucose and fructose (their ratio is 0.5–0.9), wines contain relatively large quantities of arabinose, xylose, galactose and small amounts of other monosaccharides and oligosaccharides (Table 4.5). According to the sugar content, wines are categorised as dry wines (up to 4 g of residual sugar per liter), semi-dry wines (4.1–12 g/l),

Table 4.4 Content of monosaccharides and saccharose in fresh fruits (% of edible portion).

[a] The content of saccharose in varieties of common grape vine (*Vitis vinifera*, Vitaceae) is low, but in some varieties of Fox grape vine (*V. labrusca*), originating from North America, and their hybrids it may account for up to 25% of total sugars.

semi-sweet wines (12.1–45 g/l) and sweet wines (minimum of 45 g residual sugar). Sparkling wines (champagne wines) are divided into brut nature (naturally dry, sugar content is lower than 3 g/l, where sugar has not been added), extra brut (particularly

Table 4.5 Saccharides content of wines.

Saccharides	Content (mg/l)	Saccharides	Content (mg/l)
Monosaccharides		Fucose	2–9
Ribose	6.3–62	***Oligosaccharides***	
Arabinose	1.0–242	Trehalose	0–61
Xylose	0.6–146	Cellobiose	2–7

dry, 0–8 g/l), brut (dry, <15 g/l, extra dry (especially dry, 12–20 g/l, sec (dry, 17–35 g/l), demi-sec (half dry, 33–50 g/l) and doux (sweet, >50 g/l). The galactose content of fresh fruits ranges from about 11 mg/kg in strawberries to 70–160 mg/kg in grapes and 270 mg/kg in kiwis. Some fruits contain large amounts of less common sugars. Rowanberry wine, for example, contains L-sorbose, which is formed by oxidation of D-glucitol on carbon C-5 during fermentation. Higher ketoses (heptuloses) occur in small quantities in strawberries, grapes and other fruits and in wines. Avocado has a particularly interesting composition of sugars consisting of a number of heptuloses, octuloses and nonuloses (0.2–5% of fresh weight), such as D-*manno*-hept-2-ulose (4-28), D-*talo*-hept-2-ulose, D-*glycero*-D-*manno*-oct-2-ulose (**4-29**), D-*glycero*-L-*galacto*-oct-2-ulose, D-*erythro*-L-*gluco*-non-2-ulose (**4-30**), D-*erythro*-L-*galacto*-non-2-ulose and other sugars.

The main monosaccharides in vegetables, as well as in fruits, are glucose and fructose (Table 4.6). Other monosaccharides (such as galactose, arabinose and xylose) are present at low levels. The galactose content in fresh vegetables ranges from about 22–26 mg/kg in butter lettuce to 33–108 mg/kg in potatoes and 140–400 mg/kg in red bell peppers. Free arabinose occurs in larger quantities in a dried byproduct, known as dried beet pulp, which is left after most of the sugar has been extracted from the sliced beets.

Hydrolysis of saccharose in harvested potato tubers results in the production of glucose and fructose. Changes in the reducing sugar level can be used as an indicator of stress (such as low storage temperature and physical damage) in tubers. For example, tubers stored at low temperature have a sweet taste and will produce French fries of darker colour.

4.2.2.7 Other foods

In legumes, the main monosaccharides are glucose and fructose. In beans, the content of glucose is 0.1–1.1% (fresh weight), around 0.3% in peas and in soybeans it varies from 0.04 to 0.2%. Fructose content in beans is 0.1–1.2%, in peas and soybeans about 0.2 and 0.5–3.2%, respectively. Saccharose and other oligosaccharides are present in higher amounts in legumes (see Table 4.16).

The monosaccharides and sugar alcohols content of higher fungi is generally less than 1% of dry matter. The main monosaccharide is glucose, but the sugar alcohols content is generally higher.

Glucose, fructose, mannose, galactose and other monosaccharides are the building blocks of many oligosaccharides, polysaccharides and heteroglycosides. A less common monosaccharide is apiose (**4-19**), which is an important component of pectin and in the form of glycosides occurs in vegetables of the Apiaceae family, commonly known as the carrot or parsley family, where the main carbohydrate starch is found in the root vegetables and root crops. Some gourmet vegetables belonging to the Asteraceae family, such as globe artichoke (*Cynara cardunculus*), common chicory (*Cichorium intybus*) and black salsify (*Scorzonera hispanica*), contain, in addition to starch, as a reserve polysaccharide inulin, composed of fructose units. Other main polysaccharides are, as in fruits, cellulose, hemicelluloses and pectin.

Table 4.6 Main carbohydrate content of fresh vegetables (% of edible portion).

Vegetable	Water	Glucose	Fructose	Saccharose	Vegetables	Water	Glucose	Fructose	Saccharose

4.2.3 Physiology and nutrition

The key compound of carbohydrate metabolism, and a source of energy in animals and plants, is glucose. Heterotrophic organisms obtain energy for endergonic reactions by oxidation of glucose and other primary nutrients. Carbohydrates should account for more than 55% of energy. About 80–90% of the energy intake provided by carbohydrates should come from polysaccharides, with up to 20% coming from oligosaccharides and monosaccharides.

The ingested polysaccharides and oligosaccharides must be hydrolysed to their component monosaccharides before being absorbed. The digestion of starch starts by the action of salivary α-amylase and continues with pancreatic α-amylase in the small intestine. The hydrolysis yields α-dextrins, maltose oligomers, maltose and small amounts of glucose. Maltase and isomaltase from the lining of the small intestine (so-called brush border hydrolyases) split the products produced by amylases into glucose. Saccharose is digested in the lining of the small intestine by saccharase (sucrase) into glucose and fructose. Lactose is hydrolysed to glucose and galactose by lactase, which is also found in the intestinal lining, but is absent in most adult humans (see Section 10.3.1.1). Other carbohydrates, for example pectins, pass undigested into the large intestine and are partly hydrolysed by intestinal bacteria. Some carbohydrates, such as cellulose, are not digested at all, as humans lack the enzyme cellulase. After digestion, the small intestine (mainly duodenum) absorbs the available glucose and other monosaccharides and carries them into enterocytes (see Section 3.4.3.2.2). Only glucose and galactose are actively absorbed (by co-transport with sodium using the same hexose transporter), while fructose passes into the enterocyte via facilitated diffusion through another hexose transporter. Glucose, galactose and fructose are tranported out of the enterocyte through another hexose transporter, and then diffuse into blood capillaries within the villus.

Blood glucose concentrations (glycaemia) are controlled by three hormones: insulin, glucagon and epinephrine (adrenaline). If the concentration of glucose in the blood is too high, insulin is secreted by the pancreas and stimulates the transfer of glucose into the liver, muscles and other organs that are able to metabolise glucose by the metabolic process called **glycolysis** to give pyruvic acid and ATP. Since glycolysis releases relatively little ATP, pyruvic acid is converted into acetyl-CoA, which enters the citric acid cycle. Glucose oxidation yields simple organic compounds and the final products of oxidation are carbon dioxide and water. During strenuous muscular activity, pyruvic acid is converted into lactic acid, which is transformed during the resting period back into pyruvic acid. Pyruvic acid in turn yields glucose by a process called **gluconeogenesis**. Excess glucose is stored in the liver and muscles as polysaccharide glycogen, which is formed by the process of **glycogenesis**. Glycogen is stored in the liver and muscles until the blood glucose levels are low. Then epinephrine and glucogon hormones are secreted to stimulate the transformation of glycogen into glucose by the process called **glycogenolysis**.

The blood glucose level induced by carbohydrates in food can be measured by the glycaemic index (GI), which evaluates the biological value of dietary carbohydrates and is a measure of the effects of food carbohydrates on the blood glucose level. It is defined as the glycaemic response elicited by a 50 g portion of carbohydrate food, and expressed as a percent of that elicited by 50 g of D-glucose (GI = 100). For comparison, D-frucose has a GI value of 19, D-glucitol 9, xylitol 13 and D-mannitol 0. Rice (white) has a GI value of 81, milk (whole) 39, apples 52 and banana 83.

The main pathway of galactose metabolism is the Leloir pathway, in which, in the liver, β-D-galactose is converted into UDP-α-D-glucose (a precursor of glycogen and a building block of nucleotide metabolism) via α-D-galactose, α-D-galactose 1-phosphate and UDP-α-D-galactose under the action of mutarotase, galactokinase, galactose 1-phosphate uridyltransferase and galactose-4′-epimerase, respectively. In the liver, fructose is phosphorylated to D-fructose 1-phosphate by fructokinase. Fructose phosphate is split by aldolase B into dihydroxyacetone phosphate (identical to the dihydroxyacetone phosphate produced by glycolysis) and glyceraldehyde. Under the action of triokinase, glyceraldehyde is transformed into glyceraldehyde 3-phosphate. The resulting triose phosphates can enter the gluconeogenic pathway, and can be used for glucose or glycogen synthesis, or be further catabolised.

Exogenous polyols are absorbed slowly and metabolised mainly by the hepatic enzymes. D-Glucitol (sorbitol) and xylitol are metabolised completely after oxidation. Glucitol is oxidised to fructose by glucitol dehydrogenase. Xylitol is oxidised to D-xylulose by xylitol dehydrogenase and xylulose is phosphorylated by xylulose kinase to D-xylulose 5-phosphate, which is an intermediate of the pentose phosphate pathway. D-Mannitol is poorly utilised because of the low affinity for glucitol dehydrogenase. Exogenous erythritol is very poorly metabolised, being almost completely excreted in the urine.

4.2.4 Use

Glucose and glucose syrup are raw material for the production of D-glucitol, D-mannitol, D-fructose, D-gluconic acid and its lactones, various fat and sugar substitutes, such as an indigestible synthetic polymer of glucose called polydextrose having predominantly α-(1→6) bonds. Polydextrose is obtained by fusion of glucose with glucitol and citric acid. Glucose is still the most important raw material for ethanol production by fermentation.

4.3 Derivatives of monosaccharides

4.3.1 Sugar alcohols

Reduction of carbonyl groups of aldoses and ketoses gives rise to acyclic polyhydroxy derivatives of hydrocarbons called sugar alcohols, polyols or alditols (formerly also known as glycitols). Reduction of aldoses produces only one sugar alcohol, reduction of ketoses creates a new asymmetric carbon and the products are two diastereoisomeric polyols. Polyols formed by reduction of some sugars have a plane of symmetry that bisects a molecule into halves that are mirror images of each other and the polyols are therefore achiral meso forms. Through the hydrophilic hydroxyl groups, sugar alcohols are involved in hydration of macromolecules.

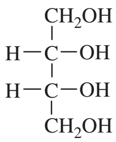
They also act in the prevention of various stress factors and lipid peroxidation in plant cells.

Other saccharides (sugar alcohols) also include cyclitols (alicyclic polyols), because they have similar properties, although they are not derived from sugars by simple reduction. Cyclitols are cycloalkanes, in which at least three ring carbon atoms are substituted (each of them only once) by hydroxyl or alkoxyl groups.

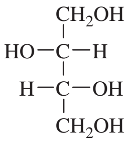
4.3.1.1 Structure and nomenclature

4.3.1.1.1 Alditols

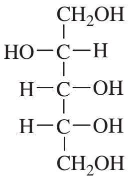
The simplest alditol, which is derived from D-glyceraldehyde, L-glyceraldehyde or 1,3-dihydroxyacetone, is glycerol (propane-1,2,3-triol).[1] The name of the optically active higher alditol is derived from the name of sugar from which the alditol is derived and to which the suffix -itol is connected (e.g. erythritol and threitol). From the four tetroses (aldoses of D- and L-series), only three tetritols can be derived by reduction. Erythritol (**4-47**), which is a meso form, arises from the D- or L-erythrose; D-threitol (**4-48**) is formed from D-threose and L-threitol from L-threose. Aldopentoses of D- and L-series (total of eight aldoses) provide four pentitols. D-Arabinitol (**4-49**) is formed from D-arabinose or D-lyxose, L-arabinitol from L-arabinose or L-lyxose, ribitol (**4-50**) from D- or L-ribose and xylitol (**4-51**) from D- or L-xylose. The reduction of the 16 aldohexoses of D- and L-series yields ten alditols: allitol (**4-52**), D-altritol (**4-53**), L-altritol, D-glucitol (**4-54**), formerly sometimes incorrectly called L-gulitol or more often D-sorbitol (by the Latin name *Sorbus* for rowan or mountain ash trees and shrubs in which glucitol was firstly identified in the fruits), L-glucitol, D-mannitol (**4-55**), L-mannitol, D-iditol (**4-56**), L-iditol and galactitol (**4-57**), formerly called dulcitol. For example, D-glucitol is also formed by reduction of D-glucose and L-gulose.



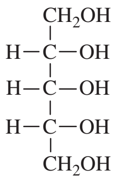
4-47, erythritol



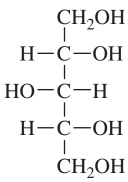
4-48, D-threitol



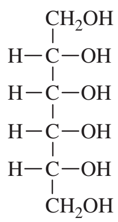
4-49, D-arabinitol



4-50, ribitol

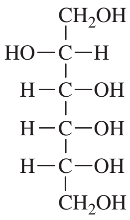


4-51, xylitol

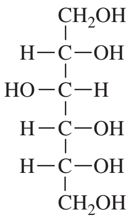


4-52, allitol

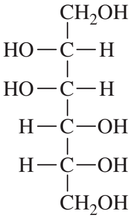
[1]Reduction of glycolaldehyde or glyoxal yields ethylene glycol (ethane-1,2-diol) and the reduction of formaldehyde gives methanol. However, these compounds are not ranked among the alditols.



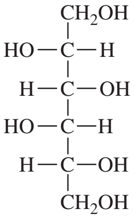
4-53, D-altritol



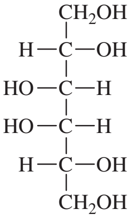
4-54, D-glucitol



4-55, D-mannitol



4-56, D-iditol



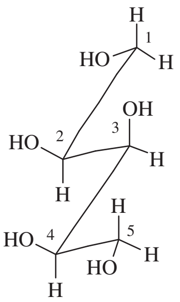
4-57, galactitol

The systematic name of D-glucitol is (2*R*,3*S*,4*S*,5*S*)-hexane-1,2,3,4,5,6-hexol, D-mannitol is (2*R*,3*R*,4*R*,5*R*)-hexane-1,2,3,4,5,6-hexol and galactitol is (2*R*,3*S*,4*R*,5*S*)-hexane-1,2,3,4,5,6-hexol.

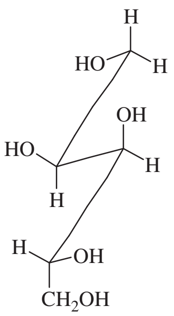
The reduction of ketoses yields both C-2 isomers. For example, the reduction of D-*glycero*-tetrulose creates erythritol and D-threitol. Reduction of D-fructose yields D-glucitol and D-mannitol.

Conformation

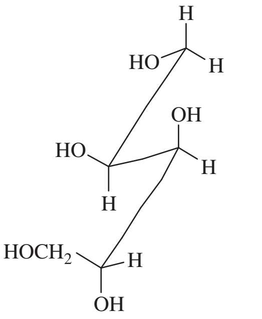
Alditols in solutions most frequently occupy the zigzag conformation with carbon atoms in one plane. The planar conformer of xylitol is shown in stereoformula **4-58** (using the Newman projection, diagrammatic formula). As in the cyclic forms of aldoses and ketoses, non-bonding syn-axial interactions also exist in planar zigzag conformers of alditols, which are the most important destabilising factor determining the relative abundance of different conformers. As a result of interactions of hydroxyl groups on C-2 and C-4 of xylitol, displaying the internal stress, the functional groups rotate around the bonds C3–C4 and the most stable conformer is **4-59** and the least stable conformer is **4-60** with the hydroxyl group at C-2 interacting with bulky hydroxymethyl group at C-4. The prevailing conformer is therefore the anticlinal (also called gauche or bent) conformer.



4-58, planar zigzag conformer of xylitol

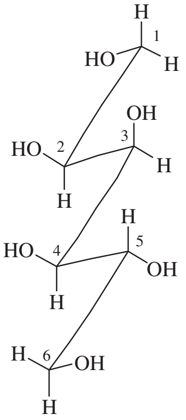


4-59, thermodynamically most stable conformer of xylitol

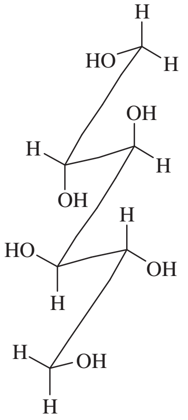


4-60, thermodynamically least stable conformer of xylitol

The syn-axial interactions also occur between the hydroxyl groups at C-2 and C-4 of ribitol, but not with D-arabinitol. Generally speaking, alditols in the configuration *xylo* largely exist as conformers of the type shown in **4-59**, and alditols in the configuration *arabino* primarily exist as planar zigzag conformers of the type shown in **4-58**. Analogously, the *syn*-axial interactions in the zigzag conformation also exist in hexitols allitol, altritol, D-glucitol (**4-61**) and D-iditol, but not with D-mannitol (**4-62**) and galactitol. Only hexitol in the *galacto* and *manno* configuration therefore occurs in the planar zigzag conformations in solutions and the predominant conformation of other hexitols is gauche with other non-planar conformations.



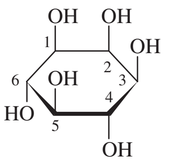
4-61, conformation of D-glucitol



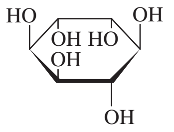
4-62, conformation of D-mannitol

4.3.1.1.2 Cyclitols

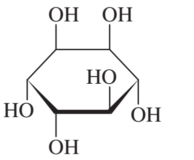
An important group of polyols are cycloalkanes, with three to six hydroxy groups bound to carbon atoms of the ring. The most important cyclitols are polyhydroxyalcohols, formally derived from cyclohexane, which are called cyclohexitols. In addition to hexahydroxy derivatives, penta-, tetra- and trihydroxycyclohexanes and their derivatives are commonly found in plants. The most important cyclohexitols are hexahydroxycyclohexanes or cyclohexane-1,2,3,4,5,6-hexols, known under the generic name **inositols** (formerly called **cycloses**). Altogether there are eight stereoisomers, which are distinguished by affixes or by numerical prefixes (locants) indicating the individual atoms of the ring (**4-63** to **4-71**). As a result of the symmetry of the molecules, seven inositols are achiral substances, optically inactive meso forms, *chiro*-inositol is the only cyclohexitol that occurs as the (+)-D- - or (−)-L-enantiomer. Formerly, this substance has been called inositol without the affix. The affix *chiro* was chosen so as to underline that *chiro*-inositol is the only optically active inositol.



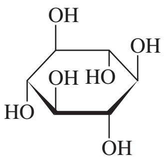
4-63, *myo*-inositol



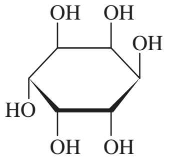
4-64, 1D-(+)-*chiro*-inositol



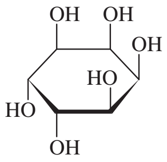
4-65, 1L-(−)-*chiro*-inositol



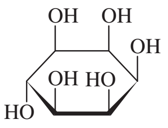
4-66, *scyllo*-inositol



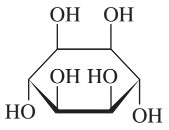
4-67, *neo*-inositol



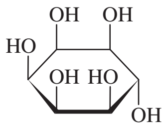
4-68, *allo*-inositol



4-69, *epi*-inositol



4-70, *muco*-inositol



4-71, *cis*-inositol

The most important compound is *myo*-inositol, (1*Z*,2*Z*,3*Z*,5*Z*,4*E*,6*E*)-cyclohexane-1,2,3,4,5,6-hexol, formerly also called *meso*-inositol (or i-inositol, phaseomannitol, nucitol, bios I, mouse antialopaecia factor or vitamin B_m). The affix *myo* was preferred to the affix *meso* as it defines a certain configuration of hydroxyl groups above and below the plane of the ring (1,2,3,5/4,6-), while the second affix has a general meaning and is used to label achiral, optically inactive compounds with the same number of identically bound enantiomeric groups.

Conformation

Analogously to pyranoses, cyclohexitols and derived carboxylic acids occur in sterically stable chair conformations. The lowest energy has *scyllo*-inositol with all substituents in equatorial positions.

4.3.1.2 Occurrence

4.3.1.2.1 Alditols

Alditols occurring in foods as natural components are the result of biochemical reactions, but they can also arise as products of Cannizzaro reaction or other non-enzymatic browning reactions. Many synthetic alditols are used as food additives (sweeteners; see Section 11.3.2.2).

The simplest alditol, glycerol, is a component of food lipids and also occurs as a byproduct of fermentation in addition to

(2*R*,3*R*)-butane-2,3-diol, also known as (−)-D-butane-2,3-diol. It is accompanied by a small amount of (2*S*,3*S*)-butane-2,3-diol, also known as (+)-L-butane-2,3-diol, and *meso*-2,3-butane-2,3-diol. The glycerol and (2*R*,3*R*)-butane-2,3-diol contents can be used as an indicator of wine quality. Erythritol is found in significant quantities in some algae, and small amounts are present in wine musts (juices) and hence, along with glycerol and other alditols, is found in wines (Table 4.7). The content of alditols in wines is higher or the same as in the musts and depends on the type of yeast and other factors. Ribitol is a constituent of riboflavin; D-arabinitol and xylitol are found fairly frequently in fruits, vegetables and mushrooms. Mushrooms (such as the common white button mushroom, *Agaricus bisporus*) contain D-arabinitol at levels of about 3.5 g/kg dry matter and xylitol at about 1.3 g/kg dry matter.

Widely spread alditols in foods are hexitols, particularly D-mannitol, which is the most common hexitol. Other common hexitols are D-glucitol and galactitol. The accumulation of D-mannitol in plants increases their resistance to the high salinity of soil. Fruits and vegetables usually contain very low amounts of mannitol (up to 0.01–0.02%); a relatively high mannitol content is found in celery (0.48%). Its content in green (unroasted) coffee is around 0.05%, whilst in soluble coffee the mannitol content ranges from 0.20 to 1.03%, and waste from the production of soluble coffee contains 1.61–2.03% mannitol. These wastes are therefore used as a raw material for isolating mannitol. Higher amounts of mannitol in wines (1–30 g/l) may be caused by attack of the *Botrytis cinerea* fungus invading the grapes, or by activities of bacteria *Bacterium mannitopoeum*. The fermentation type is called mannitol fermentation or slimy fermentation of sugars. Higher fungi can have a very high mannitol content. The level of mannitol in fungi *Tricholoma portentosum*, commonly known as the charbonnier, is 1.0%, in Saffron milk cap (*Lactarius deliciosus*) 13.7%, in horse mushroom (*Agaricus arvensis*) 6.5% and in the cultivated common mushroom (*Agaricus bisporus*) 15.7% in dry matter of young fruiting bodies, but 26% in dry matter of mature fruiting bodies. The mannitol content in brine of canned common mushrooms is 2.5–10.5 g/l.

The D-glucitol contents in some common fruits and vegetables are given in Table. 4.8. For example, rowan berries, together with the main hexitol D-glucitol, also contain D-mannitol and D-iditol. Prunes have a higher amount of glucitol, and for this reason they are used in various laxative preparations.

A higher concentration of galactitol is found in fungi and fermented milk products. Mushrooms have a galactitol content of about 0.5 g/kg dry matter, while about 9 g/kg dry matter can be found in yoghurts.

Table 4.7 Main alditols in wines.

Alditol	Content (mg/l)	Alditol	Content (mg/l)
Glycerol	4 000–10 000	Xylitol	4–11
Erythritol	35–292	D-Glucitol	9–277
D-Arabinitol	10–577	D-Mannitol	6–152

Table 4.8 D-Glucitol in fruits and vegetables.

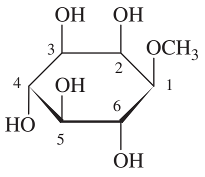
Fruits and vegetables	Content (% of edible portion)	Fruits and vegetables	Content (% of edible portion)
Apples	0.2–0.8	Apricots	0.05–0.46
Pears	1.2–2.8	Rowan berries	3.4–5.3
Plums	0.6–13.9	Grapes	0.01
Cherries	0.1	Cucumbers	0.01
Peaches	0.03–0.48	Tomatoes	0.01

4.3.1.2.2 Cyclitols

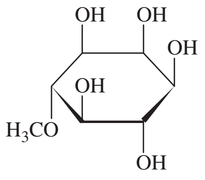
myo-Inositol is found as a free compound in fruits and vegetables, where its content ranges from 0.01 to 0.05%, 0.02–0.30% of *myo*-inositol is present in legumes, cereals and nuts, particularly in bound forms. In legumes, cereals and nuts, *myo*-inositol is mainly present as *myo*-inositol-1,2,3,4,5,6-hexakisdihydrogenphosphoric acid, known as phytic acid, occurring in the form of a mixed K^+, Mg^{2+}, Ca^{2+}, Fe^{2+} and Zn^{2+} salt called phytin (see Section 6.3.4.2.2). Phytin is the main bound form of phosphorus used during seed germination. It also occurs in other parts of plants, such as pollen, roots and tubers. For example, wheat contains about 10 g/kg of phytin. Approximately 70–80% of phytin in dough is hydrolysed by the yeast enzyme phytase to *myo*-inositol. *myo*-Inositol also commonly occurs in the form of phospholipids (phosphatides), known as phosphoinositols. In legumes, buckwheat and other crops, *myo*-inositol is accompanied by a minority cyclitol 1D-*chiro*-inositol and in grape musts by *scyllo*-inositol.

myo-Inositol is a precursor for the biosynthesis of other cyclitols, *O*-methylinositols and other derivatives. Methylation of *myo*-inositol and isomeric inositols (*scyllo*-, *chiro*-, *muco*- and *neo*-inositol) provides *O*-methylinositols bornesitol (1D-1-*O*-methyl-*myo*-inositol; **4-72**), ononitol (1D-4-*O*-methyl-*myo*-inositol; **4-73**), sequoitol (1D-5-*O*-methyl-*myo*-inositol; **4-74**), pinitol (1D-4-*O*-methyl-*chiro*-inositol; **4-75**), quebrachitol (1L-2-*O*-methyl-*chiro*-inositol; **4-76**) and others that are involved in a plant's adaptability to various forms of stress, used as seed storage substances and building blocks for biosynthesis of glycosides. D-Sequoitol occurs as a minor component in beans and in many other plants. A common methyl ether of legumes, derived from D-*chiro*-inositol, is D-pinitol.

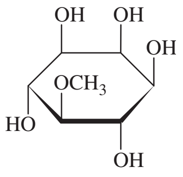
Cyclitols (hexahydroxycyclohexanes) and their ethers also occur in a variety of α-D-galactosides, which are called



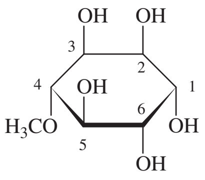
4-72, D-bornesitol



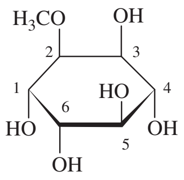
4-73, D-ononitol



4-74, D-sequoitol

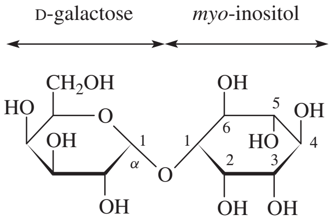


4-75, D-pinitol



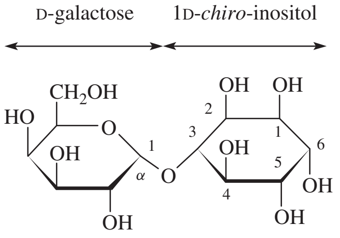
4-76, L-quebrachitol

pseudooligosaccharides. Conjugation of *myo*-inositol and galactose yields galactinol, known by its systematic name as 3-*O*-α-D-galactopyranosyl-D-*myo*-inositol, or also as 1-*O*-α-D-galactopyranosyl-L-*myo*-inositol (**4-77**), the most famous and the first representative of pseudooligosaccharides to be identified. It occurs in all plants containing triose raffinose and higher α-galactooligosaccharides (stachyose, verbascose and ajugose) and therefore occurs in all legumes, as it is employed as the starting compound for the biosynthesis of galactooligosaccharides. Also present are higher α-D-galactopyranosyl homologues of galactinol. The highest concentration of these compounds is found in germs of mature seeds.

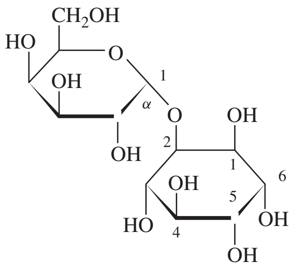


4-77, galactinol

The reaction of 1D-*chiro*-inositol with D-galactose provides fagopyritols (**4-78** to **4-81**), which are present in legumes. Fagopyritols occur at higher concentrations in the seeds and especially in the germ of buckwheat seeds (*Fagopyrum esculentum*, Fabaceae). Fagopyritols of the A series are 3-*O*-α-D-galactopyranosyl-1D-*chiro*-inositols, fagopyritols of the B series are 2-*O*-α-D-galactopyranosyl-1D-*chiro*-inositols.



4-78, fagopyritol A1



4-79, fagopyritol B1

Galactinol in soybeans and other legumes is accompanied by α-D-galactosides of pinitol, known as galactopinitols. A common compound is α-D-digalactopyranoside of pinitol called ciceritol, or by the systematic name *O*-α-D-galactopyranosyl-(1→6)-*O*-α-D-galactopyranosyl-(1→2)-4-*O*-methyl-1D-*chiro*-inositol (**4-82**). Contents of major cyclitols and their galactosides occurring in legumes are given in Table 4.9.

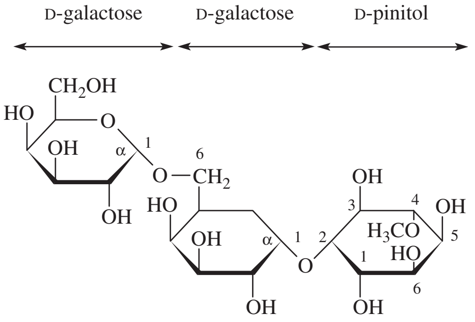
4-81, fagopyritol B2



4-82, ciceritol

4.3.1.3 Physiology and nutrition

4.3.1.3.1 Alditols

The most important hexitols are D-glucitol and D-mannitol. The most important pentitol is xylitol. The relative sweetness of both hexitols (in 10% solutions) and xylitol, compared with saccharose, is about 60 and 100%, respectively. All three polyols have very little effect on blood glucose level and are therefore used as sweeteners for diabetics. However, their content must be included in the total energy intake. They exhibit mild laxative effects (such as prunes, which contain higher amounts of glucitol than other fruits).

Xylitol exposure has an inhibiting effect on the growth of cariogenic bacteria and this may create a permanent change in their oral population. Under discussion are the anticariogenic effects of xylitol. The sweetness and pleasant cooling effect of xylitol sweetened products in the mouth (such as mints and chewing gums) create

Table 4.9 Important cyclitols and their galactosides in legumes (% of dry matter).

an increase in salivary flow. The cooling effect of xylitol is produced in its contact with saliva due to its negative heat of solution (−149 kJ/kg, which corresponds to −27 kJ/mol). Other polyols have a much lower negative enthalpy of dissolution. D-Glucitol and D-mannitol are only weakly cariogenic.

In individuals with galactosaemia (type 1), a rare disorder that affects galactose metabolism (see Section 4.2.3), galactose accumulates in the body tissues together with galactitol, which is an alternative product of degradation. Galactosaemia, which is especially dangerous in children, is caused by the lack of the enzyme galactose-1-phosphate uridyltransferase. Galactitol is toxic to the liver (which may lead to failure), brain (mental retardation) and kidney and to the eye lens (cataract).

4.3.1.3.2 Cyclitols

In nature, the most common cyclitol is *myo*-inositol. It is the key compound in the metabolism of microorganisms, plants and animals, therefore it was formerly considered one of the vitamins (see Section 5.15), but the *myo*-inositol derivative phytin (see Section 10.2.3.1) is classified as an antinutritional food constituent.

4.3.1.4 Use

Polyols xylitol, D-glucitol and D-mannitol have found extensive use primarily as sweeteners in foods for diabetics. They are used in many bakery and confectionery products (mainly xylitol and D-glucitol) to reduce water activity, as substances suppressing crystallisation of saccharose and as humectants improving hydration of dry goods.

Alditols are mainly produced from aldoses or ketoses by hydrogenation or reduction with amalgams, complex hydrides or by electrolytic reduction. Xylitol is prepared by reduction of D-xylose obtained by hydrolysis of natural xylems (hemicelluloses), D-glucitol is prepared from D-glucose and D-mannitol via hydrogenation of D-fructose obtained from either starch or invert sugar.

Also some other polyols may find some application in nutrition (as sweet substances). Examples of these polyols include L-arabinitol (sweetening power of about 100%) obtained by hydrogenation of L-arabinose, galactitol (40%) obtained from D-galactose and polyols derived from disaccharides.

4.3.2 Sugar acids

Sugar acids are saccharides with carboxyl group(s) that commonly occur in foods as free substances and components of many oligosaccharides, polysaccharides, heteroglycosides and other food constituents. Frequently these acids are formally derived from monosaccharides by oxidation of aldehyde groups or primary alcohol groups. Sugar acids are usually produced by enzymatic reactions, but some sugar acids derived from hexoses (such as saccharinic acids) and lower sugars are formed by chemical reactions during storage and processing of foods. Of particular importance in this respect is the Maillard reaction.

Some carboxylic acids, hydroxy acids and oxoacids produced by glycolysis, arising in the citric acid cycle, in the glyoxylate cycle, or their modifications and can thus also be considered sugar derivatives. An example of C_6 substances is L-ascorbic acid and other forms of vitamin C, 2-oxoglutaric acid is a C_5 substance, examples of C_4 substances are tartaric and malic acids, C_3 substances are glyceric, lactic and pyruvic acids and a C_2 substance is glyoxylic acid. Sugar acids also include carboxylic acids derived from alicyclic sugar alcohols (cyclitols) (**8-71**).

4.3.2.1 Structure and nomenclature

Oxidation of aldehyde groups of aldoses yields aldonic (generally glyconic) acids.[2] Free acids readily (especially in acidic solutions) lactonise to give relatively stable five-membered γ-lactones or less stable six-membered δ-lactones. Nomenclature of aldonic acids and their lactones is based on the substitution of the suffix -ose in the aldose name with the suffix -onic acid or -onolactone, respectively. For example, D-glucose gives rise to D-gluconic acid and its dehydration yields the corresponding gluconolactones (Figure 4.3). Another common type of sugar acids are uronic (alduronic) acids, which are derived by oxidation of primary hydroxyl groups. The name of an uronic acid is formed by replacing the suffix -ose with

[2] Under more drastic conditions (e.g. by oxidation with nitric acid), the terminal hydroxymethyl group of aldonic acids is oxidised to a carboxyl group, which produces dicarboxylic acids known as aldaric acids that are usually called glycaric acids. D-Glucose yields D-glucaric acid (also known as saccharic acid), from D-galactose arises achiral galactaric (mucic) acid.

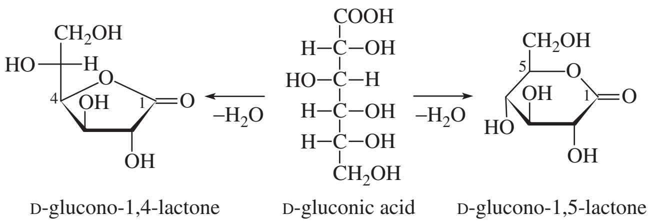

Figure 4.3 Formation of D-gluconic acid lactones.

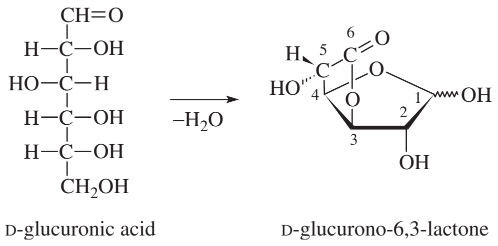

Figure 4.4 Formation of D-glucuronic acid lactones.

the suffix -uronic acid. Uronic acids easily produce 6,3-lactones of furanose or pyranose forms. D-Glucose thus forms D-glucuronic acid (occurring as pyranose) and its lactone (Figure 4.4), D-galactose yields D-galacturonic acid and D-mannuronic acid is derived from D-mannose.

The most important alicyclic acid derived from tetrahydroxycyclohexane is (3*R*,5*R*)-1,3,4,5-tetrahydroxycyclohexane-1-carboxylic acid known as (−)-L-quinic acid. The trihydroxycyclohexene derivative is (3*R*,4*S*,5*R*)-3,4,5-trihydroxycyclohexene-1-carboxylic acid known as (−)-L-shikimic acid (see **8-71**).

4.3.2.2 Occurrence

Gluconic and mannonic acids (as well as glycolic, glyceric, lactic and pyruvic acids) are present in relatively large amounts as natural components in many plant materials, as well as in those foods in which non-enzymatic browning reactions take place. Table 4.10 illustrates the composition and content of aldonic, deoxyaldonic and some other acids in chicory root and malt.

Alduronic acids, especially D-glucuronic, D-galacturonic, D-mannuronic and L-guluronic acids occur chiefly as the building blocks of some polysaccharides. Constituents of rhamnogalacturonan chains in pectin (see Section 4.5.6.6) are unusual acids such as aceric acid (3-*C*-carboxy-5-deoxy-β-L-xylofuranose, β-L-Ace*f*A, **4-83**), deoxyheptonic acid (3-deoxy-β-D-*lyxo*-hept-2-ulopyranaric acid, β-D-Dha*p*, **4-84**) and ketodeoxyoctonic acid (3-deoxy-β-D-*manno*-oct-2-ulopyranosonic acid, β-D-Kdo*p*, 4-85), which is also a component of lipopolysaccharides of gram negative bacteria.

Alicyclic acids, quinic acid and shikimic acid (intermediates in the biosynthesis of phenylalanine, tyrosine and tryptophan, numerous flavourings, natural colourings and other compounds), are common compounds in foods. They occur as free compounds and also in the form of various derivatives, for example in depsides such as chlorogenic acids (**8-82**).

4.3.2.3 Physiology and nutrition

6,3-Glucuronolactone is used in the diet of athletes as a popular supplement for body building. It was found that it accelerates formation and decelerates degradation of muscle glycogen. Glycosides of γ-lactone of D-glucuronic acid, called D-glucuronides, act in the body in detoxification reactions.

4.3.2.4 Use

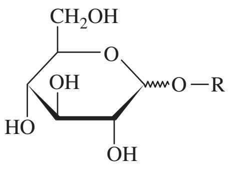
δ-D-Gluconolactone is added at levels of around 0.1% to some smoked meat products, such as fermented sausages and salami. Gradually hydrolysed lactone produces free gluconic acid that inhibits the growth of undesirable putrid microflora, especially at the beginning of product ripening together with lactic and acetic acids produced by fermentation of gluconic acid by some bacteria of the genus *Lactobacillus*.

In dermatology, gluconolactone is capable of chelating metals and may also function by scavenging free radicals, thereby protecting the skin from some of the damaging effects of UV radiation.

4.3.3 Other sugar derivatives

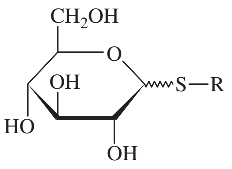
4.3.3.1 Glycosides

The reaction of the hemiacetal hydroxyl group of sugars with hydroxy compounds yields sugar glycosides also known as *O*-glycosides. For example, glycosides derived from glucose are glucosides and mannose gives rise to mannosides (**4-86**). The non-sugar part of the glycoside molecule is generally termed **aglycone** (formerly also referred to as genine). Aglycones are mostly phenols, alicyclic triterpenic alcohols and other steroids (see Section 3.7.4), but can also be other hydroxy compounds. Glycoside is then called a **heteroglycoside**. If the reacting hydroxy compound is another sugar, the resulting product is a **homoglycoside**. Homoglycosides are oligosaccharides and polysaccharides, which are common food components. They form mainly in reactions catalysed by enzymes, but also in other reactions, for example by reversion of monosaccharides.



4-86, *O*-glycoside derived from D-glucose

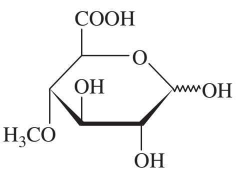
Other natural food components, such as *S*-glycosides, known as thioglycosides, can also be found (**4-87**). Examples of these compounds are glucosinolates (see Section 10.3.2.4). Nitrogen analogues of glycosides are *N*-glycosides (glycosylamines). They occur as natural food components and are also formed in the Maillard reaction. Glycosides similarly include *C*-glycosides, which are actually derivatives of anhydroalditols. Formally, *C*-glycosides resemble glycosides, but are not hydrolysed with acids to form the parent aglycone and sugar. Examples of these glycosides include some natural dyes, such as carminic acid, carthamin, mangiferin and aloin. Some *C*-glycosides also arise as products of the Maillard reaction.



4-87, *S*-glycoside derived from D-glucose

4.3.3.2 Ethers

Ethers of sugars occur in foods as minor structural units of some polysaccharides. For example, 4-*O*-methyl-D-glucuronic acid (**4-88**) is a component of hemicelluloses (arabinoxylans) and other saccharides, 4-*O*-methyl-D-galacturonic acid, 2-*O*-methyl-D-xylose and 2-*O*-methyl-L-fucose are components of pectin. Starch and cellulose ethers are used as food hydrocolloids.

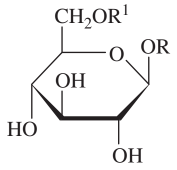


4-88, 4-*O*-methyl-D-glucuronic acid

4.3.3.3 Esters

Esters of saccharides are natural components of virtually all foods. The most common sugar esters are phosphoric acid esters (phosphates), which serve as key intermediates in metabolism by animals, plants and microorganisms. Examples are phosphates of D-glucose (D-glucose 1-phosphate and D-glucose 6-phosphate, **4-89**), but many other sugar phosphates also take part in the metabolic

processes. Phosphate esters also include metabolically active sugar nucleotides, such as adenosine diphospho-D-glucose (ADP-D-Glc), which has a role in the biosynthesis of starch. Of particular importance is D-ribose 5-phosphate, a component of pyrimidine and purine nucleotides in ribonucleic acids (RNA), free nucleotides (such as ATP) and also in many important cofactors of oxidoreductases and transferases, such as NADH and $FADH_2$.

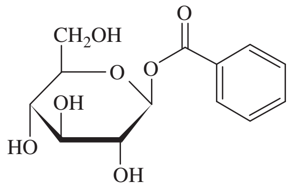


4-89, β-D-glucopyranose 1-phosphate, $R = PO_3H_2$, $R^1 = H$
β-D-glucopyranose 6- phosphate, $R = H$, $R^1 = PO_3H_2$

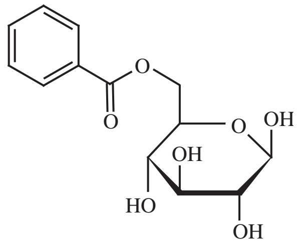
Esters with sulfuric acid often occur as components of some polysaccharides. Sugar sulfates are particularly common components in proteoglycans (mucoproteins) of animal tissues as building blocks of mucopolysaccharides. They are also components of seaweed polysaccharides agar and carrageenan.

Common sugar esters are esters with acetic acid. In animal glycoproteins (such as milk, eggs and blood serum), proteoglycans (mucoproteins), connective tissue polysaccharides and chitin are present, such as *N*-acetates of D-glucosamine, D-galactosamine and *N*-acetylneuraminic acid. Acetates of sugars are often found in various glycosides (e.g. in saponins; see Section 10.3.2.2).

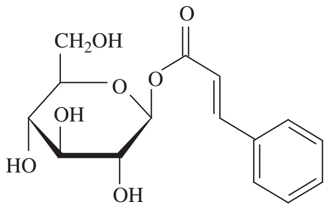
Some very widespread compounds are the esters of D-glucose with aromatic acids. A common metabolite is 1-*O*-benzoyl-β-D-glucopyranose (**4-90**), which occurs, for example, in cranberries (*Vaccinium vitis-idaea*, Ericaceae) together with 6-*O*-benzoyl-β-D-glucopyranose (**4-91**), known as vaccinin. (*E*)-1-*O*-Cinnamoyl-β-D-glucopyranose (**4-92**) has been found in strawberries (*Fragaria vesca*, Rosaceae) and cashew apples (*Anacardium occidentale*, Anacardiaceae). Hydrolysable tannins are esters of glucose with gallic acid and its derivatives (see **8-72**).



4-90, 1-*O*-benzoyl-β-D-glucopyranose



4-91, vaccinin

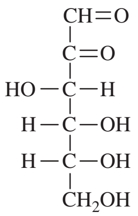


4-92, (*E*)-1-*O*-cinnamoyl-β-D-glucopyranose

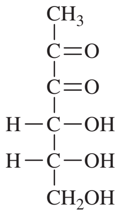
Synthetic esters of some sugars and sugar alcohols with fatty acids are used as additives, primarily as emulsifiers.

4.3.3.4 Ketoaldoses and diketoses

Monosaccharides containing both the aldehyde group and the keto group in the molecule are called **ketoaldoses** (aldoketoses or aldosuloses). If monosaccharides contain two keto groups, they are called **diketoses**. The names of ketoaldoses are formed by replacing the suffix -e in the name of aldose by the suffix –ulose, and using a suitable prefix (e.g. pento- or hexo-). The hexosulose **4-93** is D-*arabino*-hexos-2-ulose (formerly also referrd to as D-glucosulose or D-glucosone). The hexosulose arising from D-galactose during milk processing is D-*lyxo*-hexos-2-ulose (D-galactosulose or D-galactosone). The names of diketose are formed by replacing the suffix -se by the suffix -diulose. Sugars containing three keto groups are triuloses. The diketose in formula **4-94** is hexodiulose, which has the systematic name 1-deoxy-D-*erythro*-hexo-2,3-diulose. Deoxyglycosuloses are the key Maillard reaction products.



4-93, D-*arabino*-hexos-2-ulose



4-94, 1-deoxy-D-*erythro*-hexo-2,3-diulose

Hydroxymethylglyoxal can also be considered to be a ketoaldose, and methylglyoxal is deoxyketoaldose and biacetyl is dideoxydiketose. All these compounds are formed as degradation products of sugars. Other products of sugar fragmentation include deoxyaldose 2-hydroxypropanal (lactic aldehyde), deoxyketose hydroxyacetone (acetol or pyruvic acid aldehyde) and dideoxyketose acetoin (3-hydroxybutan-2-one).

4.3.3.5 Anhydrosugars

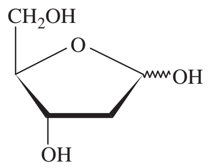
Sugar anhydrides or **anhydrosugars** were previously generally termed **glycosans**. Anhydrosugars formed from glucose were known as glucosans, anhydrosugars derived from mannose were mannosans and anhydrosugars arising from fructose were fructosans. Anhydrosugars are formed by intramolecular condensation of the hemiacetal hydroxyl group and some other hydroxyl groups

in the sugar molecule when it is heated in acidic solutions or in solid form. The anhydrosugar derived from D-glucose, 1,6-anhydro-β-D-glucopyranose (also known as β-glucosan or laevoglucosan), and other anhydrosugars are therefore normal constituents of caramel.

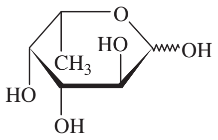
Polysaccharide agar is composed of 3,6-anhydro-α-L-galactopyranose and polysaccharide carrageenan of 3,6-anhydro-α-D-galactopyranose.

4.3.3.6 Deoxysugars

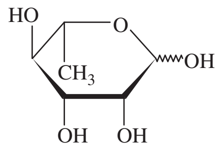
Deoxysugars are sugar derivatives in which one or more hydroxyl groups (but not the semiacetal hydroxyl) are replaced by a hydrogen atom. In foods, deoxysugars are bound in glycosides, glycoproteins or bacterial lipids. Important deoxysugars occurring in foods are 2-deoxy-D-ribose (formerly known as thyminose or 2-deoxy-D-*erythro*-pentofuranose, **4-95**), which is a constituent of deoxyribonucleic acids, and L-fucose (6-deoxy-L-galactopyranose, **4-96**), which occurs as a constituent of milk oligosaccharides. Deoxysugars L-rhamnose (6-deoxy-L-mannopyranose, **4-97**) and D-chinovose (6-deoxy-D-glucopyranose, **4-98**) are constituents of many glycosides. Various deoxysugars, especially deoxyglycosuloses, arise as intermediate products during degradation of monosaccharides in acidic media and as the Maillard reaction products.



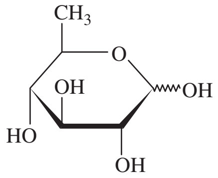
4-95, 2-deoxy-D-ribose



4-96, L-fucose



4-97, L-rhamnose

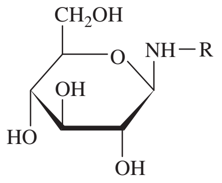


4-98, D-chinovose

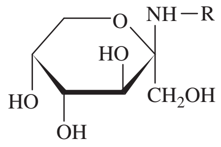
The properties of deoxysugars are similar to those of sugars, but their glycosides, especially glycosides of 2-deoxysugars, are hydrolysed faster.

4.3.3.7 Amino derivatives

Hydroxyl groups of saccharides can be replaced by amino groups. Substitution of the hemiacetal hydroxyl group by an amino group yields ***N*-glycosides** called **glycosylamines**. Aldoses produce aldosylamines (**4-99**, R = H) and ketoses ketosylamines (**4-100**). Various glycosylamines are natural components of all foods. Common compounds are nucleosides, nucleotides (such as ATP) and their polymers RNA and DNA that contain D-ribose or 2-deoxy-D-ribose, respectively. Glycosylamines also form as primary products of the Maillard reaction and in reactions of sugars with ammonia,



4-99, β-D-glucosylamine

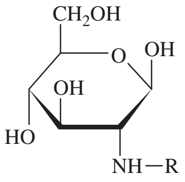


4-100, β-D-fructosylamine

respectively. With amines, amino acids and proteins, sugars yield *N*-substituted glycosylamines and reactions of glycosylamines with another molecule of sugar give diglycosylamines. Glycosylamines are generally unstable basic compounds that are hydrolysed by acids to the parent sugars and amino compounds, rearranged to aminodeoxysugars or readily decomposed.

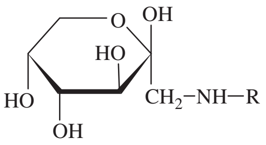
Substitution of a group other than the hemiacetal hydroxyl group for an amino group yields aminodeoxy derivatives of monosaccharides, which are commonly called **aminodeoxysugars** or **amino sugars** for short. The prefix amino in the nomenclature indicates the replacement of a hydrogen atom, therefore aminosugars are derivatives of deoxysugars. Aminosugars are generally known as glycosamines, aminodeoxysugars derived from hexoses are called **hexosamines**, aminodeoxysugars derived from aldoses are **aldosamines** and **ketosamines** are derived from ketoses. Aminosugars derived from aldoses commonly have the amino group on carbon C-2 and amino sugars derived from ketoses on carbon C-1. Amino sugars are unstable as free bases and decompose to a variety of products. Their salts (such as hydrochlorides) are more stable compounds.

Aldosamines and their *N*-acetyl derivatives are important components of various biologically active oligosaccharides and biopolymers. The most important aldosamines are D-glucosamine, D-galactosamine and D-mannosamine. D-Glucosamine is also known as D-chitosamine (2-amino-2-deoxy-D-glucose, **4-101**, R = H). *N*-Acetyl-D-glucosamine (**4-101**, R = $COCH_3$) is a structural unit of milk oligosaccharides, of polysaccharide chitin and of numerous heteropolysaccharides found in proteoglycans of connective tissue, in synovial fluids, in joints connecting bones, in respiratory tract mucus, in saliva, in glycoproteins of milk, eggs and blood serum and in peptidoglycans of bacterial cells. D-Galactosamine also known as D-chondrosamine (2-amino-2-deoxy-D-galactose) is in the form of the *N*-acetate (*N*-acetyl-D-galactosamine, R = $COCH_3$), the building unit of milk oligosaccharides occurring in various connective tissue proteoglycans (mucoproteins) and in glycoproteins of milk and eggs. D-Mannosamine is, as *N*-acetyl-D-mannosamine, a precursor of acetylneuraminic acid.



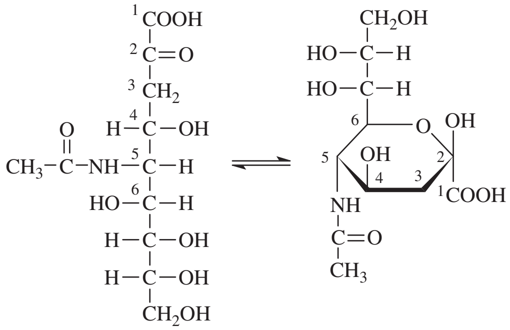
4-101, β-D-glucosamine

Ketosamines, also known as 1-amino-1-deoxyketoses, have an analogous structure (**4-102**). Some important ketosamines form as intermediates of the Maillard reaction.



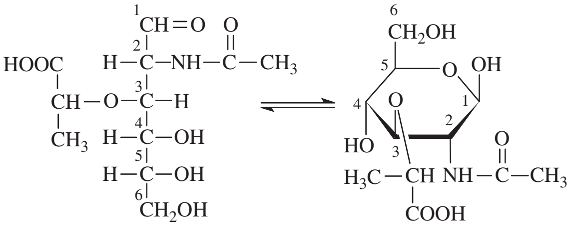
4-102, β-D-fructosamine

Biochemically important amino derivatives of sugars that are widespread in animal connective tissues (mainly in glycoproteins and gangliosides) and microorganisms are **sialic acids**. Sialic acids are a group of α-oxoacids, which are formed by condensation of *N*-acetylhexosamines with three carbon-carboxylic acids. About 50 sialic acids are known. They are *N*- or *O*-substituted derivatives of neuraminic (5-amino-3,5-dideoxy-D-*glycero*-D-*galacto*-non-2-ulopyranosonic) acid (abbreviated as Neu), a monosaccharide with a nine-carbon backbone that does not occur in nature. The neuraminic acid amino group can be acylated by acetic or glycolic acid and hydroxyl groups, except for the semiacetal hydroxyl, can be esterified with lactic, sulfuric or phosphoric acids or methylated. The most common compound, that is generally widespread, is *N*-acetylneuraminic acid (5-acetamido-3,5-dideoxy-D-*glycero*-D-*galacto*-non-2-ulopyranosonic acid, also known as the *N*-acetyllactaminic acid and as Neu5Ac for short) (**4-103**), which is biosynthesised from *N*-acetyl-D-mannosamine and pyruvic acid. The cyclic form of this acid (α-anomer), commonly called *N*-acetyl-α-neuraminic acid, is a constituent of many minor milk oligosaccharides and, together with the corresponding *N*-glycolyl derivative, occurs in numerous glycoproteins (e.g. in milk and egg white glycoproteins). Examples of other sialic acids are *N*-glycolylneuraminic acid (Neu5Gc) and *N*-acetyl-9-*O*-acetylneuraminic acid (Neu5,9Ac2), which, however, do not occur in all living organisms.



4-103, *N*-acetylneuraminic acid

Structurally related to sialic acids is *N*-acetylmuramic acid (**4-104**), the building unit of peptidoglycans of bacterial cell walls or **mureins**.



4-104, *N*-acetylmuramic acid

4.4 Oligosaccharides

Oligosaccharides include those oligomers of monosaccharides in which 2–10 molecules of monosaccharides are connected with each other through glycosidic linkages. Oligosaccharides are therefore glycosides in which the aglycone is a molecule of another saccharide. They are therefore homoglycosides. Depending on the number of monose units, oligosaccharides are divided into di-, tri-, tetra-, penta- and up to decasaccharides. Monosaccharides in oligosaccharides may occur in the form of pyranoses or furanoses. The most common monosaccharides found are hexoses.

Disaccharide can theoretically be formed by the condensation of the α- or β-anomeric hydroxyl group of a monosaccharide with any hydroxyl group of another monosaccharide. The biosynthesis of glycosides, oligosaccharides and polysaccharides but requires the activation of sugar (its 1-phosphate) by binding to nucleoside bisphosphate. The active forms of glucose, for example, are adenosine diphospho-α-D-glucopyranose, guanidine diphospho-α-D-glucopyranose and uridine diphospho-α-D-glucopyranose. The condensation of two semiacetal hydroxyls then yields a disaccharide that does not contain a free anomeric hydroxyl group and is therefore non-reducing. In any other cases, the condensation of two monosaccharides gives a reducing disaccharide, which like the parent monosaccharides exhibits mutarotation in solution, and thus occurs as the α- or β-anomer. Connecting monosaccharides to disaccharides generates trisaccharides, and subsequently higher oligosaccharides.

As an example, Figure 4.5 lists all the hypothetical condensation products of α-D-glucopyranose and β-D-glucopyranose via the anomeric hydroxyl groups with hydroxyls in position C-4. The condensation of two molecules of α-D-glucopyranose through the semiacetal hydroxyl groups yields non-reducing disaccharide known as α,α-trehalose (Figure 4.5). The condensation of the semiacetal hydroxyl of one molecule with the hydroxyl group of the second molecule of α-D-glucopyranose at C-4 gives reducing disaccharide maltose (Figure 4.5), its α-anomer, which yields a certain amount of β-anomer by mutarotation (the rate of convergence to equilibration depends mainly on pH of the reaction medium).

Maltose is also produced by condensation of the anomeric hydroxyl of α-D-glucopyranose with the hydroxyl at C-4 of β-D-glucopyranose when mutarotation again gives the equilibrium mixture of α- and β-anomers of maltose. Condensation of both semiacetal hydroxyl groups yields α,β-trehalose, known as neotrehalose (Figure 4.5). Condensation of the anomeric

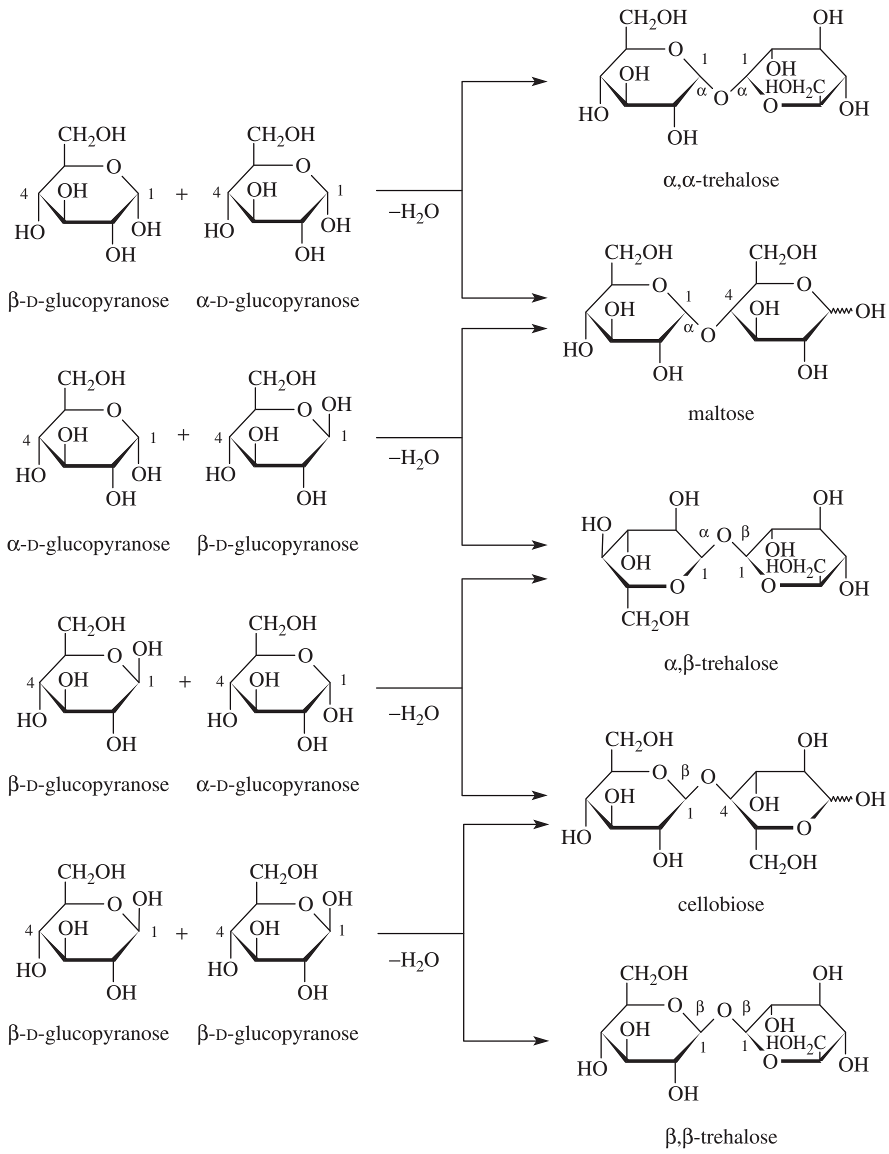


Figure 4.5 Products of condensation of α-D-glucopyranose and β-D-glucopyranose.

hydroxyl of β-D-glucopyranose with the hydroxyl at C-4 of α- or β-D-glucopyranose gives the reducing disaccharide cellobiose (Figure 4.5). Condensation of both anomeric hydroxyls of β-D-glucopyranose gives β,β-trehalose, known as isotrehalose (Figure 4.5). Eight other reducing sugars can be formed by condensation of the anomeric hydroxyl groups of α-D-glucopyranose and β-D-glucopyranose with hydroxyl groups at C-2, C-3 and C-6 of another molecule of D-glucose (see Table 4.11).

In the nomenclature of oligosaccharides, trivial names are still used for a number of substances (e.g. maltose, cellobiose or trehalose, Figure 4.5). In the case of reducing disaccharides, systematic nomenclature takes as its basis the name of the monosaccharide with a free hemiacetal hydroxyl group, which is preceded by the name of the substituted monosaccharide and the respective anomeric configuration is indicated (α- or β-). Disaccharide maltose (Figure 4.5), formed by condensation of the anomeric hydroxyl group of α-D-glucopyranose with the C-4 hydroxyl group of another molecule of D-glucose is generally **glycosylglycose** and is referred to as *O*-α-D-glucopyranosyl-(1→4)-D-glucopyranose. The previously used name was 4-*O*-α-D-glucopyranosyl-D-glucopyranose. The molecule of α-D-glucopyranose is bound by the hemiacetal hydroxyl group (at carbon C-1) and the *O*-glycoside to the hydroxyl group at C-4 (which is marked with numbers 1→4) to the second molecule of D-glucopyranose (α- or β-). In the case of the α-anomer of maltose, the trivial name α-maltose or the systematic name *O*-α-D-glucopyranosyl-(1→4)-α-D-glucopyranose can be used. The abbreviated name of maltose can be written as follows: α-D-Glc*p*-(1→4)-D-Glc*p* (abbreviated names of oligosaccharides are formed from trivial names of monosaccharide units). The systematic name of cellobiose (Figure 4.5) is *O*-β-D-glucopyranosyl-(1→4)-D-glucopyranose, for short β-D-Glc*p*-(1→4)-D-Glc*p*.

Table 4.11 Overview of important glucooligosaccharides.

Trivial name	Abbreviated notation	Occurrence
Disaccharides		
Trehalose (α,α-trehalose)	α-D-Glc*p*-(1↔1)-α-D-Glc*p*	Yeast, mushrooms, honey
Neotrehalose (α,β-trehalose)	α-D-Glc*p*-(1↔1)-β-D-Glc*p*	Honey, koji[a]
Isotrehalose (β,β-trehalose)	β-D-Glc*p*-(1↔1)-β-D-Glc*p*	Honey, glucose reversion
Kojibiose	α-D-Glc*p*-(1→2)-D-Glc*p*	Honey, koji[a]
Nigerose (sakebiose)	α-D-Glc*p*-(1→3)-D-Glc*p*	Honey, beer
Maltose	α-D-Glc*p*-(1→4)-D-Glc*p*	Starch structural unit, starch syrup, honey, malt, sugar beet
Isomaltose (brachiose)	α-D-Glc*p*-(1→6)-D-Glc*p*	Starch structural unit, starch syrup, honey
Sophorose	β-D-Glc*p*-(1→2)-D-Glc*p*	Glucose reversion, glycosides
Laminaribiose	β-D-Glc*p*-(1→3)-D-Glc*p*	Honey
Cellobiose	β-D-Glc*p*-(1→4)-D-Glc*p*	Cellulose structural unit, honey
Gentiobiose	β-D-Glc*p*-(1→6)-D-Glc*p*	Honey, glycosides
Trisaccharides		
Maltotriose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→4)-D-Glc*p*	Starch syrup, honey
Cellotriose	β-D-Glc*p*-(1→4)-β-D-Glc*p*-(1→4)-D-Glc*p*	Cellulose degradation
3-α-isomaltosylglucose	α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→3)-D-Glc*p*	Honey
Isomaltotriose (dextrantriose)	α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→6)-D-Glc*p*	Honey
Centose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→2)-D-Glc*p*	Honey
Panose	α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→4)-D-Glc*p*	Amylopectin degradation, honey
Isopanose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→6)-D-Glc*p*	Honey
Neapolitanose	β-D-Glc*p*-(1→2)-[β-D-Glc*p*-(1→6)]-D-Glc*p*	Glycosides
Tetrasaccharides		
Maltotetraose	α-D-Glc*p*-(1→4)-[α-D-Glc*p*-(1→4)]$_2$-D-Glc*p*	Starch syrup
Isomaltotetraose	α-D-Glc*p*-(1→6)-[α-D-Glc*p*-(1→6)]$_2$-D-Glc*p*	Honey

[a]Koji is a mixture of soybean meal and wheat meal fermented by fungi *Aspergillus oryzae* and *A. Soyae*. It is an intermediate in the production of soy sauce (shoyu).

Cellobiose, as well as maltose, is a reducing sugar and therefore occurs in the form of α- and β-anomers.

Non-reducing disaccharides are actually double glycosides, and are therefore called **glycosylglycosides**. Disaccharide α,α-trehalose (Figure 4.5) is α-D-glucopyranosyl-α-D-glucopyranoside for short: α-D-Glc*p*-(1↔1)- α-D-Glc*p*.

Disaccharides and higher oligosaccharides exist in the form of different conformational isomers, which differ by the energy state given by the rotation of molecules of monosaccharides around the glycosidic bond, therefore the conformational isomers differ in their various spatial orientations. They can be characterised as peptides by torsion angles ϕ and ψ (see Section 2.3.1). Equilibrium at a given temperature exists for the populations of individual conformers. The predominant species are the conformers with the lower free energy content. Most oligosaccharides have the same stable and sterically most favourable conformers in both aqueous solutions and in the solid (crystal) state. Conformers of disaccharides are commonly stabilised by hydrogen bonds between adjacent hydroxyl groups or between hydroxyl groups and the oxygen atom of pyran or furan rings.

Foods (such as fruits, vegetables, milk and honey) contain a large number of free and bound oligosaccharides, which are natural food ingredients. Oligosaccharides are usually composed of a number of common monosaccharides of the D-series (glucose, fructose, galactose and mannose) in various combinations. Aldoses are present in the form of pyranoses and fructose as furanose. Less common sugars, such as 6-deoxyhexose (methylpentose) L-rhamnose or pentoses L-arabinose and D-xylose are also present in some oligosaccharides.

The most common oligosaccharides present as natural components of foods are oligomers of D-glucose known as **glucooligosaccharides**, in which glucose is the sole or

predominant monosaccharide. Another important group are the **fructooligosaccharides** containing only D-fructose or D-fructose and D-glucose. The dominant disaccharide of this type in foods is saccharose (sucrose). Equally important are **galactooligosaccharides**, which consist of D-galactose, D-glucose, D-fructose and may contain also some other monosaccharides.

The human organism can hydrolyse some oligosaccharides, such as saccharose, lactose, maltose and isomaltose-type oligosaccharides, to monosaccharides by the hydrolytic enzymes maltase, isomaltase, saccharase (sucrase) and lactase (see Section 4.2.3). Utilisable oligosaccharides have a similar effect on blood glucose level as the corresponding monosaccharides. Saccharose and maltose exhibit strong cariogenic effects, while the effects of lactose are weaker. Lactose has some laxative effects.

In recent years, a number of various oligosaccharides have been produced and used as food additives. Raw materials for edible oligosaccharides are naturally present oligosaccharides (e.g. saccharose and lactose) and polysaccharides (starch, inulins, xylans and other polysaccharides). Currently, more than ten different types of oligosaccharides are produced. For example, saccharose is a raw material for the production of palatinose (isomaltulose), glycosylsaccharose, lactosaccharose and fructooligosaccharides. Lactulose, lactosaccharose and galactooligosaccharides are produced from lactose. Starch is the raw material for the production of maltooligosaccharides, isomaltooligosaccharides, cyclodextrins and gentiooligosaccharides. Fructooligosaccharides are produced from inulin, xylooligosaccharides from xylans and mannooligosaccharides from mannose. Hydrogenation of some disaccharides (lactose and maltose) yields the corresponding polyols. The oligosaccharides (and polyols) obtained are water-soluble substances having a slightly sweet taste. Their solutions usually have a higher viscosity than solutions of natural monosaccharides and disaccharides and only 30–60% of the sweetness of saccharose. These sugars therefore find use as fillers for low-energy products (with reduced monosaccharide and saccharose content), for products that require increased viscosity and increased water binding capacity as a prevention of drying. For example, lower water activity of products is a protection against microbial contamination and starch retrogradation during bread aging.

The physiological effects of these oligosaccharides are highly desirable. Unlike ordinary monosaccharides, oligosaccharides and starch, these oligosaccharides are not utilised by microflora of the mouth and are therefore non-cariogenic carbohydrates. Many of them are indigestible and cannot be utilised, and are used in the production of low energy foods and foods for diabetics. Some oligosaccharides exhibit:

- **prebiotic** effects, as they selectively stimulate the growth and metabolism of desirable microflora of the colon
- **probiotic** effects, as the desirable microflora confers health benefits on the host
- **symbiotic** effects (prebiotic and probiotic effects at the same time).

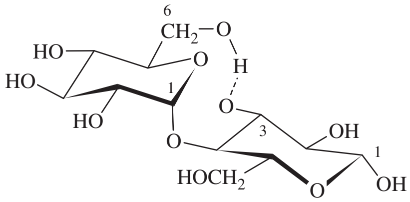
4.4.1 Glucooligosaccharides

Glucooligosaccharides include a large number of disaccharides, trisaccharides and higher oligosaccharides, which commonly (but usually in small quantities) occur in many foods or are used as food additives (Table 4.11). The most important representative of these oligosaccharides is the disaccharide maltose.

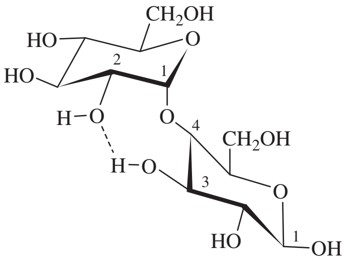
4.4.1.1 Maltose

4.4.1.1.1 Structure and nomenclature

A molecule of the reducing sugar maltose (also called malt sugar, as it is the result of starch hydrolysis in malt), known by the systematic name *O*-α-D-glucopyranosyl-(1→4)-D-glucopyranose (Figure 4.5), is stabilised in aqueous solution by hydrogen bonds between the hydroxymethyl group of one molecule of glucose (C-6) and the hydroxyl group at carbon C-3 of the second molecule of glucose (**4-105**). In crystals of maltose (and also in solutions in non-aqueous media), maltose is present as a different conformer, which is stabilised by hydrogen bonds between the hydroxy group at the C-2 carbon of one glucose molecule and the hydroxyl at the C-3 of the second molecule of glucose (**4-106**).



4-105, conformation of maltose in aqueous solutions



4-106, conformation of anhydrous crystalline maltose

4.4.1.1.2 Occurrence

Small, but sometimes also relatively large, amounts of maltose are typically found in most foods. Bread dough contains maltose formed by hydrolysis of starch by yeast (*Saccharomyces cerevisiae*) enzymes and by enzymes present in the flour. At the beginning of the fermentation, its content increases due to the hydrolysis of starch. After the preferred fermentation of glucose and fructose, the maltose content decreases, as it is also partially fermented by yeast. The level of maltose present in bread is 1.7–4.3%.

Maltose, a product of the enzymatic hydrolysis of starch, is present in germinating seeds and thus also in germinating barley

and barley malt (hence the name malt sugar). Malt may be partly substituted by starch-rich materials, such as rice, maize or wheat. Brewer's yeast ferments about 95% of maltose and 80% of maltotriose.

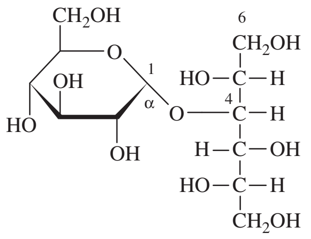
Maltose is present at a relatively large concentration in honey (2.7–16%, 7.3% on average) together with fructose (27.3–44.3%), glucose (22.0–40.8%), saccharose (0.3–7.6%) and other oligosaccharides. It is also found in cereals and fruits. Starch hydrolysates, such as maltose syrups, contain maltose at levels of up to 85%.

4.4.1.1.3 Physiology and nutrition

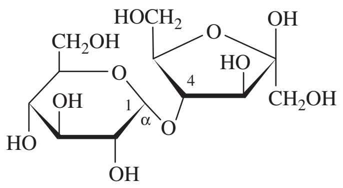
The relative sweetness of maltose is 30–60% of saccharose sweetness (see Table 8.37). After hydrolysis to glucose by maltase (α-D-glucoside glucohydrolase), maltose is a utilisable sugar. Maltose intake in foods has a significant effect on blood glucose levels and insulin secretion. It is a cariogenic sugar.

4.4.1.1.4 Use

Maltose and various products containing maltose and maltooligosaccharides (such as maltodextrins, glucose or maltose syrups) are obtained from starch, often by the combined effects of mineral acids and amylolytic enzymes. Maltose is obtained from maltose syrups. A product of maltose hydrogenation (at the reducing end of the glucose molecule) is maltitol, *O*-α-D-glucopyranosyl-(1→4)-D-glucitol (**4-107**). Its sweetening power is about 90% of that of saccharose. Maltitol has very little impact on blood sugar level and has a weak laxative effect. Isomerisation in an alkaline medium (glucose at the reducing end of the molecule isomerises to fructose) produces disaccharide maltulose (**4-108**).



4-107, maltitol



4-108, maltulose

4.4.1.2 Other glucooligosaccharides

An overview of common glucooligosaccharides occurring in foods is given in Table 4.11. Many different glucooligosaccharides are present in honey as minor sugars (Table 4.12). Their structures are shown in Table 4.11; the structures of fructooligosaccharides are shown later in Table 4.14.

Table 4.12 Composition of minor disaccharides of honey.

Disaccharides	Content (g/kg)	Trisaccharides	Content (g/kg)
Kojibiose	3.0	Erlose	1.6
Turanose	1.7	Theanderose	0.99
Isomaltose	1.6	Panose	0.91
Saccharose	1.4	Maltotriose	0.69
Maltulose	1.1	1-Kestose	0.33
Nigerose	0.62	Isomaltotriose	0.22
Isotrehalose	0.40	Melezitose	0.11
Gentiobiose	0.15	Isopanose	0.09
Laminaribiose	0.03	Centose	0.02

An important non-reducing disaccharide is α,α-trehalose, which occurs in many plants and invertebrate organisms (bacteria, fungi, worms, crustaceans), where it serves as an energy source and has a protective function in stress induced by heat and drought. In fruits and vegetables, trehalose is found in very small amounts (see Table 4.5), but larger levels are located in fungi. In the cultivated common mushroom (*Agaricus bisporus*), the content of α,α-trehalose is 0.5% in very young fruiting bodies and 0.09% in fruiting bodies at the end of their development, but it constitutes 21% of dry matter in the charbonnier mushroom (*Tricholoma portentosum*).

Numerous disaccharides and higher oligosaccharides containing glucose, in addition to other monosaccharides, are components of many glycosides. Common sugars occurring in glycosides are arabinose, xylose and rhamnose. An overview of the major reducing disaccharides occurring in anthocyanins, other flavonoids and other glycosides is shown in Table 4.13.

4.4.2 Fructooligosaccharides

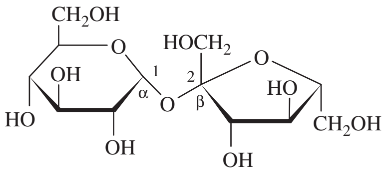
4.4.2.1 Saccharose

4.4.2.1.1 Structure and nomenclature

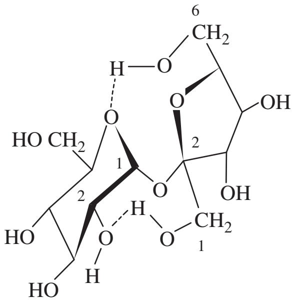
Saccharose or sucrose (**4-109**), β-D-fructofuranosyl-α-D-glucopyranoside (sugars are given in alphabetical order), also called beet, cane or table sugar, is the most important representative of non-reducing disaccharides. In aqueous solutions and in the solid state, the conformer stabilised by two hydrogen bonds predominates (**4-110**). The first bond is between the hydroxyl group on carbon C-2 of glucose ($^4C_1$-pyranose) and the hydroxyl group at C-1 of fructose ($^4T_3$-furanose), the second bond is between the pyranose ring oxygen and the C-6 hydroxyl group of the fructose.

Table 4.13 Important disaccharides occurring in glycosides.

Trivial name	Short notation	Trivial name	Short notation
Vicianose	β-L-Ara*p*-(1→6)-D-Glc*p*	Robinobiose	α-L-Rha*p*-(1→3)-D-Glc*p*
Sambubiose	β-D-Xyl*p*-(1→2)-D-Glc*p*	Chacobiose	α-L-Rha*p*-(1→4)-D-Glc*p*
Primeverose	β-D-Xyl*p*-(1→6)-D-Glc*p*	Rutinose	α-L-Rha*p*-(1→6)-D-Glc*p*
Neohesperidose	α-L-Rha*p*-(1→2)-D-Glc*p*	Solabiose	β-D-Glc*p*-(1→3)-β-D-Gal*p*



4-109, saccharose



4-110, conformation of saccharose in aqueous solutions

4.4.2.1.2 Occurrence and production

Saccharose is a very widespread sugar synthesised by most eukaryotic and some prokaryotic organisms. As the main product of photosynthesis, saccharose is commonly present in higher plants, where it has a role in transport and energy reserves and is used also in signal transmission and in stress situations. As the energy reserve in plants, saccharose is mobilised under the catalysis of the enzyme invertase to fructose and glucose and is used for seed germination, plant growth and also during fruit ripening. Another enzyme that plays a role in the catabolism of sucrose is sucrose synthetase, which splits sucrose into fructose and UDP-α-D-glucose, which is used for the biosynthesis of starch.

Saccharose is present in larger amounts in the vegetative parts of plants, such as leaves and stems (sugar cane contains 12–26%, sugar-rich varieties called sweet maize 12–17%, sweet millet 7–15% sucrose) and fruits (e.g. apples, oranges, apricots, peaches, pineapples and papayas), which contain up to about 8% saccharose (Table 4.4). Some fruits, however, do not contain sucrose (cherries, grapes, figs), because it is hydrolysed during fruit ripening. Vegetables commonly contain 0.1–12% saccharose (e.g. onion 10–11% and in sugar beets 3–20%). Mustard seeds, rapeseeds and other oilseeds contain about 4%, wheat flour from 0.1 to 0.4%, green coffee 6–7% (roasted coffee about 0.2%) and groundnuts 4–12 % saccharose. Sucrose is the transport form from the leaves to the tubers and is therefore the major sugar in immature potato tubers. The amount of saccharose in mature tubers varies between cultivars and is generally less than 0.3%. If saccharose is low in tubers at harvest, the concentration of all sugars remains low in healthy tubers under storage. However, the content of saccharose in Jerusalem artichokes is 2–3%. The saccharose content in beans is given in Table 4.17.

The main industrial sources of sucrose are sugar cane (*Saccharum officinarum*, Poaceae) and sugar beet (*Beta vulgaris* group *Altissima*, Amaranthaceae, formerly Chenopodiaceae), the varieties of which today contain 15–20% saccharose (typically 16–17%). In addition to sugar cane and sugar beet, on smaller scale and locally, other plants are sometimes used as a source of saccharose. In Algeria and Iraq, date sugar is obtained from fruits of date palm dates (*Phoenix dactylifera*, Arecaceae) that contain up to 81% saccharose in the dry state. In India, Cambodia, the Philippines and elsewhere, table sugar is traditionally made from the juice of various palms of the genus *Borassus* (e.g. *Borassus flabelliformis*) and of some other species, such as arenga palm (*Arenga pinnata*), date palm and coconut palm (*Cocos nucifera*). Maple sugar in Canada, the United States and Japan is produced from the juice of sugar maple (*Acer saccharum*, Sapindaceae), which contains about 5% saccharose. Sweet sorghum syrup, traditionally used as a substitute for sugar, is known as molasses, especially in Southern US states, although it is not true molasses. It is obtained from the stalks of sweet sorghum (*Sorghum bicolor*, Poaceae) containing 12% saccharose.

The production of saccharose from sugar beet consists of several steps, including **diffusion**, juice **purification**, **evaporation** and **crystallisation**. The processing of thoroughly washed sugar beet starts by slicing the beets into thin chips called **cossettes**. The cossettes are extracted with hot water at an elevated temperature (50–80 °C) in a process called **diffusion** (sulfur dioxide, chlorine, ammonium bisulfite or commercial biocides are used as disinfectants). The sugar-enriched water, called **raw juice** (or mixed juice containing between 10 and 15% of saccharose) is filtered, heated to 80–85 °C and cleaned by a process known as **carbonatation**, which removes non-sucrose impurities in the raw juice. Lime milk (a solution of calcium hydroxide) is added to adsorb or adhere to the impurities, and carbon dioxide gas is bubbled through the mixture to precipitate the lime as insoluble calcium carbonate crystals (see Section 6.3.2.3). After filtration (the liming processes with

subsequent carbonation and filtration are known as **epuration**), sulfur dioxide is added to the juice (termed **thin juice**) to inhibit the Maillard reaction. The next stage of the process is the juice **evaporation** to **thick juice** that contains 50–67% saccharose. The filtered juice with added pure sugar, or **standard liquor**, proceeds to the **crystallisation**. It is boiled under vacuum until it becomes supersaturated and saccharose crystallises. Sugar crystals in the mixture with liquor, known as **massecuite** (or fillmass), are separated and refined. Raw sugar obtained by crystallisation contains about 96% saccharose, 1.0–1.2% organic compounds, 0.8–1.0% inorganic substances (so called non-sugars) and 1–2% water. It is light yellow to dark brown because it contains a certain amount of molasses. It can be used as raw brown sugar. The refining is mainly done with hot water, the product is dried and cooled. The liquid separated from the sugar crystals, the **syrup**, is introduced back to the crystallisation operation; the process is repeated once again so that the yield of saccharose is 58–90%.

The final liquid obtained is **molasses**. Beet molasses contains about 50% sucrose and about 80–85% dry matter, from which about 1% accounts for glucose and fructose and 1.2% (or it can sometimes be more than 8%) for raffinose. In small quantities, some other oligosaccharides also occur. Approximately 20% of the molasses weight is accounted for by non-sugars consisting of organic acids and amino acids (particularly glutamic acid, 5-oxopyrrolidine-2-carboxylic acid) and *N*,*N*,*N*-trimethylammonioacetate (betaine, **2-14**), the content of which is generally 0.3%, and other substances. The rest (about 12%) is accounted for by inorganic substances such as potassium salts of sugars and other substances. Molasses can be further desugarised using an ion-exchange process called deep molasses desugarisation, used as a substrate for the production of yeast, ethanol, citric and lactic acid, glycerol, butan-1-ol, acetone and many other substances, or used in the production of livestock feed or for a range of other purposes. The pressed beet pulp (cossettes) is mixed with molasses that is not desugarised, then dried and used as a constituent of some animal feeds.

Sugar cane molasses contains about 80% dry matter, of which 30–40% is saccharose and 30% glucose and fructose. The content of non-sugars is about 10%. The non-sugars include small amounts of raffinose, no betaine, but also about 5% aconitic acid, which is not present in beet molasses. The content of inorganic substances is about 8%. Sugar cane molasses is mainly used for production of rum and arrack.

4.4.2.1.3 Physiology and nutrition

Saccharose occurring in foods is hydrolysed to glucose and fructose by invertase, β-D-fructofuranosidase; therefore it has a large influence on the glucose content in plasma and insulin secretion. A high sucrose intake causes a significant excess of energy and the body synthesises higher amounts of fat. Saccharose is a cariogenic sugar.

4.4.2.1.4 Use

Saccharose is predominantly used as a versatile sweetener and is also used in the production of:

- invert sugar
- fructooligosaccharides (also produced from inulin)
- palatinose and palatinitol
- glycosylsaccharose
- lactosaccharose (also produced from lactose).

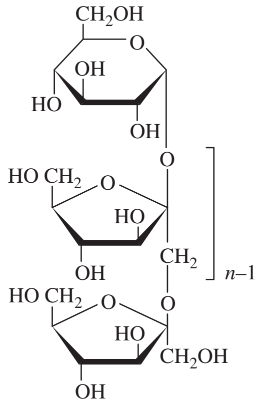
Invert sugar

Acid or enzymatic hydrolysis of sucrose, **inversion**, produces an equimolar mixture of D-glucose and D-fructose known as invert sugar. Invert sugar is used as a food additive substance, usually in the form of syrup (relative sweetness is 95–105% of saccharose sweetness). It also serves as a starting material for obtaining D-glucose and D-fructose, the sweeteners mannitol and glucitol and other substances.

Invert sugar obtained by acid hydrolysis of saccharose contains trace amounts of reversion products of glucose (especially isomaltose and gentiobiose) and fructose (dianhydrides or laevulosans). Invert sugar obtained by enzymatic hydrolysis (due to some transglucosidase or transfructosidase activity of invertase) also contains trace amounts of some less common oligosaccharides.

Fructooligosaccharides

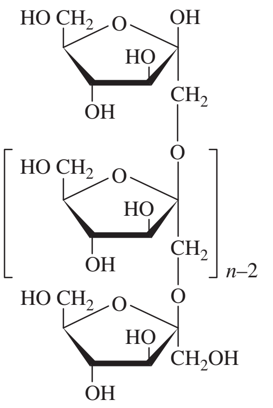
Fructooligosaccharides (**4-111**) are produced from saccharose by the action of microbial and plant fructosyltransferase (transfructosylation) or by using the transfructosylase activity of invertase. Fructooligosaccharides are oligomers of the type: [β-D-Fru*f*-(2→1)]$_{n-1}$-β-D-Fru*f*-(2↔1)-α-D-Glc*p*, for short GF_n (G = glucose, F = fructose, *n* = degree of polymerisation). The basic member of the homologous series is saccharose and the degree of polymerisation is 2–4. This mixture of fructooligosaccharides is known as **neosugar**.



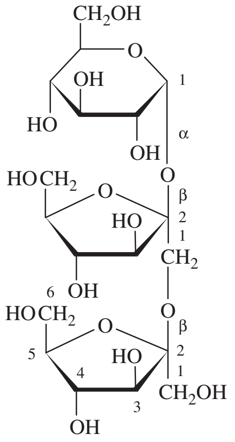
4-111, type GF_n fructooligosaccharides

Fructooligosaccharides of somewhat different composition are produced by a controlled enzymatic hydrolysis of inulin

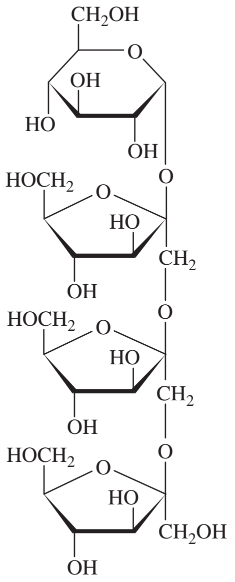
using β-D-fructofuranosidase (invertase, saccharase) from the fungus *Aspergillus niger*. The hydrolysis products are fructooligosaccharides of the type: [β-D-Fru*f*-(2→1)]$_{n-1}$-β-D-Fru*f*-(2↔1)-α-D-Glc*p*, abbreviated GF_n, or products of the type: [β-D-Fru*f*-(2→1)]$_n$, in short F_n, where $n = 2$–9. These products are called **oligofructose** (**4-112**). The basic member of the fructooligosaccharides of the GF_n type is the non-reducing trisaccharide 1-kestose (**4-113**), abbreviated to GF_2. Higher oligosaccharides are tetrasaccharide 1,1-nystose (GF_3, **4-114**) and pentasaccharide 1-*O*-β-D-fructofuranosylnystose (1,1,1,-fructosylnystose, GF_4). The GF_n type oligomers are non-reducing sugars. An example of disaccharides consisting of two molecules of fructose is inulobiose (**4-115**), abbreviated to F_2. The F_n type oligomers, which contain glucose, are reducing sugars.



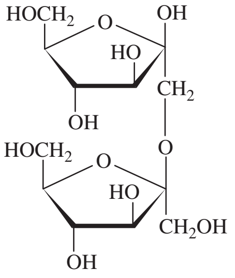
4-112, type F_n fructooligosaccharide



4-113, 1-kestose



4-114, 1,1-nystose

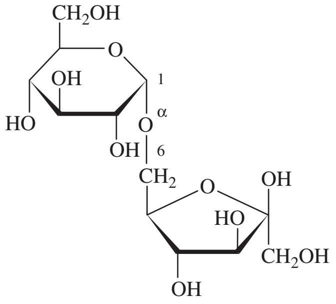


4-115, inulobiose

Fructooligosaccharides are water-soluble sweet substances, which show 40–60% of the saccharose sweetness. They are not hydrolysed by saccharidases and therefore are classified as soluble fibre. In the colon, however, fructooligosaccharides are fermented by anaerobic bacteria to lower fatty acids (mainly acetic, propionic and butyric acids), L-lactic acid and gases (carbon dioxide, methane and hydrogen). They are therefore also called intestinal food. The yield of energy of fructose bound in oligofructoses is only about 25–35% of the energy yield of free fructose (about 4.2–6.3 kJ/g). Fructooligosaccharides are the growth factor of beneficial bifidobacteria (*Bifidobacterium bifidum*). They produce carboxylic acids (mainly acetic acid and lactic acid) and the lower pH is associated with the production of substances with antibiotic and immunomodulatory effects (so-called bifidin and other substances), which results in suppression of the growth of undesirable microflora, such as *Escherichia coli*, *Streptococcus faecalis*, *S. proteus*, *Clostridium perfringens* bacteria and also *Staphylococcus aureus*, *Salmonella typhosa* and some other bacteria, which produce toxic fermentation products (ammonia, amines, nitrosamines, phenols, indoles and other toxins). In addition, bifidobacteria produce thiamin, riboflavin, niacin, pyridoxine, folacin and corrinoids. Fructooligosaccharides and the so-called soluble fibre bind bile acids in the intestine very well, and thus prevent their reabsorption, which is manifested by lowering of the cholesterol level in blood plasma.

Palatinose

Isomerisation of saccharose using immobilised microorganisms *Leuconostoc mesenteroides* or *Protaminobacter rubrum* yields palatinose, also known as isomaltulose (**4-116**, Table 4.14). The ratio of α- and β-anomers of isomaltulose (usually present in the ratio 1 : 4) depends on the reaction conditions. Palatinose is accompanied by small amount of α-D-fructofuranosyl-(1↔1)-α-D-glucopyranoside. Intermolecular condensation of these disaccharides yields higher oligosaccharides. Palatinose is a non-cariogenic sugar that stimulates the growth of bifidogenic microflora. The sweetening power of palatinose is about 40% of the sweetening power of saccharose.



4-116, isomaltulose

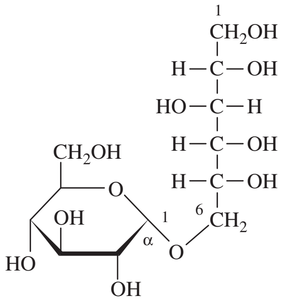
Palatinitol

Catalytic hydrogenation of palatinose yields palatinitol, which is known by the trade name of **isomalt**. Isomalt is a mixture of *O*-α-D-glucopyranosyl-(1→6)-D-glucitol (isomaltitol, **4-117**) and *O*-α-D-glucopyranosyl-(1→1)-D-mannitol in a ratio of approximately 1 : 1. The sweetening power of this non-cariogenic sugar is about

Table 4.14 Overview of important fructooligosaccharides.

Trivial name	Abbreviated notation	Occurrence
Disaccharides		
Saccharose	β-D-Fru*f*-(2↔1)-α-D-Glc*p*	Honey, sugar beet, sugar cane plants
Turanose	α-D-Glc*p*-(1→3)-D-Fru*f*	Honey
Maltulose	α-D-Glc*p*-(1→4)-D-Fru*f*	Honey, maltose reversion
Isomaltulose (palatinose)	α-D-Glc*p*-(1→6)-D-Fru*f*	Maltose reversion, saccharose isomerisation
Inulobiose	β-D-Fru*f*-(2→1)-β-D-Fru*f*	Inulin degradation
Levanbiose	β-D-Fru*f*-(2→6)-β-D-Fru*f*	Inulin degradation
Trisaccharides		
1-Kestose (isokestose)	β-D-Fru*f*-(2→1)-β-D-Fru*f*-(2↔1)-α-D-Glc*p*	Honey, inulin, invert sugar, saccharases from saccharose
6-Kestose (kestose)	β-D-Fru*f*-(2→6)-β-D-Fru*f*-(2↔1)-α-D-Glc*p*	Bananas, honey, invert sugar, molasses
Neokestose	β-D-Fru*f*-(2→6)-α-D-Glc*p*-(1↔2)-β-D-Fru*f*	Inulin, invert sugar,saccharases from saccharose
Erlose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1↔2)-β-D-Fru*f*	Honey
Theanderose	α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1↔2)-β-D-Fru*f*	Honey
Gentianose	β-D-Glc*p*-(1→6)-α-D-Glc*p*-(1↔2)-β-D-Fru*f*	Glycosides
Melezitose	α-D-Glc*p*-(1→3)-β-D-Fru*f*-(2↔1)-α-D-Glc*p*	Nectars, honey
Kelose	α-D-Fru*f*-(2→6)-β-D-Fru*f*-(2↔1)-α-D-Glc*p*	Saccharases from saccharose
Tetrasaccharides		
Nystose	β-D-Fru*f*-(2→1)-β-D-Fru*f*-(2→1)-β-D-Fru*f*-(2↔1)-α-D-Glc*p*	Inulin, saccharases from saccharose

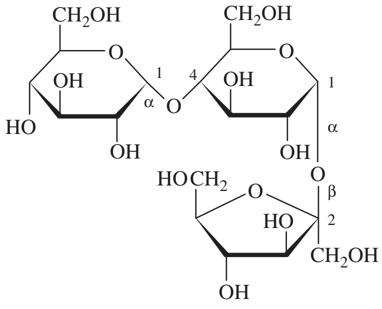
50% of the sweetening power of saccharose. It has no effect on blood glucose level, but it is relatively effective laxative.



4-117, isomaltitol

Glycosylsaccharose

Trisaccharide glycosylsaccharose (**4-118**) is produced under the trade name **neosugar** from saccharose or maltose using the enzyme cyclomaltodextrin glucanotransferase. It has about 50% of the sweetening power of sucrose, is less digestible and non-cariogenic. It is appreciated for its technological properties, such as reduced crystallisation of saccharose, reduced retrogradation of starch and low reactivity in the Maillard reaction.



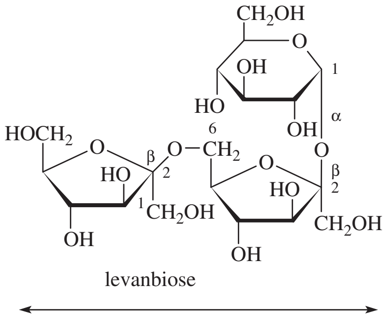
4-118, glycosylsaccharose

4.4.2.2 Other fructooligosaccharides

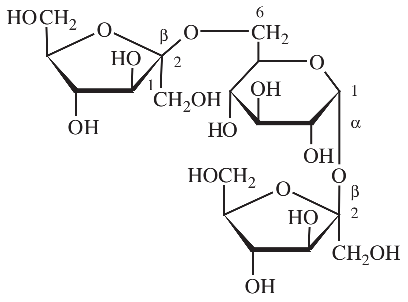
In addition to saccharose, numerous other disaccharides and higher oligosaccharides derived from glucose and fructose are present in foods as natural components. An overview of relatively commonly occurring oligosaccharides is shown in Table 4.14. Turanose, maltulose (**4-108**) and isomaltulose (4-**116**) are examples of reducing disaccharides (sucrose isomers).

Higher fructose oligomers linked by glycosidic bonds β-(2→6) are found in small amounts in foods. These sugars are mainly

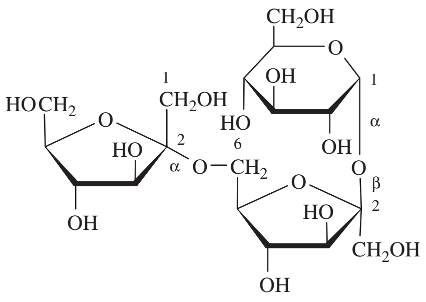
natural components of polysaccharides called fructosans (levans or phleines). The simplest substances of this type are trisaccharides 6-kestose (**4-119**), neokestose (**4-120**) and kelose (**4-121**). Trisaccharides 6-kestose and neokestose occur, for example, as minor components in molasses and invert sugar produced by acid hydrolysis of saccharose (inversion). The reaction by which these oligosaccharides are formed from lower saccharides is called **reversion**.



4-119, 6-kestose



4-120, neokestose



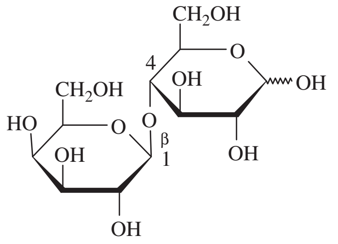
4-121, kelose

4.4.3 Galactooligosaccharides

4.4.3.1 Lactose

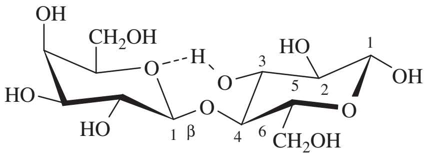
4.4.3.1.1 Structure and nomenclature

Lactose, *O*-β-D-galactopyranosyl-(1→4)-D-glucopyranose (**4-122**), is a reducing disaccharide present in mammalian milk, and therefore lactose is also referred to as milk sugar. The most stable form is α-lactose monohydrate (α-anomer). Lactose crystallises in this form from aqueous solutions at temperatures up to 93.5 °C. Drying of lactose in vacuum at temperatures above 100 °C yields hygroscopic α-anhydride. Crystallisation from aqueous solutions at temperatures above 93.5 °C gives anhydrous β-lactose (β-anhydride). An amorphous hygroscopic mixture composed of α- and β-lactose forms during rapid drying of lactose solutions and also during drying of milk.



4-122, lactose

The mutarotation rate of lactose (as with other carbohydrates) depends on pH. The minimum rate of lactose mutarotation is in solutions of pH 4–5. In solutions of pH <2 and pH >7, the mutarotation rate increases significantly. Conformation of lactose in aqueous solutions (**4-123**) resembles the conformation of cellobiose.



4-123, conformation of lactose in aqueous solutions

4.4.3.1.2 Occurrence and production

Lactose is only synthesised in the mammary glands of mammals. Cows' milk contains 4–5% of lactose, human milk 5.5–7% of lactose. In addition to lactose, milk contains smaller amounts of D-glucose and a wide variety of free oligosaccharides. Lactose is also present naturally in all milk-containing products (e.g. milk chocolates and ice creams). Its content in the products prepared using homofermentative lactic acid bacteria (such as yoghurt, acidophilic milk and kefir) is lower than in fresh milk, generally about 1% or less.

Lactose is obtained by ultrafiltration of the whey of cows' milk or by crystallisation from whey concentrated to 55–65% of solids, which is called lactose syrup. Raw sugar is purified by recrystallisation.

4.4.3.1.3 Physiology and nutrition

Lactose is used as an energy source as it is hydrolysed by lactase in the small intestine. A large part of the human population (as well as of other mammals) produces lactase only in childhood. In adulthood, a number of individuals have the enzyme activity reduced or completely absent, and consumption of milk is then problematic. Lactase is produced by lactic acid bacteria that break

down lactose into lactic acid (L- or D-lactic acid or racemate). Fermented milk products, such as yoghurt and acidophilic milk, therefore, can also be consumed by people with lactase deficiency. The relative sweetening power of lactose is about 40% (20–60%) of the sweetening power of saccharose. Intake of lactose (as well as galactose intake) leads to a significant increase in blood glucose level. Lactose has relatively low cariogenic and laxative effects.

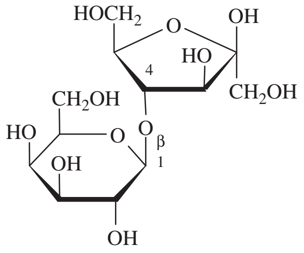
4.4.3.1.4 Use

Lactose is used as a sweet substance and also serves as a raw material for the production of oligosaccharides and some alditols:

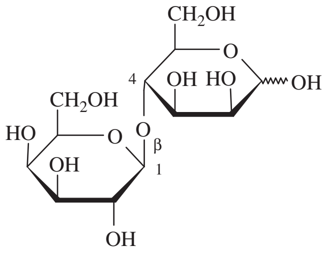
- lactulose
- lactosaccharose
- galactooligosaccharides
- lactitol
- galactose.

Lactulose

Lactulose (**4-124**) is obtained from lactose by isomerisation in alkaline solutions, where the main structure is β-pyranose followed by α-furanose and β-furanose. Epilactose is formed as a minor product (**4-125**). Lactulose is an indigestible disaccharide, which is somewhat sweeter than lactose (about 60% of sweetening power of sucrose) and has a weak laxative effect. It stimulates the growth of bifidogenic microflora.



4-124, lactulose



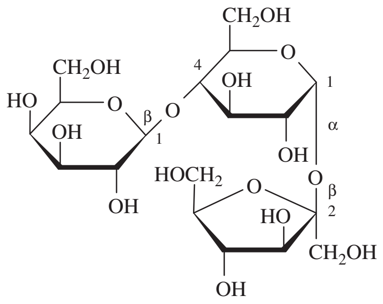
4-125, epilactose

Lactosaccharose

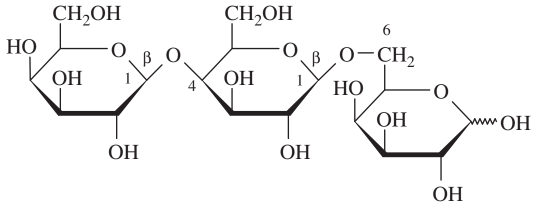
Lactosaccharose (**4-126**) is obtained from lactose and sucrose under the action of the transfructosylase activity of microbial β-fructofuranosidase.

Higher galactooligosaccharides

Galactooligosaccharides (also called transgalactooligosaccharides) are obtained from lactose using the galactosyltransferase activity of the enzyme β-galactosidase, which is reflected in solutions



4-126, lactosaccharose

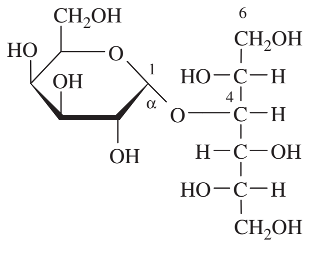


4-127, galactooligosaccharides

containing higher concentrations of lactose. These oligosaccharides contain 2–5 molecules of galactose (usually three molecules, so called galactotriose) joined by β-(1→6) bonds (**4-127**).

Lactitol

Lactitol, *O*-β-D-galactopyranosyl-(1→4)-D-glucitol (**4-128**) is an alcoholic sugar produced by hydrogenation of lactose at the reducing end. Hydrogenation of lactulose gives a mixture of lactitol and 4-*O*-β-D-galactopyranosyl-(1→4)-D-mannitol. Lactitol is currently used as a bulk sweetener in calorie-controlled foods. It has about 30–40% of sucrose sweetening power. As an indigestible and non-cariogenic compound with slight laxative properties, lactitol has no effects on blood glucose levels and insulin secretion.



4-128, lactitol

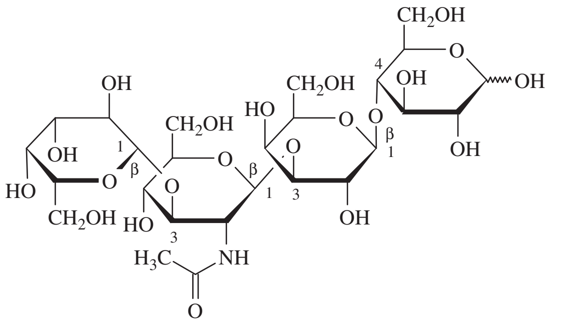
Galactose

Galactose can be obtained from vegetable raw materials containing galactans, but the most common source of galactose is lactose or protein-free whey. The process involves acid or enzymatic hydrolysis (by lactase) of galactans to an equimolar mixture of glucose and galactose. This mixture has about 40–60% of the sweetening power of saccharose. Galactose can be separated from

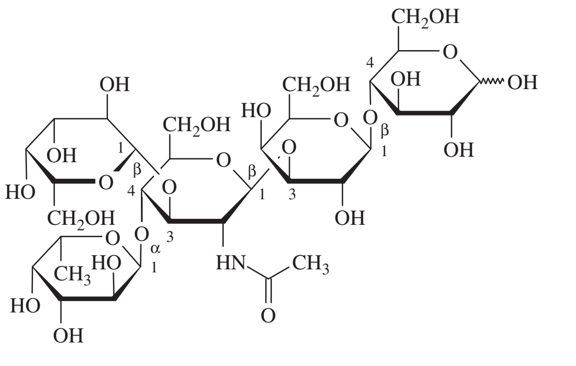
mixtures of galactose and glucose by selective fermentation of glucose to ethanol using various microorganisms or by glucose oxidase catalysed transformation of glucose to gluconic acid.

4.4.3.2 Other galactooligosaccharides

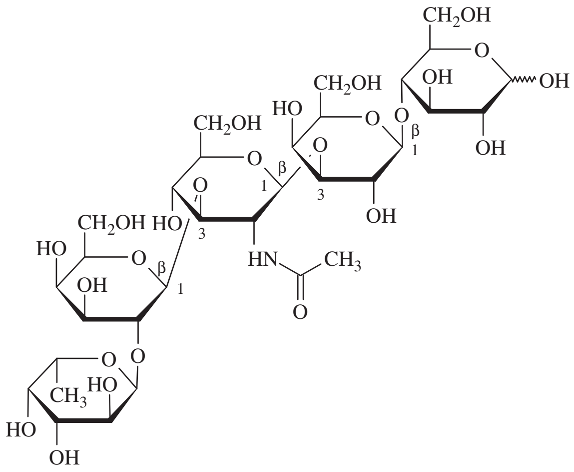
Breast milk and cows' milk contain, in addition to lactose, small amounts of mono- and oligosaccharides, such as D-glucose and D-galactose, *N*-acetyl-D-glucosamine, *N*-acetyl-D-galactosamine, L-fucose and *N*-acetylneuraminic acid (*N*-acetyllactaminic acid) and a number of oligosaccharides derived from lactose. More than 130 oligosaccharides have been identified in breast milk. Some of these, lacto-*N*-tetraose (**4-129**), lacto-*N*-fucopentaose I (**4-130**) and lacto-*N*-fucopentaose II (**4-131**), are present in relatively large amounts (at around 1–2 g/l). The total content of higher oligosaccharides in human milk is 3–6 g/l (Table 4.15). These amino sugars of milk are a growth factor for microorganisms *Bifidobacterium bifidum*. They effectively inhibit the adhesion of pathogenic bacteria on cell walls, which is regarded as the initial phase of an infectious process. Therefore, these oligosaccharides play a significant role in non-immunological protection of infants. Similar oligosaccharides composed of D-galactose, *N*-acetyl-D-galactosamine and *N*-acetylneuraminic acids are components of κ-casein. An overview of other important galactooligosaccharides found in foods in given in Table 4.16.



4-129, lacto-*N*-tetraose



4-130, lacto-*N*-fucopentaose I



4-131, lacto-*N*-fucopentaose II

Soybeans, other legumes and also other foods of plant origin contain α-galactooligosaccharides raffinose (**4-132**), stachyose (**4-133**), verbascose (**4-134**), ajugose (**4-135**) and higher homologues that do not have trivial names (see Table 4.17). The highest member of the α-galactooligosaccharide series is nonasaccharide. These oligosaccharides can be considered derivatives of saccharose or melibiose. They are accompanied by a series of cyclitols and galactocyclitols (Table 4.9). Table 4.17 shows the content of main α-galactoligosaccharides in legumes.

α-Galactooligosaccharides are not digested by saccharases in the small intestine, but stimulate the growth of bifidobacteria and can be utilised by other bacteria of the colon that produce α-D-galactosidase and metabolise these sugars to form gases (carbon dioxide, methane and hydrogen). α-Galactooligosaccharides are considered the main cause of bloating (flatulence) in the consumption of legumes. Enzymatic hydrolysis by α-D-galactosidase can reduce levels of these oligosaccharides. Use of this enzyme, which catalyses the hydrolysis of raffinose, can improve the yield of saccharose from sugar beet.

So-called soy whey, which is the waste from the production of soy protein isolates and concentrates, can be used for the isolation of a mixture of α-galactooligosaccharides, which contains saccharose, glucose and fructose. In the form of syrup, this mixture can be used as a proteinaceous food additive.

4.4.4 Other oligosaccharides

Hydrolysis of waste wheat flour containing arabinoxylans, using the enzyme *endo*-1,4-xylanase, yields xylooligosaccharides containing D-xylose molecules linked by β-(1→4) bonds. The degree of polymerisation of these oligosaccharides is $n = 2–9$. Enzymatic synthesis using D-mannose has been used for the preparation of mannooligosaccharides containing 2–8 mannose molecules linked by α-(1→6) bonds. Both types of oligosaccharides can be used as

Table 4.15 Main oligosaccharides of breast milk and cows' milk.

Oligosaccharide	Abbreviated notation[a]	Content (g/l)	
		Breast milk	Cows' milk

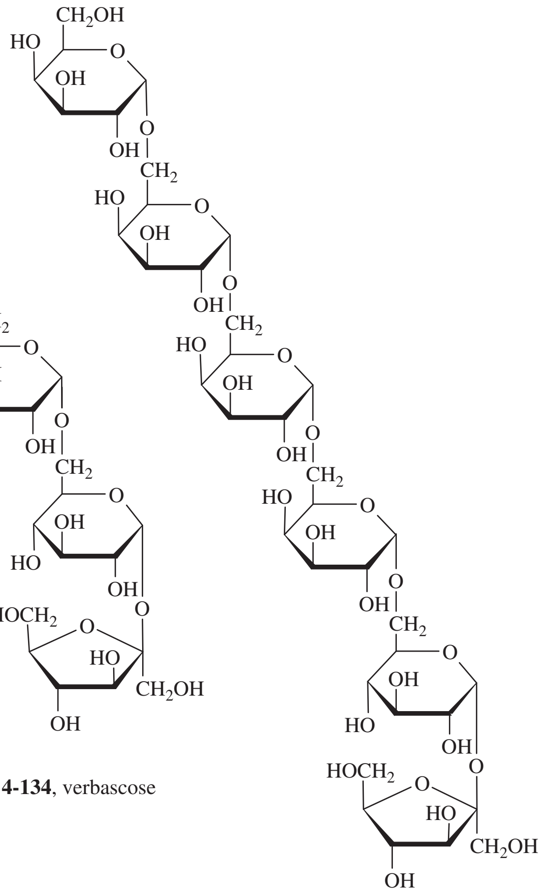
4-134, verbascose



4-135, ajugose

Table 4.17 Contents of major oligosaccharides in legume seeds (% of dry matter).

Legumes	Latin name	Saccharose	Raffinose	Stachyose	Verbascose
Common bean	*Phaseolus vulgaris*	2.2-4.9	0.3-1.1	3.5-5.6	0.1-0.3
Vigna mungo	*Vigna mungo*	1.3	0.3	1.7	2.8
Pea	*Pisum sativum*	2.3-3.5	0.6-1.0	1.9-2.7	2.5-3.1
Lentil	*Lens culinaris*	1.3-2.0	0.3-0.5	1.9-3.1	1.2-1.4
Soybean	*Glycine max*	2.8-7.7	0.2-1.8	0.02-4.8	0.1-1.8
Chickpea	*Cicer arietinum*	2.0-3.5	0.7-0.9	1.5-2.4	0.0

food additives because they possess similar physiological effects as other unavailable oligosaccharides.

4.5 Polysaccharides

4.5.1 Structure and nomenclature

Polysaccharides or glycans consist of more than ten monosaccharide units and can contain up to several thousands, hundreds of thousands or even around a million structural units linked to each other by glycosidic bonds.[3]

Polysaccharides are composed either of identical monomers (excluding terminal units) or more often of molecules of two or more different monosaccharides, or they contain monosaccharide

[3]The name polyglycose is not synonymous with the name glycan since polyglycose can be a polymer in which monosaccharides are also linked by means other than glycosidic bonds.

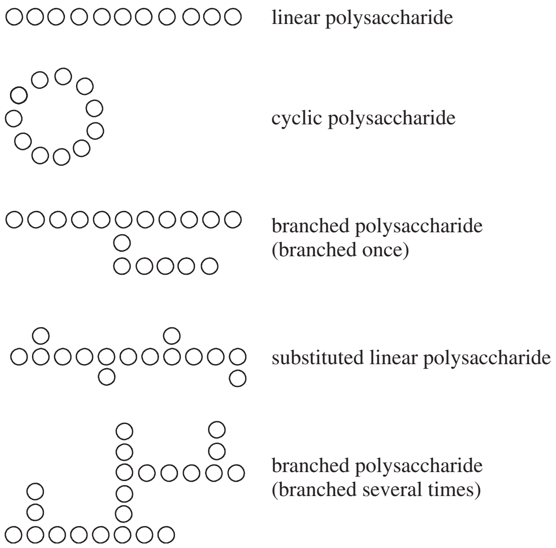


Figure 4.6 Structure of polysaccharide chains.

derivatives such as glycuronic acids, their esters and deoxysugars. It is therefore possible to distinguish:

- homopolysaccharides (homoglycans)
- heteropolysaccharides (heteroglycans).

Homoglycans are, for example, components of starch, amylose and amylopectin, glycogen and of cellulose, which are composed exclusively of D-glucose molecules. Most of the other polysaccharides are heteroglycans. Polysaccharide (and also oligosaccharide) chains (Figure 4.6) can be:

- linear (e.g. amylose and cellulose)
- cyclic (e.g. higher cyclodextrins).

Linear chains can be:

- unbranched (as in amylose and cellulose)
- branched (as in amylopectin).

The branched chains can be branched only once as in dextran, substituted as in guar gum or can be branched several times as in amylopectin.

Names of homoglycans are derived from the monosaccharide name by substitution of the ending -ose by the ending -an. Some older trivial names have changed, and coincide with today's terminology (e.g. caragenin or carrageenin or carrageenan); others are still in use (dextrin, pectin and inulin, and also starch and cellulose).

The building blocks of homopolysaccharides are mostly pentoses, hexoses and glycuronic (alduronic) acids. Their respective polymers are called:

- **pentosans**
- **hexosans**
- **glycuronans** (formerly also **polyuronides**).

The most common pentose bound in pentosans is D-xylose present in **xylans**. The most common building blocks of hexosans are D-glucose, D-mannose, D-galactose and D-fructose. Homopolysaccharides, termed **glucans**, are composed entirely of glucose units (amylose, amylopectin and cellulose). If glycosidic bonds link exclusively the α-anomers of a monomer, the glucans are called α-glucans (amylose). Cellulose is β-glucan or, more precisely, **β-(1→4)-glucan**. **Fructans** are composed exclusively from fructose units, **mannans** of mannose units and **galactans** of galactose units. Common components of many polysaccharides are alduronic acids, such as D-galacturonic acid in pectin and D-mannuronic and L-guluronic acids in alginates.

Names of heteroglycans having the main chain composed of a single type of monosaccharide, ends with the name of the homopolysaccharide forming the main chain. Other sugar residues present in side chains are shown in alphabetical order before the basic name. For example, pentosans include **arabinoxylans**, whose main chain consists of D-xylose units and the side chain contains L-arabinose. Sugars D-xylose and D-glucose occur in **xyloglucans**. Hexoses D-glucose, D-fructose, D-mannose and D-galactose are common constituents of heteropolysaccharides known as **glucofructans** (inulins and phleins) **glucomannans** (konjac gum) and **galactomannans** (guar gum). If the main polysaccharide chain is not homopolymeric, all monosaccharide residues contained in the chain are shown in alphabetical order. Examples of such heteropolysaccharides are **arabinoglucuronoxylans**. An overview of the main building blocks of major polysaccharides is presented in Table 4.18.

Polysaccharides mostly have the reducing monosaccharide residue at one end of the chain, but some may have the non-reducing residues on both ends. Linear homopolysaccharide amylase has monosaccharide non-reducing residue at the beginning of the chain, and the end of the chain unit consists of a reducing unit with a hemiacetal hydroxyl group. Branched polysaccharides, such as amylopectin, have one reducing unit and $n + 1$ non-reducing units at the beginning of each of the n molecule chain branches.

The **primary structure** of a polysaccharide (monosaccharide sequences) is regular in homoglycans (such as amylose and cellulose) and in some heteroglycans (arabinoxylans). The individual monosaccharides are also regularly alternating in a number of heteroglycans (carrageenan), or the regular structure is disrupted and the order of monomers varies (e.g. in pectin) in certain chain sections.

The type of monosaccharide units, their conformation and type of linkages affect the conformation of macromolecules, the so-called glycan **secondary structure**. Linear macromolecules, such as cellulose, are often stabilised by hydrogen bonds between hydroxyl groups of one molecule of glucose and oxygen atoms of the second pyranose ring. Another type of conformations are known as egg

Table 4.18 Main building monosaccharide units of important polysaccharides.

Monosaccharide	Abbreviated notation	Polysaccharides
α-L-Arabinofuranose	α-L-Ara*f*	Plant gums (arabic, larch, ghatti), pectins, arabinoxylans
β-L-Arabinopyranose	β-L-Ara*p*	Plant gums (arabic, larch, ghatti), pectins, arabinoxylans
α-D-Xylopyranose	α-D-Xyl*p*	Arabinoxylans, xyloglucans
β-D-Xylopyranose	β-D-Xyl*p*	Tragacanth
α-L-Rhamnopyranose	α-L-Rha*p*	Pectins, plant gums (arabic, karaya), okra, gellan gum
α-L-Fucopyranose	α-L-Fuc*p*	Xyloglucans, pectins, tragacanth
α-D-Glucopyranose	α-D-Glc*p*	Starches, modified starches and their derivatives, starch hydrolysates, glycogen, dextran, elsin, pullulan
β-D-Glucopyranose	β-D-Glc*p*	Cellulose, modified celluloses, xyloglucans, glucomannans, β-glucans with mixed linkages, xanthan, gellan gum, curdlan, scleroglucan
β-D-Glucopyranuronic acid	β-D-Glc*p*A	Pectins, plant gums (arabic, karaya, ghatti)
α-D-Mannopyranose	α-D-Man*p*	Xanthan, plant gums (ghatti)
β-D-Mannopyranose	β-D-Man*p*	Galactomannans, glucomannans, xanthan
β-D-Mannopyranuronic acid	β-D-Man*p*A	Alginates
α-L-Gulopyranuronic acid	α-L-Gul*p*A	Alginates
α-D-Galactopyranose	α-D-Gal*p*	Galactomannans, pectins, plant gums (arabic, karaya), okra
β-D-Galactopyranose	β-D-Gal*p*	Xyloglucans, pectins, plant gums (arabic, larch, ghatti, tragacanth), agar, carrageenans
α-D-Galactopyranuronic acid	α-D-Gal*p*A	Pectin, plant gums (tragacanth), okra
3,6-Anhydro-α-D-galactopyranose	α-D-Gal*p*3,6An	Carrageenans
3,6-Anhydro-α-L-galactopyranose	α-L-Gal*p*3,6An	Agar
β-D-Fructofuranose	β-D-Fru*f*	Glucofructans and fructans (inulins and phleins)

box conformations, which have hydrogen bonds between hydroxyl groups of monomers and calcium cations (in pectins), or ionic bonds between dissociated carboxyl groups and calcium ions (e.g. alginates). For some polysaccharides, helical conformations are typical (e.g. in carrageenans).

The combinations of secondary structures form **tertiary structures**, such as crystalline microfibrils in cellulose or double and triple helices in κ-carrageenan.

Polysaccharides are polydisperse substances, as they occur as mixtures of polymers with different degrees of polymerisation, and thus have an average molecular weight.

4.5.2 Classification

Polysaccharides are commonly divided according to their origin. Natural **polysaccharides of plants** have the greatest importance in human nutrition, while **polysaccharides of animals** and other natural polysaccharides have little or no importance. Many polysaccharides of plants (guar gum or locust bean gum), seaweed (such as agar, carrageenans and alginates) and microorganisms (e.g. xanthan gum) are becoming part of many foods as additives in natural or modified forms (modified starches and celluloses and modified chitin called chitosan).

According to the basic functions that are executed in the tissues of animals, tissues and cells of plants, algae, higher fungi and microorganisms, polysaccharides are divided into:

- **storage** or **reserve polysaccharides**
- **structural polysaccharides**
- **polysaccharides with other functions**.

The storage polysaccharide in animals is glycogen. Structural functions are carried out by chitin, forming the exoskeletons of crustaceans, molluscs and insects, and mucopolysaccharides occurring in proteoglycans of connective tissues.

Plant storage polysaccharides in seeds, tubers, rhizomes, bulbs and roots are:

- **starches** formerly also known as amyloids (e.g. in cereals, legumes and potato tubers)

- **non-starch polysaccharides**, which include glucofructans and fructans (chicory root and cereal seeds), galactomannans that are known as seed gums (storage polysaccharides of some legumes, such as guar gum and locust bean gum), glucomannans (konjak tubers) and xyloglucans (e.g. rape and tamarind seeds).

Functioning as building materials in the walls of plant cells are:

- **cellulose**

- **non-cellulose polysaccharides** associated with cellulose.

The non-cellulose polysaccharides include:

- **hemicelluloses** (xyloglucans in fruits, most vegetables, root crops and legumes, arabinoxylans and β-glucans in cereals and galactomannans in some legumes)

- **pectins** (in fruits and vegetables).

The polymer of phenylpropanoid units is **lignin**, which is not composed of saccharide units, but is associated with cellulose as well as with structural non-cellulose polysaccharides, is also a structural material of plant cell walls. Lignin is accompanied by other phenolic compounds (tannins), proteins and polymers of lipids.

Other plant polysaccharides seem to have different functions related to water management and protection of damaged tissues. These polysaccharides include:

- **plant exudates** or **gums** of some plants (such as gum arabic and tragacanth)

- **mucilages** (e.g. okra).

Some structural polysaccharides from algae are used for consumption as food additives, especially agar, carrageenans and alginates. Some extracellular polysaccharides of microorganisms also have significance as food additives (such as xanthan gum). They have functions other than structural and reserve. Some extracellular and structural polysaccharides of microorganisms and higher fungi, such as β-glucans with a different structure to that of β-glucans of cereals, have found use as immunomodulators and anticarcinogenic substances.

4.5.3 Natural occurrence in foods

Pectin is the dominant polysaccharide in fruits, which also contain (in smaller amounts) some other polysaccharides, cellulose and hemicelluloses (the predominant components are xyloglucans) and lignin. Starch is only found in immature fruits (e.g. about 2.5% in immature apples) and its content decreases during ripening, and is virtually absent in ripe fruits. The exceptions are bananas, which even at full maturity contain at least 3% starch by weight and about 1% glucofructans (fructans).

Table 4.19 Content of main polysaccharides and lignin in wheat flour.

Polymer	Content (%)	Polymer	Content (%)
Starch	60–80	β-Glucans	0.5–2
Nonstarch polysaccharides	3–11	Xyloglucans	0.2–0.4
Cellulose	0.2–3	Pectins	0.3–0.5
Hemicelluloses	2–7	Glucofructans (fructans)	1–4
Arabinoxylans	1–3	***Lignin***	0.7–12

Starch is the predominant polysaccharide of root vegetables and root crops (potatoes). Unlike fruits, its content increases during ripening and a higher content of starch is found in over-ripe vegetables. In dicotyledonous (dicot) vegetable plants of the aster family (Asteraceae), such as black root, artichokes (grown mainly for the inflorescences, which are consumed fresh or preserved), Jerusalem artichokes (tubers) and in bulbs of monocotyledonous (monocot) plants of the lily family (Liliaceae), such as garlic and onion, the main reserve carbohydrates are glucofructans (fructans). Cellulose, hemicelluloses (predominantly xyloglucans), pectins and lignin are important components of most vegetables.

Starch is also the major polysaccharide in all cereals. Of the non-starch polysaccharides, the predominant ones are hemicelluloses, whose main components in wheat and rye are arabinoxylans and in oat and barley so called β-glucans. Also found in significant quantities are glucofructans (fructans), xyloglucans, cellulose and lignin, which is mainly present in the bran. The main polysaccharides contents of wheat flour are given in Table 4.19. The content of polysaccharides varies widely, particularly since it depends on the degree of milling (known as flour extraction rate; the highly straight run flours are higher in non-starch polysaccharides) and other factors. Endosperm represents about 83% of grain by weight, bran 15% and germ 2%. The starch content in the bran is about 15%, but the cellulose content is about 35% and the content of hemicelluloses reaches 40–50%.

4.5.4 Physiology and nutrition

From the nutritional point of view the following are recognised:

- **utilisable polysaccharides**

- **non-utilisable polysaccharides** (formerly known as ballast polysaccharides), since the enzyme machinery for their digestion in humans and other monogastric animals is lacking and they are not cleaved by saliva, the pancreas or small intestine saccharases.

Table 4.20 Fibre composition of fruits, vegetables and cereals (in %).

Fibre source	Noncellulose polysaccharides		Cellulose		Lignin	
	Range	Average	Range	Average	Range	Average
Fruits	46–78	62.9	9–33	19.7	1–38	17.4
Vegetables	52–76	65.6	23–42	31.5	0–13	3.0
Cereals	71–82	75.7	12–22	17.4	0–15	6.7

Utilisable plant polysaccharides are starches (the main source of energy) and animal glycogen. Non-cellulose polysaccharides include hemicelluloses and pectin, as well as polysaccharides used as food additives (seaweed polysaccharides, microbial polysaccharides, vegetable gums and mucilages, modified polysaccharides) and lignin and chitin of animal polysaccharides (and modified chitin, or chitosan). Some non-cellulose polysaccharides, such as pectin, can be relatively easily utilised (see Table 4.22 later), but these substances are known by the widespread and accepted term **fibre** or **dietary fibre**, although the name is misleading, inaccurate and poorly definable. Some older definitions included plant polysaccharides (except starch) and lignin under the term dietary fibre, which are materials resistant to hydrolysis by human digestive juices. Other definitions included all undigested and unabsorbed food components, including undigested proteins, minerals and phytates, and possibly also endogenously excreted mucopolysaccharides. The EU definition of dietary fibre describes carbohydrate polymers with three or more monomeric units, which are neither digested nor absorbed in the human small intestine and belong to the following categories:

- edible carbohydrate polymers naturally occurring in the food as consumed;
- edible carbohydrate polymers that have been obtained from food raw material by physical, enzymatic, or chemical means, which have a beneficial physiological effect demonstrated by generally accepted scientific evidence;
- edible synthetic carbohydrate polymers, which have a beneficial physiological effect demonstrated by generally accepted scientific evidence.

The current definition of dietary fibre is based on the chemical composition of polysaccharides and includes all non-utilisable carbohydrates, including polysaccharides and oligosaccharides used as food additives (e.g. plant gums and mucilages, algal and microbial polysaccharides and modified starches, celluloses and chitosan). Regarding lignin, it is stated that the carbohydrate polymers of plant origin that meet the definition of fibre may be closely associated in the plant with lignin or other non-carbohydrate components such as phenolic compounds, waxes, saponins, phytates, cutin and phytosterols. The definitions do not take into account the fact that fibre is not a static concept, as it does not pass through the digestive system completely intact. A substantial component of dietary fibre (due to the amount consumed) is a certain percentage of not-completely-degraded starch known as **resistant starch**. The gross composition of the dietary fibre of fruits, vegetables and cereals is presented in Table 4.20.

According to the solubility in water, the following two categories are recognised:

- **soluble dietary fibre**
- **insoluble dietary fibre**.

Soluble dietary fibre includes a certain proportion of hemicelluloses. For example, about one third of cereal structural arabinoxylans are soluble. Also, one quarter to about one half of barley β-glucans are soluble, and even a certain proportion of glucomannans and galactomannans of legumes are soluble. Other soluble polysaccharides are pectins, plant mucilages, seaweed polysaccharides, modified starches and modified celluloses (Table 4.21).

The main components of insoluble fibre include cellulose, a certain proportion of hemicelluloses and lignin. Higher lignin content is found in the bran and seeds of consumed fruits, such as garden strawberries, raspberries and currants. Insoluble fibre increases the volume of food, reduces the time of its passage through the digestive tract and increases peristalsis. Soluble fibre increases the viscosity of the contents of the stomach and intestines, slows down the mixing of their content and limits the access of pancreatic amylase and lipase to substrates. As a result, the nutrient absorption by the intestinal wall slows down; slower passage of the intestinal contents reduces the diffusion of bound nutrients and minerals (especially calcium, iron, copper and zinc ions), and thus their availability is modified. Part of the bound ions are released during fermentation in the colon. Accompanying tannins also partially inhibit digestive enzymes.

Dietary fibre is a beneficial material for constipation, gastric and duodenal ulcers, haemorrhoids, rectum and colon (colorectal) cancer, commonly known as bowel cancer, and other diseases. Eating foods high in fibre is recommended for the modulation of glucose levels in blood serum and in some forms of diabetes (especially type 2 diabetes). This also has the effect of reducing serum cholesterol level, and can thus help to prevent cardiovascular diseases. The effect is explained by the reduced absorption of cholesterol from viscous foods and by cholesterol binding to fibre,

Table 4.21 Proportion of soluble and insoluble dietary fibre in selected foods.

	Dietary fibre (% of dry matter)				Dietary fibre (% of dry matter)		
Food	**Soluble**	**Insoluble**	**Total**	**Food**	**Soluble**	**Insoluble**	**Total**
Fruits				***Legumes***			
Apples	5.6–5.8	7.2–7.5	12.8–13.3	Beans	7.2–12.4	9.1–9.6	16.8–21.5
Peaches	4.1–7.1	3.4–6.4	7.5–13.5	***Potatoes***			
Strawberries	5.1–7.7	6.8–10.6	11.9–18.3	Raw	2.8–3.5	2.4–3.2	5.2–6.7
Oranges	6.5–9.8	3.9–5.2	10.4–15.0	Boiled	4.8	2.6	2.2
Vegetables				***Cereals***			
Carrot	4.4–14.9	10.4–11.1	14.8–26.0	Wheat flour (white)	2.0	1.2	3.2
Cabbage	13.5–16.6	4.2–20.8	27.6–37.4	Wheat flour (whole)	2.6	7.7	10.3
Tomatoes	0.8–3.5	3.2–12.8	6.7–13.6	Wheat bread	1.6–2.7	1.1–2.9	2.7–5.6
Peas	5.9	15.0	20.9	Rye bread	6.7	6.6	13.3

which results in increased excretion of cholesterol in the faeces. Bile acids are also bound to dietary fibre and excreted. The result is a decrease of bile acid reserves in the liver. This deficit of bile acids has to be compensated by biosynthesis from cholesterol, which reduces the cholesterol concentration in the blood plasma. Cholesterol synthesis in the liver is also inhibited by lower fatty acids being formed during fibre fermentation by intestinal microflora.

Soluble fibre is partially hydrolysed by digestive enzymes already in the small intestine. Insoluble fibre is not hydrolysed in the small intestine, and along with soluble fibre is partly metabolised only by colon and appendix microorganisms (e.g. xanthan gum is not metabolised at all). Colon and appendix microorganisms assimilate on average 70% of dietary fibre polysaccharides (Table 4.22). The final products are gases (carbon dioxide and hydrogen, often methane) and lower fatty acids (acetic, propionic and butyric acids). The amount of energy obtained in the form of these acids is around 3 kJ/g carbohydrate (compared with about 17 kJ/g obtained from starch). It is estimated that the consumption of 20–30 g of dietary fibre (the Recommended Daily Allowance of dietary fibre is >25 g per day in Europe) contributes to the total energy intake in the range of 0.5 to 1%; the rest is covered by the main nutrients. The ratio of insoluble and soluble fibre in the diet should be 3 : 1.

Table 4.22 Utilisation of soluble fibre components.

Polysaccharide	Utilisation (%)	Polysaccharide	Utilisation (%)
Hemicelluloses	19–85	Karaja gum	5
Pectins	65–97	Agar	21–28
Guar gum	76	Carrageenans	9–16
Locust gum	<15	Alginates	0–78
Gum arabic	71	Dextran	78–90

4.5.5 Properties and use

Polysaccharides in foods contribute to the formation of texture and also affect other organoleptic properties. Soluble polysaccharides are used in many food industry sectors and other fields as fillers, thickeners, to increase the viscosity of products, act as stabilisers of dispersions and some are thickening agents and gelling substances.

The importance of polysaccharides has increased with the development of new technologies and of products with reduced fat and saccharose contents. Previously the market was dominated by native starch, but its consumption is declining and consumption of modified starches is significantly increasing. Important substances are modified celluloses, plant gums and polysaccharides of seaweeds and microorganisms. At the forefront of world consumption of non-starch polysaccharides are plant seed gums (guar gum and locust gum), followed by carrageenan, agar, gum arabic, pectins, alginates, modified celluloses (carboxymethyl cellulose) and xanthan gum. There have also been major increases in the sale of food supplements containing natural soluble fibre, which occurs mainly in the form of arabinoxylans (such as psyllium dietary fibre supplements),[4] modified fructans and chitosan.

4.5.6 Plant polysaccharides

4.5.6.1 Starch

Starch is the main plant storage polysaccharide, which serves as a prompt supply of energy. Unlike structural polysaccharides, which are part of the plant cell walls, starch is found in organelles

[4] *Psyllium* is the common name used for several members of plantains that belong to the genus *Plantago* (Plantaginaceae). For example, sand plantain (*P. psyllium*) is grown for seeds known as black, French or Spanish psyllium.

Table 4.23 Basic characteristics of starch granules.[a]

Source	Diameter (μm)	Mean value (μm)	Source	Diameter (μm)	Mean value (μm)
Wheat	4-6; 15-25	15	Potatoes	38-50	33
Barley	3-5; 19-25	15	Cassava	6-36	20
Rice	3-9; 15-30	5	Amaranth	1.07-1.10	1.1

[a]Cereal starches have bimodal distribution of granules. Large granules (A type granules) have a lens shape and diameter of about 20 μm, small granules (B type granules) are spherical particles with a diameter of about 5 μm.

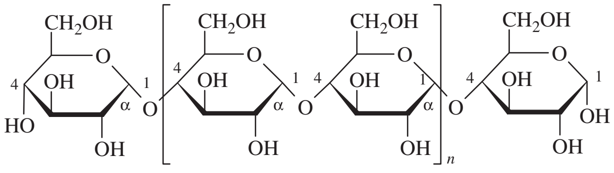
of cytoplasm called plastids, where its biosynthesis takes place. Chloroplasts of the specialised photosynthetic tissues produce so-called **transient starch** during the day, which serves as a temporary sugar reserve. Storing of glucose obtained by photosynthesis in the form of starch strongly reduces high intracellular osmotic pressures, to which cells would otherwise be exposed. All transient starch granules synthesised during the day undergo nocturnal breakdown and serve as a major source for saccharose synthesis at night that is needed for metabolism in the whole plant. Saccharose is then transported to the storage organs of plants, such as seeds, fruits, tubers and roots, where the specialised leucoplasts, known as amyloplasts,[5] synthesise and store the so-called **reserve starch**. This starch is stored in insoluble micelles called **starch granules** or starch grains that have species-specific shapes (e.g. round and oval) and dimensions (Table 4.23).

4.5.6.1.1 Structure

The majority of native starches are mixtures of **amylose** and **amylopectin**, two homopolysaccharides composed of α-D-glucopyranose molecules in $^4C_1$ conformation. Amylose and amylopectin usually occur in a weight ratio of 1 : 3. In some varieties of cereals (maize, barley and rice) and other plants (potatoes), either amylose (starches of high amylose content or amylostarches) or amylopectin (starches high in amylopectin or waxy starches) predominate.

Amylose

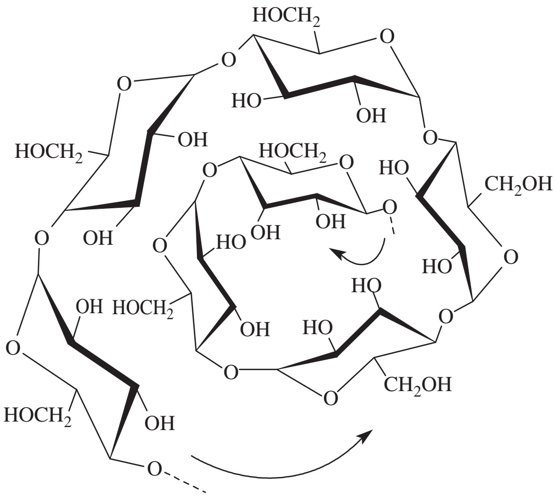
Amylose is a linear α-D-(1→4)-glucan (**4-136**), and, therefore, is actually a polymer of the disaccharide maltose. To a limited extent, branching occurs at about ten sites of the molecule. Amylose is partially esterified with phosphoric acid (wheat starch contains 0.055% and potato starch 0.07–0.09% of phosphorus) and in cereal starches forms complexes with lipids. An amylose molecule has one reducing monosaccharide residue.



α-D-Glc*p*-(1→4)-[α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→4)$_n$-α-D-Glc*p*

4-136, amylose

Owing to the prevailing bonds 1 (axial) → 4 (equatorial), the amylose molecule can be randomly coiled in water and in neutral solutions, but generally tends to wind up into a rather stiff left-handed single helix or forms even stiffer parallel left-handed double helical junction zones (**4-137**). Single helical amylose has hydrogen-bonded O-2 and O-6 atoms. In alkaline solutions, globular structures dominate. As with each polysaccharide, amylose is a mixture of polymers with different degrees of polymerisation. The average content of glucose units is 1000–2000 (in cereal starches), but also up to around 4500 (in potato starch). The molecular weight of amylose ranges between 180 and1000 kDa.



4-137, helical section of amylose molecule

Amylopectin

An amylopectin molecule (**4-138**) consists of chains of D-glucose units linked by α-(1→4) linkages (maltose polymer), which is branched after 10 to 100 (average of 25) units by non-random α-(1→6) side chains (building unit is isomaltose). Occasionally there may also be an α-(1→3) bond (building unit of this biose is laminaribiose). One of about 400 glucose residues is esterified with phosphoric acid.

The degree of polymerisation is 50 000–1 000 000, thus the molecular weight varies between 10 and 200 MDa. Amylopectin macromolecule is a many times branched structure consisting of three types of chains: outer chain A, inner chain B and main chain C. About 5% of glucose molecules form the branch points. The inner and outer short side chains are called S chains and internal

[5]Specialised amyloplasts that are heavier than the cytoplasm are statolites, located in cells at the tips of roots. They are used to register the direction of Earth's gravity by plants.

long chains are L chains in modern terminology. The amylopectin molecule has one reducing end in the main chain (Figure 4.7).

Starch granules

The ultrastructure of starch granules varies depending on the plant source, but they have a common general model (Figure 4.8). The amylopectin molecules are oriented radially (from the centre to the edge) in the starch granule. The non-reducing amylopectin ends are situated outside the granules and form their surface. In areas of non-reducing ends and in the central parts of the chains (corresponding to the length of about 15 glucose units) antiparallel double helices with an ordered (crystalline) three-dimensional structure are formed. The presence of amylose in starch tends to reduce the crystallinity of the amylopectin, and influences the ease of water penetration into the granules. In

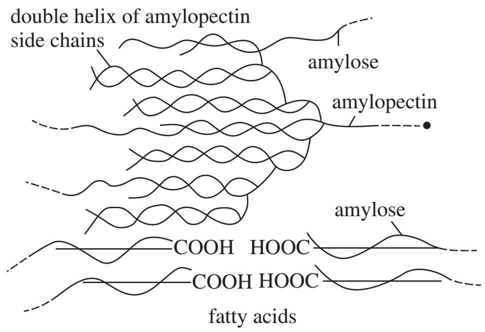

Figure 4.8 Arrangement of starch grain components. Stephen 1995, fig 2.3. Reproduced by permission of Taylor & Francis – Marcel Dekker.

areas of chain branching, amylopectin and the accompanying amylose have an unordered amorphous structure. Crystalline and amorphous regions alternate regularly. Depending on the degree of crystallinity of the granules (related to the structure and chirality of double helices of amylopectin side chains in crystalline regions of granules), four polymorphic forms of starch have been identified. They are labelled A, B, C and V. The most stable form, A, is found in cereal starches with the exception of starches with high content of amylose. A double spiral creates a central channel that is filled by another double helix and in the space between the double helices is bound water (tighter than in form B). The least stable form is form B, where the central channel double helix is only filled by water molecules. This form occurs in starches of root vegetables, potatoes and starches of cereals with high amylose content (>40%). Form C is present in legumes (it can be a combination of forms A and B). Retrogradation in gelatinised starches with amorphous structure first forms the less stable form B that is subsequently transformed into form C, which is transformed into the most stable form A. Form V occurs in gelatinised starch containing lipids, in which amylose interacts with fatty acids.

The amylopectin molecules are associated with amylose molecules that form in certain parts of the molecule of left-handed helices, oriented with non-reducing ends to the surface of the granules. They are located mainly in the amorphous zones, together with radially oriented lipid molecules whose fatty acids are immersed in helical parts of amylose molecules. These interactions create non-stoichiometric complexes called inclusion compounds. An integral part of the granules are also small amounts of proteins with relative molecular weights of 5–97 kDa. For example, the hardness of the endosperm of cereals is attributed to the protein friabilin (15 kDa). Proteins are found mainly in the surface layers of granules (Table 4.24).

4.5.6.1.2 Occurrence and production

The starch content and its composition (amylose content) in some foods is given in Table 4.25, amylopectin content is the difference to make up the 100%. The main sources of starch in foods and industrial sources of starch are potatoes (*Solanum tuberosum*, Solanaceae) and cereals, especially wheat (*Triticum aestivum*, Poaceae), rye (*Secale cereale*), barley (*Hordeum vulgare*), oats

Table 4.24 Content of lipids and proteins in starches.

	Content (%)			Content (%)	
Starch	Lipids	Proteins	Starch	Lipids	Proteins
Wheat	0.38–0.72[a]	0.3	Peas	0.1	0.7
Maize	0.02–1.09	0.3	Potatoes	0.05	0.06
Beans	0.1	0.9	Cassava	0.1	0.1

[a]Lipids in starch form 25% of total flour lipids; the main components are lysophospholipids.

Table 4.25 Content of starch and its composition in important sources.

Source	Starch (%)	Amylose (%)
Amaranth	48–69	0–22
Barley[a]	52–62	38–44
Beans[b]	46–54	24–33
Cassava	28–35	17–19
Maize	65–75	24–26
Oats	40–56	25–29
Potatoes[c]	17–24	20–23
Rice	70–80	8–37
Rye	52–57	24–30
Sweet potatoes	10–30	19–25
Wheat	59–72	24–29

[a]Waxy barley contains 2–8% amylose, waxy maize about 1%, and barley amylostarch and maize amylostarch 60–70%.
[b]Lentils and ripe seeds of peas have similar levels of starch and amylose as beans. Green peas have about 4% starch, soybeans contain less than 1% starch.
[c]Developed potato varieties have the starch content at the upper limit of that range.

(*Avena sativa*), maize (*Zea mays*) and rice (*Oryza sativa*) and also new pseudocereals, such as amaranth (*Amaranthus hypochondriacus*). Important sources of starch are also ripe seeds of legumes, such as pea (*Pisum sativum*, Fabaceae), various types of beans (*Phaseolus* spp.) and lentils (*Lens culinaris*). The starch content of cereal grains ranges from 40 to 90% of dry matter, legumes contain 30–70% of starch and plant tubers starch content is 65–85%. An important source of starch in many countries is sweet potato (*Ipomoea batatas*, Convolvulaceae), the Jerusalem artichoke, also called topinambours (*Heliantus tuberosus*, Asteraceae) and tubers of *Manihot esculenta* (Euphorbiaceae), an important source of food carbohydrates in the Tropics, known in Asia and Africa by the name cassava and in South America as manioc, yucca or tapioca. Another source of starch is sago (sago palm) obtained from the spongy pith of stems of various tropical palms, especially true sago palm (*Metroxylon sagu*, Arecaceae). The sago cycad (often also called sago palm) is obtained from the pitch of *Cycas revoluta* (Cycadaceae).

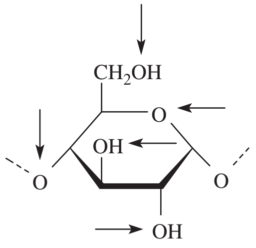
Ripe fruit, with some exceptions, does not contain starch. Bananas (*Musa* sp.) contain a small amount of starch, followed by sweet chestnuts, also known as marrons (*Castanea sativa*, Fagaceae) and various nuts. A higher starch content is found in the seed of the cashew tree (*Anacardium occidentale*, Anacardiaceae), commonly called cashew nuts.

Production of starch is relatively simple. Starch granules occurring in amyloplasts are not chemically or physically bound to other components of raw materials. Their density is high (around 1600 kg/m^3); therefore pure starch can be separated from the crushed material by either washing or decantation on sieves or by centrifugation.

4.5.6.1.3 Properties and changes

Gelatinisation

At ambient relative humidity, starch granules take about 0.2 g of water per 1 g of dry starch from the atmosphere and contain about 17% water (wheat starch is about 13% water and potato starch 18–22% water), without changing the volume of the grains. The process is called imbibition (see Section 7.8.3.1). One molecule of glucose binds 1.5 water molecules. The structural units of glucans contain a total of five oxygen atoms that can interact with water (**4-139**).



4-139, interaction of glucose unit with water molecules

Starch granules are insoluble in cold water and form a suspension. In cold water, the suspension of undamaged starch granules may absorb a small amount of water. Relatively large amounts of water are absorbed during heating without disturbing the integrity of the granules. Up to a certain temperature, called the initial **gelatinisation temperature** (T_o) at which swelling of granules occurs, it is a reversible process. The final gelatinisation temperature, when the gelatinisation process ends (T_e), the gelatinisation temperature range $T = T_e - T_o$ and the energy necessary to complete the process (gelatinisation enthalpy H_p) are also important starch characteristics. The initial gelatinisation temperature is generally 50–70 °C (Table 4.26) and depends on the starch origin, the ratio between starch and water, pH and the presence of other components (salts, sugars, lipids and proteins). The gelatinisation temperature range is usually 10–15 °C. It refers to the temperature range over which all the granules are fully swollen.

Table 4.26 Gelatinisation temperatures of selected starches.

Starch source	Gelatinisation temperature (°C)			Starch source	Gelatinisation temperature (°C)		
	Initial	Medium	Final		Initial	Medium	Final
Wheat	52	58	64	Rice	66	72	78
Maize	62	67	72	Potatoes	50	60	68
Waxy maize	63	68	72	Cassava	61	66	71

The changes to swollen starch granules in the process of gelatinisation are irreversible. Thermal motion of molecules interrupts the existing hydrogen bonds; water molecules penetrate the amorphous regions of granules and interact with free binding sites of the polymers. Hydrated polymer chains move away from each other, revealing new binding sites, which also interact with water; double helices of the side chains of amylopectin break down, which leads to the disappearance of crystalline zones, and the whole structure becomes disorganised and amorphous. Granules swell intensely and their volume increases. For example, the size of wheat starch granules at this stage can be up to 30 μm (Table 4.23).

Upon further heating, some amylose and amylopectin molecules (originally located in the granule in the radial direction) reach the surface. Linear amylose molecules (less bulky than amylopectin molecules) penetrate this tangentially located sieve of molecules and are released into the extragranular environment (partly also broken down into shorter molecules), where they are fully hydrated. A small proportion of amylopectin molecules are also released to the extragranular environment.

As a consequence of hydration at elevated temperatures (e.g. at 70 °C), granules absorb water of about 25 times their weight. For example, 1 g of dry potato starch can take up a volume of about 200 ml after swelling. The release of amylose from the granules increases the viscosity and at sufficient concentration (roughly in a 1% suspension), starch yields viscous **starch paste**. It contains collapsed starch grains, but magnified many times. They contain mainly molecules of amylopectin and any remaining molecules of amylose (e.g. wheat starch contains about 8% of the original amount of amylose after heating to 90 °C). The branched amylopectin molecules give viscosity to the cooked paste. Their side chains and bulky shape keep them close enough to bond together.

Additional heating results in decreased viscosity and further loss of integrity of granules. Viscosity gradually increases again when the solution is chilled because of renewing hydrogen bonds between the macromolecules of amylose and amylopectin, and continuous chilling makes the solution cloudy. Left to stand, the solution becomes white and in cases where there is a higher concentration of starch, it gels. The **starch gel** is a solid three-dimensional network that captures a large amount of water. Less concentrated starch suspensions form a viscous paste or viscous colloidal solution (Table 4.27). Starch gel is a complex system of gelatinised granules located in the matrix formed by amylose that does not contribute significantly to viscosity, but they contribute to the gel formation as the linear chains can orient parallel to each other, moving close enough together to bond. Amylose forms a gel at room temperature at concentrations higher than 0.9–1.0%. Amylose gels are thermally stable even at a temperature of 120 °C. Amylopectin molecules do not usually contribute to gel formation. Amylopectin forms gels only at concentrations higher than 10% and temperatures lower than 5 °C. The gel formation is slow and the formed gels are thermoreversible (they melt when heated to 40–60 °C), like starch gels.

The rheological properties of starch gels depend on the origin of the starch, the degree of granule degradation, the ratio between the interacting polysaccharides (amylose and amylopectin), temperature, the amount of water present and the type and amounts of other compounds. Cereal starches, for example, generally form turbid, opalescent gels. Gels formed from amylose starches are formed faster and at higher temperatures than gels from waxy cereal varieties. They are stronger and their strength increases with starch concentration, but they quickly undergo retrogradation and loss of water binding capacity caused by recrystallisation of amylose through cooling. Starches from waxy varieties of cereals, where amylopectin predominates, form gels with difficulty and only after cooling to low temperatures. These gels are clear, soft and often have a paste-like consistency. The linear segments of amylopectin also have a tendency to associate over time. Prolonged storage at low temperatures causes retrogradation, as in amylose gels. Clear and moderately firm gels are formed from potato starch. The viscosities of diluted dispersions of major polysaccharides and starch are compared in Table 4.27.

Retrogradation

Gelatinised starch is not in thermodynamic equilibrium, therefore the structure and rheological properties of starch gels, pastes and diluted dispersions change after several hours of storage. Intermolecular associations by hydrogen bonds between aligned chains of amylase lead to a loss of sites that bind water molecules, hence water binding capacity decreases. Gels and concentrated pastes get a rubbery texture and higher strength, dilute dispersions lose viscosity and precipitate, bound water is released and eliminated, which gives rise to a solid–liquid two-phase system. These changes are related to the properties of amylose (its recrystallisation) and only very little to the properties of amylopectin. This process is generally called **syneresis**. Syneresis in starch gels is known as **retrogradation**. The process of retrogadation is actually the opposite of gel formation. The rate and extent of retrogradation depend on

Table 4.27 Typical viscosity of starch and other hydrocolloid dispersions at 25 °C.

Polysaccharide	Dispersion concentration (% w/w)	Dynamic viscosity (mPa/s)	Polysaccharide	Dispersion concentration (% w/w)	Dynamic viscosity (mPa/s)
Wheat starch	10	10	Tragacanth	1	54
Pectin	1	50	Agar	1	4
Guar gum	1	3025	Carrageenan	1	57
Locust gum	1	59	Alginate (Na)	1	214
Gum arabic	10	17	Xanthan	1	2000

many factors, such as the origin of the starch (the amount and degree of polymerisation of amylose), temperature, water content and the presence of other components. For example, maize starch undergoes retrogradation more easily than potato starch.

During low temperature storage (below about −5 °C), retrogradation of starch gels containing 45–50% water is strongly inhibited. At temperatures ranging from −5 °C to just below room temperature, the retrogradation rate is higher than its rate at room temperature. Higher temperatures (32–40 °C) effectively suppress retrogradation and at temperatures around 65 °C and above, retrogradation does not occur at all. Therefore, waxy starches high in amylopectin, where the range of retrogradation is suppressed, are recommended for frozen foods. When stored at low temperatures, even gels of these starches lose clarity and water binding capacity, which is attributed to intermolecular associations of amylopectin side chains. Retrogradation is also influenced by water content in starch gel.[6] It occurs in gels containing 20–90% water. The greatest tendency to retrogradation is seen in gels with 45–50% water. In the presence of salts (sodium chloride) or sugars, the degree of retrogradation is lower. The effect of individual sugars varies and depends on many factors, such as concentration. Retrogradation is also suppressed in the presence of lipids that form inclusion compounds with amylose.

Changes in foods

Bread and other cereal products Along with starch, foods very often contain water, sugars (mono- and oligosaccharides), lipids, proteins, salts and acids that influence the formation of gels. Grain grinding mechanically damages about 5–10% of starch granules and during dough rising, amylases (also known as flour diastase) preferentially attack the damaged starch granules. Starch is partially hydrolysed by α-amylase (1,4-α-D-glucan glucanohydrolase) a β-amylase (1,4-α-D-glucan maltohydrolase) to maltose, which is hydrolysed to glucose by maltase (α-glucosidase, α-D-glucoside glucohydrolase). Endoglycosidase α-amylase randomly attacks α-(1→4) glycosidic bonds in amylose polymer yielding glucose, maltose and units of higher molecular weight, known as **linear dextrins** or **α-dextrins**, and is therefore known as dextrinogenic enzyme. Exoglycosidase β-amylase hydrolyses α-(1→4) glycosidic bonds of amylose molecules from the non-reducing end, splits off maltose molecules (if the chain has an odd number of glucose units, glucose and maltotriose are also formed) and is therefore known as saccharogenic enzyme. Amylopectin is attacked by both enzymes, but it is hydrolysed from about 50–60%, because amylases only hydrolyse the molecule to the point of branching and do not hydrolyse α-(1→6) glycosidic bonds. β-Amylase hydrolyses amylopectin from the reducing end to the branching points so that residues containing 2–3 glucose units remain unhydrolysed. Products of this concerted action of amylases are maltose and dextrins (maltodextrins). Highly branched dextrins of this type are called **limit dextrins** or **β-dextrins**. Limit dextrins are further hydrolysed gradually by pullulanase (1,6-amyloglycosidase or amylopectin 6-glucano hydrolase), which hydrolyses α-(1→6) bonds, and remnants of dextrins are further broken down by amylases.

Rheological properties of dough are mainly determined by the properties of gluten. The desired structure of the dough also arises partly as a result of interactions of swollen starch granules with gluten proteins, with pentosans, denatured proteins and starch gelatinisation. If dough contains a limited amount of water, starch is only partially gelatinised (raw starch with no water added does not undergo gelatinisation, but instead undergoes dextrinisation if heated). This condition exists in the production of bread and pastries (similarly in the cooking of potato tubers and opposed to cooking a pudding). Because the water content of the bread crumb stays virtually unchanged, the resulting degree of starch gelatinisation and crumb consistency depends on the amount of water used, but also on the origin of the flour (its chemical composition), the amount of fat, emulsifiers and other factors.

---

[6]Gelatinised starch gel is completely amorphous with uniformly distributed water molecules. Retrogradation is a non-equilibrium recrystallisation process dependent on the temperature difference between storage temperature and the glass transition temperature (T_g). Above this temperature (when the water content is about 50%, T_g is about −5 °C) polysaccharide chains are mobile and their mobility determines the speed of association by hydrogen bonds that causes retrogradation. Water as a plasticiser affects the value of T_g of amorphous gels. At low water content, the T_g value is higher than room temperature and the amorphous gel occurs in a highly viscous glassy state. Recrystallisation increases with increased water content and is a maximum at water contents of 45–50%, as the mobility of molecules grows. At higher water contents, recrystallisation is lower due to the dilution of macromolecules.

During bread and thicker pastry baking, the enzymatic hydrolysis of starch by amylases proceeds for quite a long time (α-amylase is very thermostable and the optimum temperature is around 90 °C). Bread and pastry therefore always contain less starch and more products of its fission (dextrins and lower sugars) than dough. Sugars bind a certain proportion of water, which can further contribute to the formation of gel. The decrease of water activity results in increased gelatinisation temperature and reduced rate of gel formation, and also reduces its viscosity and strength. Slow baking at lower temperatures produces higher amounts of lower sugars. For example, pumpernickel, a very heavy rye bread produced in Germany (Westphalia), is baked very slowly (24–100 h at 100–150 °C). It is sweet as it contains up to 20% reducing sugars. They undergo non-enzymatic browning reactions and products of these reactions confer a bread crumb with a typical dark brown colour and distinctive flavour.

Starch in bread crust exposed to temperatures of 160–180 °C during baking is non-enzymatically hydrolysed into smaller units, which condense in larger molecules called **pyrodextrins** that contribute to bread flavour, colour and crispness. Pyrodextrins contain glucose units bound by α-(1→6) glycosidic bonds or (6→6) ether bonds, which are not cleaved by saccharases present in the digestive tract.

Lipids (fats and oils) and monoacylglycerols used as emulsifiers form inclusion compounds with amylose, slow down the swelling of starch granules and the extent of starch gelatinisation. For example, around 96% of starch is fully gelatinised in white bread, which is low in fat. Bakery products rich in fat, especially in the surface layers with lower water activity, contain a considerable proportion of ungelatinised starch. Small concentrations of sodium chloride have only limited impact on gel formation.

A typical symptom of retrogradation is aging (hardening) of bread and pastries. Re-heating of such bread or bakery products, for exampe in microwave ovens or during bread toasting, causes new starch gelatinisation, but such products harden very quickly.

Other foods Starch gelatinisation also occurs during hydrothermal processes, such as extrusion cooking. In some cases, the release of amylose from the granules into the environment is an undesirable phenomenon (e.g. during pasta and rice cooking), causing stickiness of the material. To prevent this in pasta products, monoacylglycerols or other emulsifiers are added. In rice, cooking is helped by the decantation of starch and addition of oil to cooking water.

Preservation of unripe fruits and vegetables with higher starch content (e.g. apples and ripe green peas) often gives turbid and viscous brines. Acidic solutions can cause hydrolysis of starch to dextrins, which is manifested by less viscous solutions. Hydrolysis of starch also occurs in puddings containing acidic fruit juices. The liquefaction of dressings and mayonnaises containing starch is likewise caused by the action of enzymes (saccharases) of fresh vegetables and spices.

4.5.6.1.4 Physiology and nutrition

Starch is a utilisable polysaccharide easily digested in the small intestine. In the digestion of starch, the enzymes α-amylase (in saliva), pancreatic α-amylase and isoamylase (isomaltase or glycogen 6-glucanohydrolase) cleave the α-(1→6) of amylopectin and glycogen.

Most starches belong to the category of quickly or slowly digestible starches and, under normal conditions, are completely hydrolysed in the small intestine. However, some starches are partially resistant to enzymatic hydrolysis or are unacceptable to the host amylolytic enzymes and rank among the non-utilisable polysaccharides that become the components of dietary fibre (e.g. cereal grains consumed raw and protected by cell walls, preventing access to amylases). Four types of resistant starch are recognised (Table 4.28). Resistance to digestion in the small intestine can be also lowered by the method of preparation and storage of food. For example, retrogradation of starch increases the resistance to amylolytic enzymes by about 1%. Resistant starches represent about 1% of the total amount of starches consumed. They pass through the colon, where they are partially metabolised (also in the appendix) and used by the colon microflora. Resistant starch can therefore be considered as a low energy material that has a theoretical energy value of only about 8–12 kJ/g (2–3 kcal/g), while the energy value of digestible starch is 17 kJ/g (4 kcal/g).

4.5.6.1.5 Use

Starches are important natural components of many food commodities, which significantly affect or determine their texture and

Table 4.28 Classification and examples of digestible and resistant starches.

Starch type	Characteristics	Small intestine digestion	Source
Quickly digestible	Digestible	Total	Freshly cooked starchy foods
Slowly digestible	Digestible	Slow, but total	Majority of row cereals
Resistent starch I	Physically inaccessible	Undigestible	Unprocessed grains, seeds and legumes
Resistent starch II	Natural granules	Slow, partial	Raw potatoes and bananas, high amylose maize
Resistent starch III	Retrograded	Partial or resistant	Boiled and stored potatoes, old bread, bread crust, legumes, cornflakes
Resistent starch IV	Chemically modified	Resistent	Not found in nature

functional properties. Native and modified starches are used as additives in many products. The commercial and technological uses of starch are extremely diverse. Native starches are used as fillers and thickeners, gelling agents, water binders, fat substitutes, carriers of odour-active compounds and stabilisers of foams or emulsions. Those applied directly include native starch granules, dispersed granules, extruded starch and films obtained by drying starch dispersions. Starches are also an essential raw material for the manufacture of modified starches, sugars and some sugar derivatives. Roughly half of the starches produced are used as natural or modified starches in food and feed production, the rest are used in many other industries (pharmaceutical, paper, textile, construction industries, in cosmetics and so on).

Modified starches

The use of native starches is limited due to their physical and chemical properties. Starch grains are insoluble in cold water, and to obtain starch dispersion it is necessary to cook the starch. Starch viscosity is often high and confers to products a rubbery and cohesive texture. Amylose containing starches form rigid, turbid and retrogradable gels; waxy starches form clear, but soft gels, which become turbid during storage at low temperatures. Furthermore, native starches are easily hydrolysed in acidic solutions, for example, in acidic sauces during prolonged heating. Native starches are therefore modified in various ways so that some of these undesirable properties are limited or the obtained products have desirable properties. Modified starches are divided into:

- **transformed** (converted, degraded) starches
- **cross-linked** starches
- **stabilised** starches
- **otherwise modified** starches.

Transformed starches

Transformed starches are obtained from native starches by:

- **acid hydrolysis** (starches modified by acids)
- **oxidation** (bleached and oxidised starches)
- **heating** (dextrinised starches).

Acid hydrolysis is carried out by heating concentrated aqueous dispersions of starch (36–40%) with dilute mineral acids (usually with <7% HCl or 2% H_2SO_4) for several hours at a temperature of 40–60 °C, which is lower than the initial gelatinisation temperature. The suspension of starch is then neutralised, washed with water and the starch separated by filtration and dried. Under these conditions, amylose and amylopectin are partially hydrolysed in the amorphous regions of granules and the product is a so-called **soluble starch** as the damaged granules swell in cold water and collapse when heated above the gelatinisation temperature (higher than that of the original starch). The obtained dispersion is less viscous (its fluidity increases), so that modified starches can be dispersed at higher concentrations. This is significant when starches are used as fillers, as saccharose or fat substitutes. Hot sols are clear and on cooling form cloudy, opalescent gels (relatively clear gels are formed from waxy starches) that are more stable than the unmodified starch gels. Starches modified by acids are used primarily in the manufacture of confectionery (gum drops and candy). Soluble starch in blends with native starch is used to prepare pudding powders.

Oxidation is used to produce two types of starch:

- **bleached** starch
- **oxidised** starch.

Bleaching is carried out in an aqueous suspension by mild oxidation with small amounts of peracetic acid, hydrogen peroxide, sodium hypochlorite (NaOCl), potassium permanganate ($KMnO_4$), ammonium peroxosulfate $(NH_4)_2S_2O_8$, chlorine or other oxidising agents. Under these conditions, starch oxidation is minimal, but accompanying colouring substances (especially carotenoids) are removed.

Oxidation is carried out in aqueous suspensions using the same oxidising agents in a weakly alkaline medium. For example, sodium hypochlorite oxidises the primary hydroxyl group at C-6 to a carbonyl group and further to carboxylic group (under the formation of glucuronic acid), the secondary alcohol groups at C-2 and C-3 are oxidised to formyl groups, through the ring opening between the C-2 and C-3 carbon atoms, and subsequent oxidation yields a dicarboxylic acid. Ring opening and oxidation of a formyl group in the reducing end of the molecule yields gluconic acid. To some extent, the secondary hydroxyl groups are oxidised to keto groups (Figure 4.9).

Oxidised starches form clear liquid sols with greater fluidity than native starches. Stable gels are formed by cooling with a reduced tendency to retrogradation. Carboxylic groups with electric charges of the same sign repel one another and the tendency of molecules to associate is lower. Oxidised starches have the same use as starches modified by acids. In addition, they are suitable for coating meat and fish, because the package adhesion is significantly higher in comparison with unmodified starches. Starches oxidised with nitric acid have found use in the textile industry.

Heating of native dry starch or starch acidified by diluted mineral acids (about 0.2% HCl, H_3PO_4 or H_2SO_4), depending on the dextrination conditions (heating at 100–200 °C for several minutes to hours) and type of starch yields three basic types of products:

- **white dextrins** (in more acidic media by short heating at lower temperatures)
- **yellow dextrins**
- **British gums** (in less acidic media).

The main reactions are hydrolysis (the products are mainly linear molecules branched at 2–3% of the glucose units) and

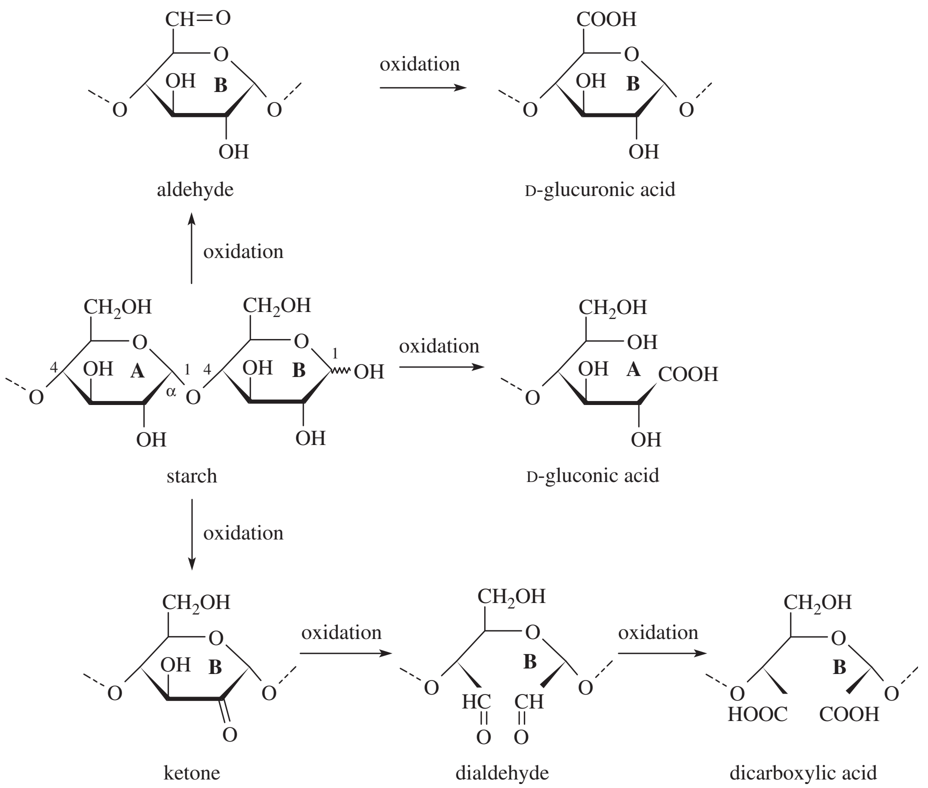


Figure 4.9 Major products of starch oxidation with sodium hypochlorite.

transglucosidation (yielding branched dextrins resistant to amylase attack). In later stages of the reaction, high molecular weight dextrins form by re-polymerisation of the formed products. The dispersions of white dextrins (hydrolysis predominates) are viscous and have the highest tendency to retrogradation. Yellow dextrins (hydrolysis prevails at the beginning of the process, later transglucosylation and finally polymerisation take place) contain about 20% branched molecules. British gums (the main reaction is transglucosylation) produce the most stable and least viscous dispersions containing 20–25% of branched molecules. Yellow dextrins and British gums are soluble in cold water (starch dispersions have to be prepared in hot water); the least soluble products are white dextrins. Dextrins find use as adhesive substances for the preparation of shiny surfaces of sweets and tablets, carriers, such as aromatic compounds, spices, dyes and for encapsulation of oils and water soluble flavours.

Cross-linked starches

Two main types of cross-linked starches are produced:

- **adipates**
- **phosphates**.

Adipates are prepared by reacting starch with adipic acid anhydride (mixed with acetic anhydride) in a weakly alkaline medium (Figure 4.10). Besides cross-links, the modified starch

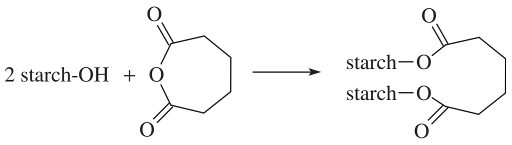

Figure 4.10 Formation of starch adipates.

contains small amounts of acetylated hydroxyl groups (especially at C-6). Reaction with phosphorus oxychloride ($POCl_3$) or sodium trimetaphosphate ($Na_3P_3O_9$) in alkaline medium is used for the preparation of distarch phosphates (Figure 4.11).

The degree of starch cross-linking is relatively low (usually one cross is in 1000–2000 glucose units), but it significantly modifies the rheological properties of starch. Swollen granules retain their integrity and the considerable viscosity of dispersions remains virtually unchanged. In contrast to cohesive pastes formed from unmodified starches, pastes of cross-linked starches are non-cohesive. Cross-linked starches are used for thickening, stabilising

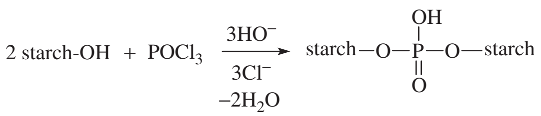

Figure 4.11 Formation of starch phosphates.

and adjusting the texture of foods (pastry fillings, dressings, thickening of soups and sauces), but they are not suitable for products stored at low temperatures. Other cross-linked starches (e.g. xanthates formed by reaction with carbon disulfide) are used in the textile industry.

Stabilised starches

The modification consists in the substitution of some hydroxyl groups of polysaccharides. Stabilised starches are divided into:

- **starch esters** (e.g. acetates, phosphates and succinates)
- **starch ethers** (such as hydroxyalkyl ethers).

Stabilised starches are usually made from native starches, but also from starches modified by other means (acid hydrolysis, dextrination and cross-linking). Acetylated starches are obtained by reaction of starch suspensions with acetic anhydride (also with vinyl acetate) in a weakly alkaline medium (Figure 4.12). They contain up to 2.5% of acetyl groups. The degree of substitution expressing the average number of substituted hydroxyl groups on each glucose unit is 0.1. The maximum number is 3 (Figure 4.9). The esterification occurs mainly at C-6 hydroxyl groups, less at C-3 and partially on C-2 hydroxyl groups. The modification is manifested by a reduced gelatinisation temperature of modified starches (especially of high amylase starches), higher stability in acidic media and higher stability against retrogradation during storage of products at low temperatures. The increasing degree of acetylation reduces the ability to form gels by cooling. Dispersions remain liquid even at higher concentrations of starch and at lower temperatures and in neutral and alkaline solutions are unstable (acetyl groups are hydrolysed). Acetylated starches (especially pre-cross-linked starches) are used for similar purposes as cross-linked starches.

Phosphorylated starches are obtained by reaction of aqueous suspension of starch with *ortho*- (Na_3PO_4), pyro- ($Na_4P_2O_7$) and tripolyphosphates ($Na_5P_3O_{10}$) in a weakly alkaline medium at temperatures of 120–170 °C (Figure 4.13). The degree of substitution is usually <0.25. The decrease in gelatinisation temperature versus

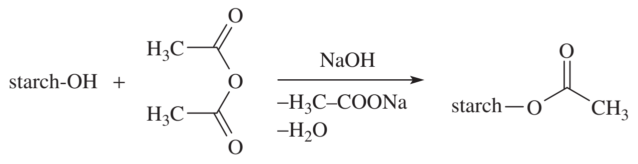

Figure 4.12 Formation of acetylated starches.

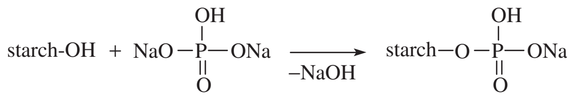

Figure 4.13 Formation of phosphorylated starches.

non-esterified starches is so great that even phosphates with a degree of substitution of 0.07 swell in cold water. Phosphorylated starches provide non-gelatinised dispersions with higher clarity, viscosity and stability at low temperatures. Like other polyelectrolytes, they interact with polyvalent cations (e.g. in hard water) under flocculation. Phosphorylated starches are used for thickening and stabilising unsalted, non-acidic (sodium salt) and stored refrigerated products, and for production of pudding powders soluble in cold milk.

Succinylated starches are prepared by reacting an aqueous suspension of starch with succinic anhydride or alk(en)ylsuccinic anhydrides in a neutral or slightly alkaline medium (Figure 4.14). The degree of substitution is 0.02 (one substituent to 50 units of glucose). Succinylated starches are used as thickeners. Some alk(en)ylsuccinylated starches have interesting properties, such as oct-1-enylsuccinated starch (Figure 4.14, $R = [CH_2]_6–CH{=}CH_2$), which is used as the sodium salt or acid. Some types are soluble in cold water and form a stable dispersion of higher viscosity than the original starch, which do not have a tendency to form pastes and gels. By the combination of hydrophobic substituent with ionised or non-ionised carboxyl groups, the starch has the functional properties of an emulsifier. It is used primarily to stabilise emulsions of oil-in-water in the pharmaceutical (e.g. encapsulation of vitamin A) and food industries (stabilisation of non-polar flavours in soft drinks, mayonnaises and dressings) or as a substitute for gum arabic.

For these and a variety of special non-food purposes esters with higher fatty acids, succinic, adipic and citric acids and carbamates (reaction products with urea), have also been prepared. Examples of starch ethers are 2-hydroxyethyl and 2-hydroxypropyl starches prepared by reaction of starch with oxirane (ethylene oxide) and methyloxirane (propylene-1,2-oxide). The reaction occurs preferentially at the secondary hydroxyl groups at C-2, with less on the C-3 and C-6 hydroxyl groups. The most common products are those shown in Figure 4.15. The degree of substitution tends to be <0.2. According to the reaction conditions, polyoxaalkyl starches[7]

[7] Instead the degree of substitution, these derivatives with polymeric substituents are characterised by the molar substitution, which is the number of moles of reagent bound per mole of (anhydro)glucose units.

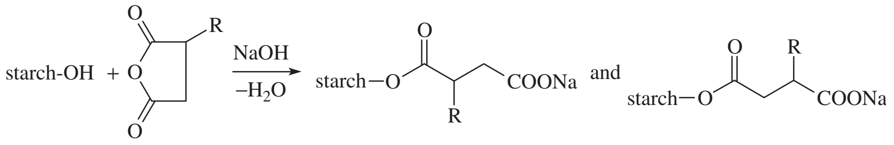

Figure 4.14 Formation of succinylated starches.

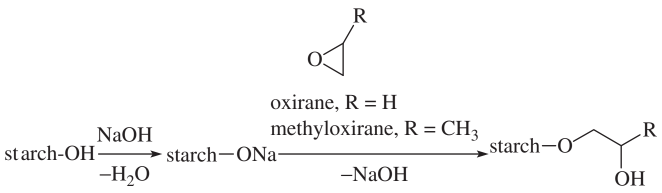

Figure 4.15 Reaction of starch with oxiranes.

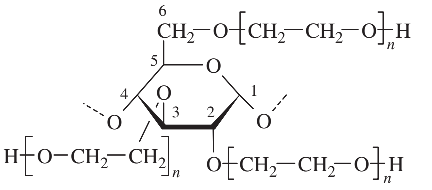
substituted at positions O-2, O-3 and O-6 (**4-140**) can be also prepared.



4-140, polyoxaalkyl substituted starch derivatives

In the food industry, hydroxypropylated distarch phosphates are mainly used, providing a series of appropriate functional properties. They have greater stability at low temperatures, therefore they are used mainly for frozen products. They are suitable for products of low acidity (with pH 5–6), but also for acidic salad dressings. In acidic conditions and at higher temperatures they show a tendency towards partial hydrolysis, but the ether bond is generally more stable than the ester bond. Reaction with chloroacetic acid leads, by analogy, to carboxymethyl starches that swell quickly in cold water. They are used in the paper and textile industries (e.g. as glue). Reaction with chloroethane yields ethyl starches, reaction with ethenenitril (vinylcyanide) gives cyanoethylether starches, which also have various non-food uses. Quaternary ammonium and tertiary alkylamino groups are present in starches that are used as stabilisers of non-food dispersions.

Other modified starches

The functionality of modified (cross-linked and stabilised) starches can be increased by additional modifications, which usually include a combination of acid hydrolysis and dextrination, dextrination and cross-linking and other modifications. A possibility of increasing the functionality of modified starches is another modification by the action of enzymes. For these purposes pullulanase (isoamylase) is used, hydrolysing α-D-(1→6) bonds of amylopectin and dextrins. Such products are, for example, substitutes of caseinates in cheese imitations. Starches swelling in cold water or milk (used for the production of puddings) are prepared by drying of swollen starches called **pregelatinised starches**.

Physiology and nutrition

Modified starches are considered normal food components, because analogous products are formed during technological operations and starch digestion *in vivo*. Their digestibility is therefore comparable to the digestibility of native starches. Starches stabilised by esterification have comparable degrees of digestibility. Somewhat lower digestibility is shown by cross-linked starches and starch ethers.

Starch hydrolysates

In the past, starch hydrolysis was conducted exclusively by acids. At present, starch (native, less frequently modified, for example, pregelatinised) is hydrolysed by acids, enzymes (commonly several different enzymes are used) or combined methods (partially acid hydrolysed starch is hydrolysed enzymatically). Depending on the enzymes and technological procedures used, a number of products can be obtained. They are used as sweeteners, fat and sugar substitutes in low energy products, agents regulating texture and other properties of foods. Starch hydrolysates are also used as raw materials for production of other sugars and substances.

Acid hydrolysis

Partial hydrolysis with acid is carried out at higher temperatures than the production of soluble starch, generally in 40% starch suspensions containing HCl at a concentration of 0.02–0.03 mol/l at temperatures of 135–150 °C for 5–8 min.

Enzymatic hydrolysis and other reactions

Enzymatic hydrolysis provides similar products as acid hydrolysis (dextrins, maltooligosaccharides, maltose and glucose), but the resulting products are better defined and the process can be better controlled. Biotechnological procedures can be used to obtain products that cannot be provided by chemical hydrolysis (such as fructose and cyclodextrins). Amylolytic enzymes used for starch hydrolysis are exclusively of microbial origin. These enzymes hydrolyse α-(1→4) bonds in amylose and amylopectin with the formation of oligosaccharides of different chain lengths. The following basic groups of enzymes are:

- **endoamylases** (thermolabile and thermostable α-amylases)
- **exoamylases** (maltogenic β-amylase and glucogenic or amyloglucosidase or glucoamylase).

Thermostable α-amylases derived from bacteria of the genus *Bacillus* (*B. subtilis* var. *amyloliquefaciens* and *B. licheniformis*) break down starch into maltooligosaccharides. For example, the primary intermediate generated by α-amylase from *B. licheniformis* is linear maltopentaose, which is gradually degraded to lower carbohydrates. The main degradation product is maltotriose, formed by splitting off maltose, followed by maltose, glucose and maltotetraose. Maltotriose and maltose are the final products that are not further hydrolysed. These sugars are also the main products of thermolabile maltogenic α-amylase derived from the fungus *Aspergillus oryzae*. Maltogenic β-amylase breaks down starch (amylose) to maltose almost exclusively. The end product of hydrolysis of amylopectin by β-amylase only is called **maltodextrin**. This enzyme,

which also partly cleaves α-(1→6) bonds of amylopectin, can be obtained from bacteria of the genera *Bacillus* and *Pseudomonas* and from *Clostridium thermosulfurogenes*.

Glucogenic amyloglucosidase attacks α-(1→4) bonds of amylose and amylopectin molecules from the non-reducing end and splits off β-D-glucopyranose. It also partly cleaves α-(1→6) bonds of amylopectin. At high concentrations of glucose, this enzyme acts as transglucosidase and catalyses the reversion of glucose to maltooligosaccharides and isomaltooligosaccharides.

The α-(1→6) bonds of amylopectin and dextrins cleave α-(1→6)-saccharidases known by the trivial names of pullulanases or 1,6-amyloglycosidases or by the systematic name of amylopectin 6-glucanohydrolases. These bonds are also cleaved by isoamylases (isomaltases) known by the systematic name of glycogen 6-glucanohydrolases. Pullulanase and isoamylase are obtained from the bacteria *Klebsiella aerogenes*, and isoamylase also from bacteria of the genus *Pseudomonas*. Conversion of glucose into fructose is catalysed by glucose isomerase, which is obtained from *Bacillus circulans*.

Hydrolysis of starch (amylodextrins) to non-reducing cyclomaltooligosaccharides called cyclodextrins is catalysed by cyclodextrin glycosyltransferase (also known as CGTase). Cyclodextrin glycosyltransferase is produced largely by bacteria of the genus *Bacillus*. *B. macerans* synthesises mainly cyclomaltohexaoses (known as α-cyclodextrins), *B. stearothermophillus* produces cyclomaltohexaoses and cyclomaltoheptaoses (β-cyclodextrins) and the enzyme from *B. subtilis* yields cyclomaltooctaoses (γ-cyclodextrins).

Products of starch hydrolysis

The degree of hydrolysis of starch is characterised by the so called **dextrose** (glucose) **equivalents** (DE) that indicate the percentage content of free glucose, respectively, the content of terminal (reducing) glucose in maltose, maltotriose and other reducing maltooligosaccharides after conversion to dry matter. Native starch has the value of DE = 0, the hydrolysate containing only glucose has the value of DE = 100. Products with a DE value of about 20 or less form viscous solutions and have a sweet taste. The viscosity of starch hydrolysates decreases with the increased value of DE, while their sweetness (which ranges from 25 to 50% of saccharose sweetness) increases. A wide range of products with the values of DE within about 5–95 and more are produced. Depending on the extent of hydrolysis, these products contain variable amounts of glucose, maltose, maltotriose and higher glucooligosaccharides. The predominant components that can be identified are:

- **maltodextrins**
- **starch syrups** or **maltose syrups** or **glucose syrups**.

Maltodextrins are products of hydrolysis with a DE value of ≤20. They generally contain from 0.3 to 1.6% of glucose, 0.9 to 5.8% of maltose, 1.4 to 11.0% of maltotriose, 1.4 to 6.1% of maltotetraose and 75.5 to 96.0% of higher sugars. Hydrolysates containing maltodextrins are mostly dried or, exceptionally, prepared as syrups. They increase the viscosity, smoothness and surface gloss of confectionery products, prevent the formation of crystals in ice creams and frozen dairy products and are used as carriers for flavours, pigments and fats, as well as for replacement of gum arabic. Their main use is as fat substitutes.

According to their DE values, starch syrups are divided to type I (DE = 20–38), type II (DE = 38–58) and type III (DE = 58–73). Types II and III fall into the category usually called maltose syrups. Type IV (DE > 73) are glucose syrups. Their basic chemical composition is shown in Table 4.29. Starch syrups are used for making sweets, soft drinks, fruit syrups, jams, they serve as stabilisers of consistency (in ice creams), are used as substitutes for fat and as raw material for production of caramel and other products. They are fermentable and also serve in the biotechnological production of various substances (such as ethanol and citric acid). Maltose is isolated from syrups with a high maltose content. Isomerisation of maltose in maltose syrups in alkaline media is employed for the preparation of products that contain as the main component maltulose, which is sweeter than maltose. Hydrogenation yields sugar alcohol maltitol, correspondingly a mixture of alditols that contain as the essential components maltitol and maltotriitol. Glucose syrups are used for isolation of glucose and are also used for the production of fructose syrups. Hydrogenation yields a mixture of sugar alcohols, in which the main component is D-glucitol.

Fructose syrups are obtained by the action of bacterial enzyme glucose isomerase (from *Bacillus circulans*) on glucose syrups. Historically, the first products contain fructose in the amount of about 42% of dry matter (content of glucose was 52%, contents of higher sugars and dry matter was 6 and 75%, respectively). Today produced syrups contain 55% fructose (40% glucose, 5% higher sugars and 77% dry matter) and have a similar composition and similar sweetening power as invert sugar (about 100% relative to saccharose sweetening power). Using different physico-chemical methods, these syrups are used to produce high fructose syrups containing up to about 90% fructose (9% glucose, 1% higher sugars, 80% dry matter). Their sweetening power is 160–180% the saccharose sweetening power. Fructose syrups are used similarly to invert sugar and saccharose and are particularly suitable to sweeten soft drinks and confectionary. High fructose syrups are added to foods as a sweetener for diabetics.

Special products similar to maltose syrups are maltooligosaccharides containing 2–7 glucose units linked to each other by α-D-(1→4) bonds. They are obtained by enzymatic hydrolysis of starch with isoamylase or pullulanase and by hydrolysis of the obtained products using α-amylase. Maltooligosaccharides are fully utilisable sugars, which are used similarly to maltose syrups.

Other special products are isomaltooligosaccharides containing 2–5 glucose units linked by α-D-(1→6) and partly by α-D-(1→4) bonds, which occur in the trisaccharide panose. They are obtained by hydrolysis of starch by α-amylase and by the hydrolysis of the thus obtained products using β-amylase and α-glucosidase (α-D-glucoside glucohydrolase) under controlled conditions. They are not utilisable, but stimulate the growth of bifidogenic bacteria in the colon.

Glucose syrups are also transformed by enzymatic transglucosylation (using amyloglucosidase activity) to gentiooligosaccharides

Table 4.29 Composition of selected starch hydrolysates (% of dry matter).

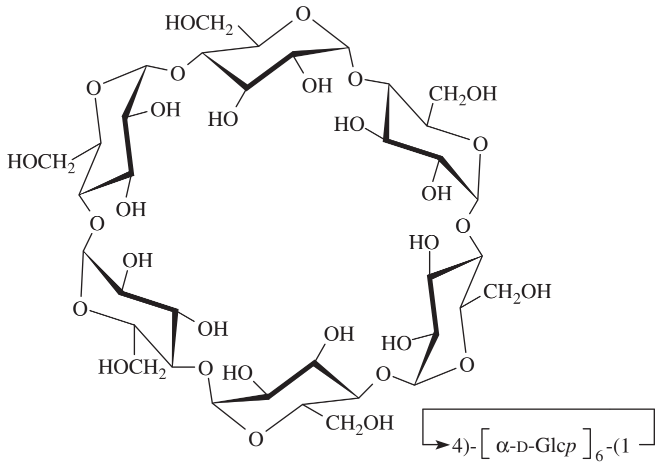
[a] The first number for combined acid and enzymatic hydrolysis is the DE value after acid hydrolysis and the second number is the DE value after enzymatic hydrolysis.
[b] The content is included in the content of higher sugars.
[c] The total content of oligosaccharides is the sum of up to 100%.

that contain 2–5 glucose units linked by β-D-(1→6) glycosidic bonds that occur in the disaccharide gentiobiose (Table 4.11). They are used for the same purposes as other indigestible oligosaccharides, mostly as fillers in low-energy products. Like other indigestible oligosaccharides, gentiooligosaccharides also stimulate the growth of bifidogenic microflora in the colon.

Cyclodextrins

Cyclodextrins (formerly called Schardinger dextrins) are cyclic maltooligosaccharides to maltopolysaccharides containing 6–12 glucose molecules joined by α-D-(1→4) bonds. They are obtained by hydrolysis of amylodextrins (DE < 10) by the action of cyclodextrin glucanotransferase. The main representatives are cyclomaltohexaose (formerly Schardiner α-dextrin or α-dextrin, **4-141**), cyclomaltoheptaose (β-cyclodextrin) and cyclomaltooctaose (γ-cyclodextrin), which are composed of 6, 7 and 8 glucose monomers, respectively.



4-141, cyclomaltohexaose

Cyclodextrins form crystalline inclusion complexes with many organic compounds, including some gases, which are bound within the molecule. Formation of these complexes is called **encapsulation**. Encapsulation results in a change of the physico-chemical properties of encapsulated compounds (e.g. volatility of flavour-active compounds and their increased stability against oxidation and photodegradation). Cyclodextrins are, therefore, of greatest use as carriers (encapsulators) of odoriferous substances, emulsion stabilisers and are also used to remove bitter substances from citrus juices (see Section 8.3.5.1.1).

4.5.6.2 Other storage polysaccharides

Tubers, roots, seeds and also some vegetative parts of plants contain non-starch storage polysaccharides, which are involved in processes associated with germination and growth. Most of these polysaccharides are structurally similar to non-cellulose polysaccharides of cell walls that are classified as hemicelluloses and pectins. The most important representatives of this group of polysaccharides are:

- **heterofructans**
- **heteromannans**
- **heteroglucans**.

4.5.6.2.1 Heterofructans

Polymers and oligomers of D-fructose are called fructans or fructosans, but they often include D-fructose polymers containing one molecule of D-glucose as the terminal unit, the correct name for which is glucofructans or glucofructosans. Fructans and glucofructans are synthesised as energy reserves of about 15% in higher plants and some microorganisms (some species of the mould

genera *Aspergillus*, *Claviceps*, *Fusarium*, *Penicillium* and yeasts, such as *Saccharomyces cerevisiae* and others). In addition to being storage polysaccharides, they play a role in osmoregulation in plants and in their tolerance to some stress factors (cold and lack of water).

Structure

Natural fructans (glucofructans) are usually classified into:

- **inulins**
- **levans** otherwise called **phleins**.

Polymers referred to as inulins are composed of linear chains of D-fructofuranoses (fructans) usually containing a D-glucopyranose molecule (glucofructans) as a terminal unit. They are mutually bound by β-(1→2) glycosidic bonds. Typically, inulin is found in some plants of the Asteraceae family, for example in chicory roots (*Cichorium intybus*), yacon roots (*Smallanthus sonchifolius*), native to the Andean region of South America, tubers of Jerusalem artichokes also known as topinambours (*Heliantus tuberosus*) and dahlias (*Dahlia* spp.) and the fleshy flower heads of globe artichokes (*Cynara scolymus*).

Levans are branched polymers of D-fructofuranoses associated exclusively by β-(2→6) glycosidic bonds. In addition to inulin, they may also contain D-glucose as the terminal unit. Typical levans are synthesised, for example, by bacteria *Bacillus subtilis* from saccharose or raffinose in sugar beet juice during sugar production. Levans with β-(2→6) glycosidic bond also predominate in oats.

Glucofructans that contain both types of bonds (1–4% of branched molecules) occur most frequently as components of numerous cereals (wheat, rye, triticale and barley), fruits and vegetables.

In the past, the name inulin was only used for polysaccharides of chicory, Jerusalem artichokes and dahlias. Inulin of asparagus (*Asparagus officinalis*, Asparagaceae) was called **asparogesin**. Trivial names were also used for some cereal fructans and glucofructans. Wheat levan with β-(2→6) bonds was called **pyrosin**, rye levan was **secalin**, wheat polysaccharide with both types of bonds was **triticin** and the corresponding polysaccharide of rye was known as **graminin**.

If the molecule end is α-D-glucopyranose, the abbreviated notation is GF_n (G = glucose, F = fructose, n = degree of polymerisation, **4-111**). The prototype of glucofructans of inulin type is actually disaccharide saccharose (GF, **4-109**). The enzymatic hydrolysis of inulin by native plant endoglycosidases, known as 2,1-β-D-fructan fructanohydrolase or inulase, provides linear polymers of type GF_n or, after hydrolysis of glucose, F_n type polymers. The latter type is a linear homopolymer of fructose, which always accompanies inulin. Low molecular weight sugars with a degree of polymerisation 2-10 are called fructooligosaccharides or oligofructoses (**4-112**). Typical microbial levans (of bacteria *Bacillus subtilis* and other bacteria) are of type G-F_n or F_m-G-F_n. The structure of a glucofructan of levan (phlein) type, or rather of a mixed type occurring in wheat and other grains, is shown in formula **4-142**.

4-142, glucofructan of phlein type

Occurrence

Glucofructans together with oligofructoses (oligosaccharides formed by partial enzymatic hydrolysis) occur in many foods of plant origin. They are highly polydisperse mixtures of related compounds with a degree of polymerisation (number of bound fructose molecules) n = 2–60 and sometimes more. Therefore, they can be classified simultaneously as oligosaccharides and polysaccharides. In some plants oligosaccharides are exclusively present and higher polymers are absent. For example, levans of oats contain 2–5 monosaccharide molecules, the main glucofructan of onion is an oligomer with a degree of polymerisation n = 5, yacon roots are also of a low degree of polymerisation (n = 3–9) containing as the main component the GF_3 oligosaccharide, inulin of Jerusalem artichokes (topinambours) has an average degree of polymerisation n = 30, while the globe artichokes synthesise inulin containing up to 200 monosaccharide molecules. Glucofructans and fructans are commonly accompanied by saccharose (n = 1), fructose, glucose and other saccharides (Table 4.30). Some aminoacyl sugars, saccharoses acylated with amino acids (glycine, alanine, valine, threonine, tyrosine, tryptophan and histidine) have also been identified at the C-2 of the glucose moiety in sweet potato (*Ipomoea batatas*, Convolvulaceae).

Properties and changes

In the enzymatically active material, inulin is easily hydrolysed by endogenous inulase (inulinase) and the resulting monosaccharides are degraded during thermal processes. Examples could be changes in the content of inulin during storage and thermal processing of chicory root, which is used for the manufacture of coffee substitutes. When chicory root is stored at 5 °C, inulin is completely enzymatically hydrolysed to oligofructoses F_n (n = 3–7) within six weeks. Roasting of chicory root leads to extensive degradation of inulin, oligofructoses and higher reducing sugars, which caramelise and participate in the Maillard reaction with proteins and amino acids also present. The reaction is dependent on the temperature and roasting time. The optimum roasting time is about 55–60 min at 170 °C or 14–15 min at 175–200 °C. A good roasted product

Table 4.30 Content of glucofructans and fructans in the fresh edible part of some crops.

Source	Latin name	Glucofructans (%)	Fructans (%)
Asparagus	*Asparagus officinalis*	2–3	2–3
Bananas	*Musa* sp.	0.3–0.7	0.3–0.7
Chicory (root)	*Cichorium intybus*	15–20	8–11
Garlic	*Allium sativum*	9–16	3.5–6.5
Globe artichokes	*Cynara scolymus*	3–10	0.3–1
Jerusalem artichokes	*Heliantus tuberosus*	16–20	12–15
Onion	*Allium cepa*	1.1–7.5	1.1–7.5

Rye	*Secale cereale*	0.5–1	0.5–1
Wheat	*Triticum aestivum*	1–4	1–4
Yakon	*Smallanthus sonchifolius*	10–12	-

should then contain 13–20% of fructose and 28–32% of the original amount of inulin (a fraction with a lower degree of polymerisation than that of original inulin).

Physiology and nutrition

Glucofructans and fructans are physiologically acting polysaccharides or oligosaccharides that are classified as dietary fibre because they are not hydrolysed in the upper gastrointestinal system by saliva and pancreas hydrolases and by intestinal hydrolases (α-amylase, saccharase, maltase and other saccharidases). They also act as a growth factor for bifidobacteria in the colon. The daily intake of inulin and its hydrolytic products per capita in developed countries is estimated at 2–12 g.

Use

Inulin extracted from Jerusalem artichokes or chicory roots was used as the raw material to produce fructose syrups for diabetics and for the production of fructooligosaccharides. The main raw material for the production of fructose syrups is now starch and fructooligosaccharides are mainly produced from saccharose.

4-143, basic structure of galactomannans

4.5.6.2.2 Heteromannans

In addition to starch and heterofructans, the storage polysaccharides of some seeds are heteromannans. Their main chain is homopolymeric and formed by D-mannose units being linked to each other by β-(1→4) glycosidic bonds. Some of the mannose units are bound by (1→4) bonds to α-D-galactose. These heteromannans are therefore called **galactomannans** (**4-143**).

Galactomannans that differ in their degree of substitution of the main chain by D-galactose (4–96% of mannose units are substituted) are found in seeds of many plants. Palm seeds (e.g. seeds of dates) contain galactomannans, in which about 4% of mannose units are substituted. Related galactomannans with a degree of substitution of 30–96% are located in the endosperm of coffee seeds and in some legumes. The most important representatives of galactomannans, which have found use as food hydrocolloids, are **guar gum** and **locust gum**.

Related polysaccharides are linear copolymers, in which some of the mannose units are randomly substituted by residues of D-glucopyranose bound by β-(1→4) bonds. These heteromannans are called **glucomannans**. The ratio of mannose and glucose varies from 1.5 to 4. About 2–6% of sugars in the main chain are substituted by β-D-galactopyranose bound by (1→3) glycosidic bonds. Mannose residues (every fifth to twentieth) may be acetylated in the C-2 and C-3 positions (**4-144**). Glucomannans are found in varying amounts in plant tubers, roots and seeds. The only glucomannan that is used as a food hydrocolloid is **konjak gum**.

4-144, basic structure of glucomannans

Guar gum

Guar gum (guaran) is obtained as the flour from the endosperm of guar bean seeds (*Cyamopsis tetragonoloba*, Fabaceae) after separating the germ and the surface layer. The plant is native to Central Africa, but today it is grown primarily in India, Pakistan and the United States (Texas). Guar gum is a neutral galactomannan, whose primary structure is shown in formula **4-143**. Approximately every second residue of D-mannose is substituted by a D-galactose residue (ratio of mannose and galactose varies from 1.5 to 1.8). Minority sugars are D-glucose, D-xylose and L-rhamnose (Table 4.31). The average molecular weight of guar gum polysaccharides is usually in the hundreds of kilo daltons.

Guar gum is soluble in water giving highly viscous solutions stable in the pH range 4–10. Gel is formed in the presence of small amounts of borates. Guar gum can be combined with almost all natural gums, starches, pectins, cellulose and its derivatives and very often is combined with xanthan gum, which increases (as a synergist) viscosity of dispersions.

Guar gum has a very wide range of applications and is the most commonly used gum of plant seeds. It is used as a thickener, viscosity modifier and stabiliser of dispersions in foods and beverages. It is used not only in the food industry, but also in the paper industry as a glue, and is often used in cosmetics.

Locust gum

Locust gum, also called locust bean gum, carob, carobin or algarroba, is obtained as flour from the endosperm of seeds of the carob tree also known as St John's bread (*Ceratonia siliqua*, Caesapliniaceae). The tree comes from the Western Mediterranean region (Southern Europe, Northern Africa), but now grows mainly in Spain and in the subtropical regions of the United States and Australia.

Locust gum is galactomannan (**4-143**), as is guar gum, and substituted on approximately every fourth mannose unit by galactose residues (the ratio of mannose and galactose is 3.6 to 4.2; Table 4.31). The average molecular weight is approximately 310 kDa. The galactomannan content in the flour is around 88%.

The properties of locust gum are similar to those of guar gum, but the flour from locust beans in cold water only swells and is insoluble, although a viscous dispersion (of somewhat lower viscosity than a dispersion of guar gum) is obtained by heating. Locust gum is compatible with the majority of plant and microbial hydrocolloids and proteins (gelatine). It (as guar gum) does not form gels, but increases the elasticity and strength of agar and carrageenan gels, but a gel is formed with xanthan, which does not form a gel itself. In acidic media, locust gum is prone to hydrolysis.

Locust gum binding water is used as an emulsion stabiliser (e.g. in meat products), as a thickening agent for dairy products, and fillings for frozen foods and bakery products as it bounds water. Like guar gum, locust gum is not suitable for the preparation of clear dispersions as it contains insoluble residues of seeds. It is also used in the manufacture of cosmetic and pharmaceutical products. Locust gum is a relatively expensive hydrocolloid, so it is frequently substituted with cheaper guar gum.

Konjak gum

The only commercially important glucomannan is konjak gum also known as konjak mannan. Konjak flour is obtained from the starchy tubers of the plant *Amorphophallus konjac* (Araceae), grown in subtropical to tropical eastern Asia (Japan, China and Indonesia).

The basic structure of konjak gum polysaccharides is represented by formula **4-144**. The dominating sequences are composed of one, two and five molecules of mannose and one and two molecules of glucose. The ratio of mannose and glucose is around 1.6 and the acetyl groups content is about 15%. The average molecular weight is high, around 6000 kDa.

Konjak mannan dissolves in water to give highly viscous dispersions, which are pseudoplastic systems. Heating with a small

Table 4.31 Basic composition of guar and locust gum monosaccharides.

		Neutral sugars (% w/w)			
Gum	Latin name of plant	L-Arabinose	D-Glucose	D-Mannose	D-Galactose
Guar	*Cyamopsis tetragonoloba*	1.3–2.2	1.5–4.5	45.6–56.5	28.6–37.2
Locust	*Ceratonia siliqua*	0.8–1.4	1.5–2.7	59.3–69.9	16.0–18.2

amount of alkaline agents gives (under deacetylation) longer blocks of an unsubstituted polymannose skeleton capable of mutual associations with the formation of thermostable elastic gels.

Konjak flour is used mainly in East Asian countries as a thickener and gelling agent, especially in traditional Japanese cuisine for preparing noodles and gels, which are insoluble even in boiling water. It is also used for the preparation of edible films and coatings, which are semi-permeable to water vapour and oxygen. It acts synergistically with κ-carrageenan, xanthan gum and starch and affects the viscosity of their dispersions and structure of the gels.

4.5.6.2.3 Heteroglucans

Other plant storage polysaccharides are **xyloglucans**. Their primary structure consists of a chain of D-glucose units linked by β-(1→4) bonds. The chain branches consist of D-xylopyranose units linked by α-(1→6) bonds. The C-2 of about one half of the xylose units are connected to β-D-galactose molecules by glycosidic bonds (**4-145**). These xyloglucans are related to structural xyloglucans of cell walls (components of hemicelluloses), but they are not bound to cellulose and are extractable with hot water. The only xyloglucan that is used as a food hydrocolloid is **tamarind gum**.

Tamarind gum

Tamarind gum is a xyloglucan (**4-145**) located in the endosperm of the seeds of the tamarind tree (*Tamarindus indica*, Fabaceae), probably originating from Africa, but now grown in tropical regions on other continents.

The viscosity of dispersions is increased by heating. Under acidic conditions, however, the tamarind gum polysaccharides undergo rapid hydrolysis. In the presence of high concentrations of saccharose (>65%) and over a wide range of pH values, tamarind gum forms gels that are stronger than pectin gels. Tamarind gum is only rarely used in food production, except in some special applications (as a thickener and foam stabiliser). The main use of tamarind gum is in the textile industry.

4.5.6.3 Cellulose

Cellulose is the most widespread natural organic compound. It occurs as a basic structural polysaccharide in the cell walls of higher plants. Cellulose is also found in green algae, fungi and, exceptionally, in cell walls of simple marine invertebrates (tunicates of the subphylum *Tunicata*).

4.5.6.3.1 Structure

Homoglucan cellulose (**4-146**) is a high molecular weight linear polymer of D-glucose units linked by β-(1→4) glycosidic bonds. Each of the glucose units bound in the chain is turned towards the previous unit and this position is maintained by intramolecular hydrogen bonds between the hydroxyl group at C-3 and oxygen of the pyranose ring and the hydroxyl groups at C-2 and C-6 (**4-147**).

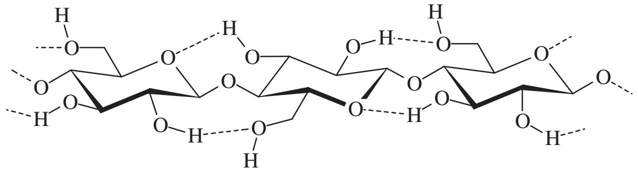
4-146, cellulose primary structure



4-147, linear cellulose chain stabilised by hydrogen bonds

The degree of polymerisation is as high as 15 000. Individual cellulose macromolecules interact with each other through hydrogen bonds to form more or less organised three-dimensional structures in the walls of plant cells, called cellulose fibres or cellulose **microfibrils**, with high tensile strength. They have a thickness of approximately 10–20 nm, a length of several μm and contain about 30–100 cellulose macromolecules that are arranged in parallel in microfibrils and form a planar unit (sheet). Individual sheets are composed so that they are alternately shifted by half the length of the glucose units. The arrangement is stabilised by intermolecular hydrogen bonds between the glucose units in adjacent sheets (between oxygens of the pyranose rings and hydroxy groups at C-6). Such arranged areas of microfibrils with high numbers of intermolecular bonds are crystalline; less structured areas with a low degree of interactions are amorphous (Figure 4.16). The crystalline and amorphous regions in the microfibrils alternate. A higher proportion of crystalline areas are in the microfibrils of secondary cell walls (e.g. in wood); amorphous regions predominate in primary cell walls found in the flesh of fruits and vegetables. Compared with starch, cellulose is much more crystalline and several crystalline structures (allomorphs) are recognised. Cellulose I is natural cellulose, cellulose produced by bacteria and algae is mainly a cellulose I_α allomorph, while cellulose I_β is mainly found in higher plants.

Metabolically active (primary) cell walls of plant tissues have a common structure consisting of randomly oriented cellulose microfibrils with a predominantly amorphous structure. They make the major contribution to the mechanical strength of the plant

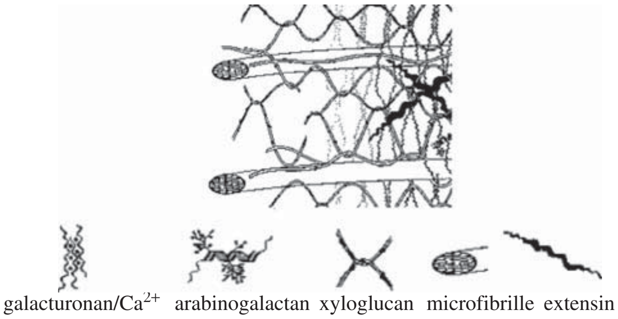


Figure 4.17 Schematic structure of plant cell walls. Carpita and Gibeaut, 1993. Reproduced by permission of John Wiley and Sons.

cell walls and act as the framework thereof. Microfibrils are bound through interactions and covalent bonds by a gel matrix composed of other structural polysaccharides, called non-cellulose polysaccharides (hemicelluloses and pectins), lignin and polypeptides, such as extensin (Figure 4.17) to form a biocomposite. The most important hemicelluloses in fruits and vegetables are xyloglucans, while cereals contain mainly arabinoxylans and β-glucans.

Differences in the structure of cell walls of various plants and their parts are related to the differentiation of the primary cells, cellulose crystalinity and the type and amount of non-cellulose polysaccharides. Deposition of additional layers of cellulose (in the form of clearly oriented parallel microfibrils), deposition of non-cellulose polysaccharides and lignification of the polysaccharide network, which is due to polymerisation of phenolic compounds, results in the formation of thick secondary cell walls, which have various special functions. For example, they ensure the rigidity of tissues, transport of water and have protective and other functions.

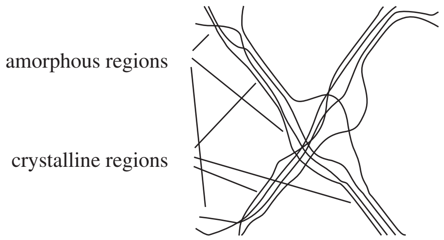

Figure 4.16 Amorphous and crystalline cellulose.

4.5.6.3.2 Occurrence

Cellulose represents a significant proportion of non-starch polysaccharides in foods (Table 4.20) and forms the so-called insoluble fibre (Table 4.21). Fruits and vegetables contain around 1–2% of cellulose, cereals and legumes 2–4%, wheat flour contains only 0.2–3% of cellulose, depending on the milling process (Table 4.19), because a large proportion of cellulose is found in the bran that contains 30–35% of cellulose. Cellulose also forms about 40–50% of wood mass, 80% of linen fibres and 90% of cotton fibres.

4.5.6.3.3 Properties

Cellulose is insoluble in water, dilute acids, bases and most solvents. Solvents, however, penetrate into the more accessible amorphous

regions of microfibrils, which leads to swelling, but the degree of swelling is always lower than that of starches. Cellulose can be dissolved in concentrated acids, because, depending on the conditions (acid concentration, temperature), it is hydrolysed to soluble fragments with shorter chains, such as disaccharide cellobiose, or to glucose. Swelling in solutions of hydroxides is greater than swelling in water or in acidic solutions. At elevated temperatures cellulose is hydrolysed or oxidised.

4.5.6.3.4 Physiology and nutrition

Cellulose is hydrolysed by a complex of cellulolytic enzymes of certain microorganisms (bacteria and moulds) and higher fungi called cellulases that break down plant tissues. Cellulase or *endo*-1,4-β-glucanase (1,4-β-D-glucan 4-glucanhydrolase) is an endoenzyme that splits β-(1→4)-D-glucosidic bonds in the amorphous regions in cellulose microfibrils with the formation of glucooligosaccharides and cellobiose. Cellobiohydrolase, also known as *exo*-β-D-1,4-glucanase (1,4-β-D-glucan cellobiohydrolase or avicelase) is an exogenous enzyme that splits β-(1→4) bonds from the non-reducing end of the chain to form oligosaccharides and cellobiose. Another enzyme, β-glucosidase or cellobiase (β-D-glucosid glucohydrolase), splits off cellobiose from the partially hydrolysed cellulose and higher oligosaccharides are hydrolysed to β-D-glucose.

Vertebrates have their own cellulase, but the digestive tracts of herbivores contain symbiotic bacteria that produce cellulolytic enzymes. Cellulose is therefore a utilisable polysaccharide for polygastric animals. It is broken down into glucose, which is fermented by bacteria to give lower fatty acids that are absorbed and utilised by the animals. Monogastric animals, including human beings, do not have cellulolytic enzymes and cellulose is a non-utilisable polysaccharide. Together with other polysaccharides, known as dietary fibre, cellulose is a nutritionally important and beneficial component of foods.

4.5.6.3.5 Use

Native cellulose is added to some foods as a non-calorific thickener, causing turbidity and is added to products processed by extrusion. However, **modified celluloses** have more applications in the food industry. Cellulose can be modified by either physical or chemical processes.

Modified celluloses

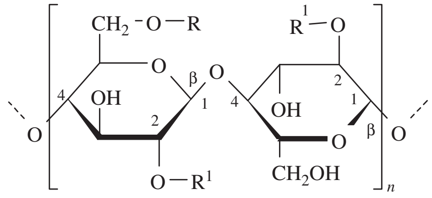
Physical modification (influence of high tangential stress and pressure) leads to cleavage of cellulose microfibrils and the product, with a high ability to bind water, is called **microfibrillar cellulose**. It can be used in food products as a non-calorific thickening agent and flavour carrier, in skin creams, paints and as a carrier for medicines.

The two main groups of chemically modified celluloses are:

- **hydrolysed cellulose**
- **derivatised cellulose**.

The only representative of hydrolysed cellulose is **microcrystalline cellulose**. It is obtained by partial hydrolysis of cellulose with hydrochloric acid, which dissolves the amorphous zones, but the crystalline zones remain unchanged. The product is most commonly known under the trade name Avicel, which has properties of thixotropic and pseudoplastic systems. Viscosity is independent of temperature and pH. Functional properties remain constant even at high temperatures and in acidic media (during baking, microwave heating and UHT processes). Microcrystalline cellulose is used as a dietary fibre, low-energy bulking agent, carrier of flavourings, stabiliser of foams and in extrusion technologies.

Of the many derivatives of cellulose, only some cellulose ethers have been used in food technologies. The most commonly used derivative is **carboxymethylcellulose** (its sodium salt), followed by **methylcellulose** and **hydroxypropylcellulose** (**4-148**).



4-148, cellulose ethers

R = CH_2COONa, R^1 = H, carboxymethylcellulose (sodium salt), degree of substitution 1.0
R = R^1 = CH_3, methylcellulose, degree of substitution 2.0
R = R^1 = $CH_2\,CH(OH)CH_3$, hydroxypropylcellulose, degree of substitution 2.0

The polyelectrolyte carboxymethyl cellulose (sodium salt) is produced by reaction of cellulose with chloroacetic acid in alkaline solution (NaOH). The degree of substitution ranges from 0.4 to 1.5. In solutions of $pH < 4$, carboxymethyl cellulose is present mainly as the free acid of low solubility that gives turbid solutions with divalent cations, such as Fe and Zn (salts are poorly soluble). In the presence of trivalent ions (Al and Fe), carboxymethyl cellulose forms gels and precipitates. Dispersions are non-Newtonian fluids that behave as pseudoplastic or thixotropic systems according to the degree of substitution. Carboxymethylcellulose is used as a thickener (cottage cheeses and cheese spreads), emulsion stabiliser (sauces, soups and dressings), protein solubiliser (gelatine and casein) and retarder of crystal formation (ice creams). Methylcellulose is obtained by cellulose methylation with methyl iodide in alkaline solutions. Reaction with propylene oxide yields hydroxypropylcellulose. The degree of methylcellulose substitution is <2.0, the degree of molar substitution of hydroxypropyl derivatives extends up to 4.0. A common cellulose ether is also hydroxypropylmethylcellulose (hypromellose), which contains two functional groups. It is used in the manufacture of pharmaceutical tablets. Less common is ethylmethylcellulose, which contains methoxyl and ethoxyl functional groups. The products are known, for example, under the trade name Methocel.

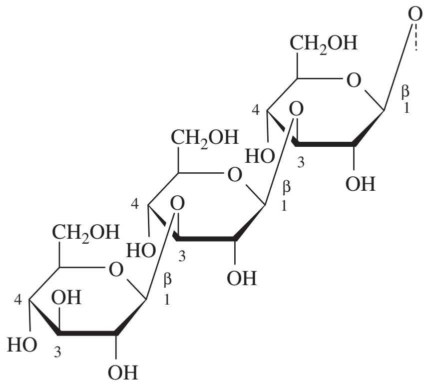
Unlike other gums, cellulose ethers show thermal gelatinisation as their colloidal solutions (at concentration of >1.5% by weight) form gels by heating to 50–85 °C. On cooling these gels

melt to viscous colloidal solutions, which are non-Newtonian pseudoplastic systems. Gels are formed in the presence of inorganic salts (phosphates and sulfates).

Cellulose ethers are used as thickeners, stabilisers of emulsions (in salad dressings) and foaming agents (hydroxypropyl cellulose). They can be added to bread to increase its water binding capacity and to reduce fat absorption by the product (e.g. of donuts during frying), to slow the retrogradation of frozen products and to produce edible films (gels) that protect, for example, frozen products against dehydration (desiccation).

4.5.6.4 Callose

Callose is an amorphous β-(1→3) glucan accompanying cellulose in plant cells walls, but it is less common than cellulose. Most plants synthesise this polysaccharide in response to injury or only at certain stages of development of cell walls. The basic building unit of callose is disaccharide laminaribiose, β-D-glucopyranosyl-(1→3)-D-glucopyranose (**4-149**).



4-149, callose

β-D-Glcp-(1→3)-β-D-Glcp-(1→3)-β-D-Glcp-(1→....

4.5.6.5 Hemicelluloses

The term hemicellulose is a common name for non-cellulose structural polysaccharides of cell walls of plants that fill the spaces between the cellulose fibres (Figure 4.17). Hemicelluloses include two main groups of polysaccharides:

- **heteroglucans**
- **heteroxylans**.

Plant cell walls contain a large number of other polysaccharides that can be included under the term dietary fibre. Other important hemicelluloses are **heteromannans** (galactomannans and glucomannans) that are present in lower amounts in plant cell walls. They constitute about 12–15% of cell wall polysaccharides in the flowering plants (angiosperms). Their role as the building components of cell walls is still not well known. In larger quantities, heteromannans are present in some legume seeds, where they have the function of storage polysaccharides. Structures of heteromannans are illustrated by formulae **4-143** and **4-144**.

4.5.6.5.1 Heteroglucans

The main structural heteroglucans that are classified as hemicelluloses are:

- **xyloglucans**
- **β-glucans**.

Xyloglucans

The basic structural unit of the xyloglucan molecule is β-D-(1→4)-glucan (cellulose), with units of D-xylopyranose in side chains that are bound to glucose by α-(1→6) glycosidic bonds. Unlike the related reserve xyloglucans present in seeds of plants (**4-145**), structural xyloglucans contain the residue of D-galactose bound to D-xylose near the reducing end of the polysaccharide, which is bound by β-(1→2) bonds. They may also contain L-fucopyranose linked to an L-galactose by an α-(1→2) bond (**4-150**).

Xyloglucans of the hemicellulose type (structural xyloglucans) are the dominant hemicelluloses of cell walls of dicotyledons (dicots), plants that include most vegetables, root crops, legumes and fruit trees. The xyloglucans content is a characteristic of various tpyes of fruits. For example, their content in strawberries is 14.6–15.9 g/kg depending on the variety, cultivation and degree of maturity. Xyloglucans are therefore a good indicator of the amount of fruit present in various products, for example in fruit yoghurts.

Xyloglucans are present in small amounts in monocotyledon plants (monocots) that include some vegetables (e.g. onion, garlic and asparagus) and, especially, cereals. The greater portion of the xyloglucans is a component of insoluble fibre.

β-Glucans

Polysaccharides known as β-glucans or β-(1→3), (1→4)-D-glucans or mixed linkage β-glucans (formerly lichenins) are found in negligible amounts in the cell walls of dicot plants, but in larger quantities are present in the cell walls of cereals, where they constitute up to 30% of dry matter of non-starch polysaccharides. While their content in wheat and rye is only 0.2–2% by weight of grain and 1–2% in unhulled rice, the European and American varieties of oats contain 3.2–6.8% of β-glucans and their content in barley is 3–7%. Some cultivars of barley contain even 14–16% of β-glucans.

The oat bran contains β-(1→3), (1→4)-D-glucan, which is also called oat gum. Typical β-glucans for barley have two or more neighbouring (1→4) linkages (**4-151**). β-D-Glucans contain small quantities of arabinosyl and xylosyl residues. The relative molecular weights of β-glucans vary over a wide range, according to their origin, from tens to thousands of kilo daltons. Similar polymers, also called β-glucans or β-(1→3), (1→6)-D-glucans or mixed linkage β-glucans, are synthesised by higher fungi, moulds and yeasts.

β-Glucans can be partly soluble or partly insoluble dietary fibre. Solubility in water to give viscous solutions depends on their structure, which is related to the origin and decreases in the order:

4-151, basic structure of mixed linkage β-glucans containing (1→3), (1→4) bonds

barley > oats > wheat. The more (1→4) bonds is in the molecule, the lower is the solubility of the polymers. More soluble polymers contain about 30% of (1→3) bonds and 70% of (1→4) bonds, and their chain is composed of 2–3 units of β-D-glucose linked by (1→4) bonds, between which is located a unit linked by a (1→3) bond. Solubility of β-glucans increases with temperature. For example, at 40 °C only about 20% of barley β-glucans can be extracted, while at 65 °C this amount increases to 30–70% (β-glucans of wheat are not extracted at this temperature). Native molecules do not form gels; however, a gel is formed after partial hydrolysis. β-Glucans bound to proteins are insoluble.

β-Glucans are particularly important in brewing technology. Their content in malting barley is 0.2–1% and varies according to a variety of climatic conditions, storage period and other factors. During mashing, water-soluble fractions of β-glucan are extracted, the accompanying proteins are hydrolysed by carboxypeptidases and initially insoluble substances are dissolved. β-Glucan molecules are hydrolysed by *endo*-β-(1→3), (1→4)-glucanase, *endo*-β-(1→3)-glucanase and β-glucosidase (laminarinase). The intermediates are soluble mixed linkage β-glucan dextrins and dextrins with β-(1→3) bonds. The final products are cellobiose, laminaribiose and glucose. The mashing temperature must not inactivate the enzymes hydrolysing the β-glucans, as native (undegraded) β-glucans can cause various problems in the production of beer. They prevent sedimentation of solid particles in the wort; beer filtration is complicated an unfiltrable haze or sediments can form in beer as a result of aggregation of β-glucan molecules among themselves or with other polymers, such as proteins and polyphenols.

β-Glucans of oats and barley reduce the bioavailability of feeds, which results in lower weight gain in poultry.

4.5.6.5.2 Heteroxylans

Structure

The main chain of heteroxylans consists of D-xylanopyranose units mutually linked by β-(1→4) bonds. The terminal unit is α-L-arabinofuranose. Most of xylose chain units are not substituted, although there is some substitution by α-L-arabinofuranose linked

4-152, basic structure of arabinoxylans of cereals

by (1→3) bonds and less often by (1→2) bonds. Xylose is often substituted by two molecules of arabinofuranose (at C-2 and C-3), which forms short side chains connected by (1→2), (1→3) or (1→5) bonds (**4-152**). Some heteroxylans, such as heteroxylans from cereal brans, are acetylated on C-2 of the xylose residues. Heteroxylan molecules also contain sections in which xylose units are substituted twice, once or are unsubstituted. For example, wheat endosperm contains heteroxylans with xylose units substituted in position C-2 and C-3 (about 12–20%), xylose units (19–31%) substituted once (at C-3) and unsubstituted xylose units (55–69%). Rye heteroxylans contain chain segments exclusively substituted at C-2 and a smaller number of segments containing disubstituted xylose residues at C-2 and C-3.

With regard to the primary structure, these heteroxylans are called **arabinoxylans** and often also **pentosans**. The name is not very logical, because in addition to arabinose and xylose, these heteroxylans contain D-glucose and some other minor hexose building units such as D-galactose, D-glucuronic acid and its 4-*O*-methyl derivative, as well as some other sugars that are rarely found as terminal units in the side chains. The average xylose content is 52–60%, arabinose content is 36–46% and glucose content is 1.5–4.8%.

Arabinoxylans of various cereals differ not only in how the xylan chains are substituted, but also have different arabinose contents or ratios of these two sugars. The ratio of arabinose and xylose in wheat arabinoxylans varies from 0.50 to 0.71 and in less substituted rye arabinoxylans it ranges from 0.48 to 0.55. D-Glucuronic acid and its 4-*O*-methyl ether are found mainly in arabinoxylans of husked rice, rice hulls (husks), sorghum and maize brans. For example, these arabinoxylans, sometimes also referred to as **arabinoglucuronoxylans**, constitute about 4% of barley bran by weight.

A special feature is the presence of ferulic acid (its *cis*- and *trans* isomers in a ratio of about 1 : 1), which is 0.1–0.2% by weight of arabinoxylans. Ferulic acid is bound by an ester linkage at C-5 of the arabinose residue, which is connected to the C-3 of the xylose residue. In the secondary cell walls, ferulic acid forms ethers, C–C dimers and addition products with thiol residues of proteins, which play an important role in the development of cross-links between arabinoxylan molecules and other components of cell walls (Figure 4.18). Ferulic acid in lignified cells is bound to lignin. Proteins are also present (0.9–3.9% by weight) as in a number of other polysaccharides.

The average molecular weight of arabinoxylans of wheat ranges from about 220 to 260 kDa and of rye arabinoxylans from 520 to 770 kDa. The arabinoxylan molecules are relatively rigid long chains resembling cellulose chains. There is a clear link with the considerable viscosity of the dispersion and high ability to bind water.

Occurrence

Heteroxylans are the main polysaccharides of primary cell walls of vegetative parts of monocot plants and of lignified cells of monocot and dicot plants that are very important components of human diet. They occur in the stems of plants and in larger quantities in

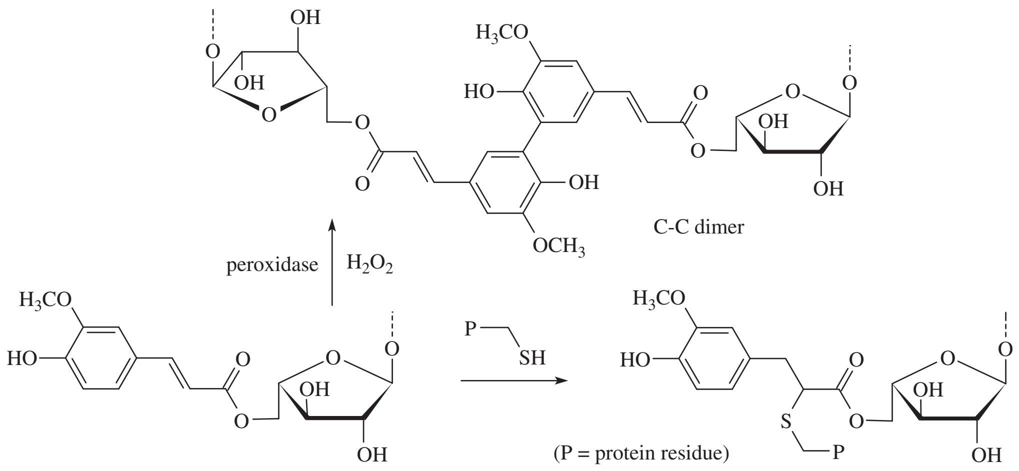

Figure 4.18 Reactions of ferulic acid residues in arabinoxylans.

maize ears that contain seeds (20–35%) and in wood mass (20–30% of dry matter).

In foods heteroxylans are mainly present in cereals, found in thin endosperm cell walls, the aleurone layer and lignified bran cells. The endosperm cell walls of most cereals contain 60–70% arabinoxylans, with 20% in barley and 40% in rice. Glumes (husks) of wheat grains contain about 64% heteroxylans. Wheat grains contain on average 1.4–2.1% of heteroxylans, of which 0.8–1.5% represent water soluble pentosans. Rice grains contain 7–8% heteroxylans.

Properties

Arabinoxylans have high water binding capacity (15–100 g of water per 1 g of dry matter). Some fractions are soluble in water and form extremely viscous dispersions. The differences in solubility depend on the degree of branching; therefore soluble molecules are more branched. In the presence of oxidising agents, arabinoxylans form soft and elastic gels. Ferulic acid bound in arabinoxylans plays a key role in their formation.

Soluble arabinoxylans are important components of wheat and particularly of rye flour. They have considerable influence on water uptake (hydration) by the flour and its distribution in the dough, the dough viscosity and its rheological properties. Other desirable baking properties of flour also depend on the presence of arabinoxylans (e.g. larger bread volume as a result of carbon dioxide retention, reduced rate of starch retrogradation connected with aging of bread and pastries, impact on desirable organoleptic properties of bread crust). Reaction products of water-soluble pentosans, especially reactions of ferulic acid with cysteine residues of gluten proteins, significantly contribute to the desirable rheological properties of dough, but water insoluble pentosans deteriorate the baking properties of flour. Like many other polysaccharides, arabinoxylans positively influence the composition of colon microflora.

4.5.6.6 Pectins

The general term **pectin**(s) or **pectic** (pectin) **substances** now refers to previously differentiated categories, which were polygalacturonates with higher amounts of methoxyl groups (**pectinic acids**), their salts **pectinans**, non-esterified polygalacturonates known as **pectic acids** and their salts **pectates** and the accompanying neutral polysaccharides (arabinans and arabinogalactans of different structures). Native, insoluble cell wall pectins associated with cellulose are known as **protopectins** (formerly pectoses). Enzymatic hydrolysis, by the enzyme complex protopectinase, converts protopectins into more or less soluble pectin substances with shorter chains, for example during fruit ripening.

Pectins are a group of highly polydisperse, complex, acidic polysaccharides of alternating chemical composition. They occur in all tissues of higher plants, except monocots, as part of the primary cell walls and intercellular space (Figure 4.17). Pectins are formed and stored mainly in the early stages of growth, when the area of the cell walls increases. The presence of pectins and their changes during growth, maturation, storage and processing have a major impact on the texture of fruits and vegetables.

4.5.6.6.1 Structure

A pectin molecule consists of three domains: homogalacturonan, rhamnogalacturonan I and rhamnogalacturonan II. These three polysaccharides are bound together by covalent bonds.

The basic structure of homogalacturonan consists of a linear chain composed of 25–100 units of D-galacturonic acid linked by α-(1→4) bonds. This polymer is often called **polygalacturonic acid**. Galacturonic acid units are, in various degrees (70% in average), esterified with methanol so they do not have any electrical charge, while the remaining units contain dissociated carboxyl group and are negatively charged. These carboxyl groups located in different chains can be cross-linked by calcium ions. Some α-D-galactopyranuronates or methyl α-D-galactopyranuronates are acetylated at positions C-2 or C-3 (**4-153**), which increases the polysaccharide hydrophobicity. Pectins of the goosefoot family of plants (Amaranthaceae, formerly Chenopodiaceae), such as spinach, also contain small amounts of ferulic acid linked by ester

bonds to neutral sugars (arabinose and galactose), similar to in arabinoxylans.

The degree of esterification (methylation) is defined as a percentage of esterified carboxyl groups. If the degree of methylation exceeds 50%, then the pectin is called **highly methoxylated** or **highly esterified** pectin. If the degree of methylation is lower than 50%, the pectin is called **low methoxylated** or **low esterified** pectin. The degree of acetylation is generally low, but sugar beet pectin contains a higher amount of acetyl groups (Table 4.32).

Rhamnogalacturonan I (degree of polymerisation is about 1000) contains chains of repeating units of α-D-galacturonic acid ($^{4}C_1$ conformers) with terminal α-L-rhamnopyranose linked by α-(1→2) bonds that correspond to the disaccharide residue α-D-Gal*p*A-(1→2)-α-L-Rha*p*-(1→4)-. The total content of rhamnose in pectin is 1–4%. Galacturonosyl and rhamnosyl residues are approximately in the ratio of 2 : 1 (**4-154**). Some units are methylated galacturonic acid molecules (4-*O*-methyl-D-galacturonic acid). About half of the rhamnosyl residues contain a galacturonic acid residue at C-4.

Molecules of rhamnogalacturonans I also contain a significant amount of branched side chains with a considerable number of arabinose and galactose units (**4-155**). These chains have the structure of **arabinans** and **arabinogalactants**. The side chains are attached to the main chain through a rhamnose molecule at C-4 or C-3, or less frequently through C-2 or C-3 of galacturonic acid. Pectins with type I arabinogalactans have been found in a number of fruits and vegetables. Apple pectins have 25–100% of rhamnosyl residues substituted by arabinose and galactose units, while carrot pectin substitution is 10–50%. About 32% of galacturonosyl residues of potato pectin and up to 75% of galacturonosyl residues of rapeseed pectin are branched.

Table 4.32 Content of galacturonic acid (GalA), degree of methylation (DM) and degree of acetylation (DA) of selected pectins.

Pectin source	GalA (%)	DM (%)	DA (%)	Pectin source	GalA (%)	DM (%)	DA (%)

Grapes	63	69	2	Sugar beet	65	62	35

Arabinans and galactoarabinans of rhamnogalacturonan I create the so-called hair regions of the pectin molecule, while smooth (unsubstituted) regions consisting of polygalacturonic acids in homogalacturonan are binding zones. Rhamnose is a sugar incompatible with the regular conformation of polygalacturonates; therefore its location in the chain determines the size of bonding zones that play a crucial role in the formation of pectin gels.

4-155, general structure of arabinans in side chains of polygalacturonan I

Rhamnogalcturonan II is a low molecular weight polymer (degree of polymerisation is about 60 and relative molecular weight is about 4.8 kDa) with a chain consisting of α-D-galacturonic acids linked by α-(1→4) bonds. Different side chains composed of α- and β-D-galactopyranuronic acids, α- and β-D-rhamnopyranoses, α-D-galactopyranose, α-L-fucopyranose, α-L-arabinopyranose, β-L-arabinofuranose, α-D-xylopyranose and D-glucopyranuronic acid are connected to this main chain. The side chains also contain

four unusual sugar residues derived from 3-*C*-(hydroxymethyl)-β-D-erythrofuranose known as β-D-apiofuranose (β-D-Api*f*, 4-19), 3-*C*-carboxy-5-deoxy-β-L-xylofuranose (β-L-Ace*f*A, aceric acid, **4-83**), 3-deoxy-β-D-*lyxo*-hept-2-ulopyranaric acid (β-D-Dha*p*, **4-84**) and 3-deoxy-β-D-*manno*-oct-2-ulopyranosonic acid (β-D-Kdo*p*, from the previously used trivial name **keto****d**eoxy**o**ctonic acid; **4-85**). Xylose and fucose partly occur as 2-*O*-methyl ethers (**4-157**; anomeric configuration of the terminal L-galactopyranose is not known). The rings of rhamnogalacturonan II are furthermore cross-linked by boric acid, $B(OH)_3$ (borate ions), covalently bound to the *cis*-hydroxyl groups at positions C-2 and C-3 of the apiose molecules located in different chains of rhamnogalacturonan II. Therefore, this part of the pectin molecule is present predominantly as a dimer (see Section 6.3.18). The overall arrangement of pectin chains, indicating the binding zones responsible for the formation of gels, is shown schematically in Figure 4.19.

4.5.6.6.2 Occurrence

Pectins are found in virtually all fruits and vegetables. Their content is not high; in fruit flesh it varies around 1%. Higher amounts of pectin occur, for example, in apples, plums, damsons, currants, gooseberries, quinces and cranberries, while lower amounts are found in cherries, sour cherries, blueberries and elderberries (≤0.5%). Vegetables generally contain low levels of pectin; there the higher amounts are in tomatoes and carrots. Sugar beets also have a higher pectin level. The pectin content of some fruits and vegetables is given in Table 4.33.

4.5.6.6.3 Properties

Pectins are generally soluble in water and insoluble in most organic solvents. Water solubility decreases with increasing molecular weight and degree of esterification of the carboxyl groups (highly esterified pectins dissolve in hot water). Salts of polygalacturonic acids are generally more soluble than free acids (salts with monovalent ions are more soluble than calcium salts; salts of low esterified pectins are soluble in cold water).

Pectin dispersion has a relatively low viscosity and therefore pectin is not used as a thickener. The viscosity of highly esterified pectins is increased by adding saccharose, and that of low esterified pectins increases in the presence of Ca^{2+} ions. Both types of pectins form gels under convenient conditions.

Formation of gels

The mechanism of gel formation depends on the degree of pectin esterification. Highly esterified pectins form gels with sugar in acidic solutions. Sugar binds water, thus reducing the degree of hydration of the pectin. Acids suppress the dissociation of carboxylic acid groups. The higher the degree of esterification, the smaller the amount of acid necessary, therefore totally esterified pectins form gels with sugar only. Fast gelling pectins form gels at pH $\cong$ 3.3, slowly gelling pectins form gels at pH $\cong$ 2.8. These gels are thermoreversible. Low esterified pectins (<50% of esterified carboxyl groups) form gels only in the presence of Ca^{2+} ions. Gelatinisation depends on the temperature, pH, ionic strength and amount of added calcium. Under acidic conditions (pH $\cong$ 3.5), higher amounts of calcium ions are needed than in less acidic solutions. Gels of low esterified pectins are also thermoreversible.

Pectin molecules have a negative electrical charge in a neutral environment (p$K \cong$ 3.5), and therefore react with polymers carrying positive charges, such as proteins (in solutions of pH < pI). Under acidic conditions, pectin stabilises casein, which allows heat treatment of fermented dairy products. The interaction of pectin with plant proteins affects the consistency and texture of fruit products.

Firmer thermoreversible gels arise in the presence of sodium alginate in acidic solutions (pH < 3.5), in the presence of low amounts of sugar and in the absence of calcium ions. Mechanical properties of these mixed gels depend on the ratio of pectin to alginate, and the degree of pectin esterification. Alginates with higher guluronic acid content form stable gels in combination with pectin with a degree of esterification of about 70%.

Changes and reactions

Hydrolysis of pectin substances proceeds by the action of enzymes and in acidic or alkaline solutions. A number of native enzymes and enzymes produced by microorganisms are involved in the enzymatic hydrolysis of pectins of fruits and vegetables. Two groups of enzymes can be distinguished:

- **pectinesterases**
- **pectin depolymerases**.

Pectinesterases (pectinmethylesterases or pectinpectylhydrolases) catalyse the hydrolysis of methyl esters to low esterified pectins, also known as pectic acids (Figure 4.20). The resulting acids react with the naturally present divalent ions, which may

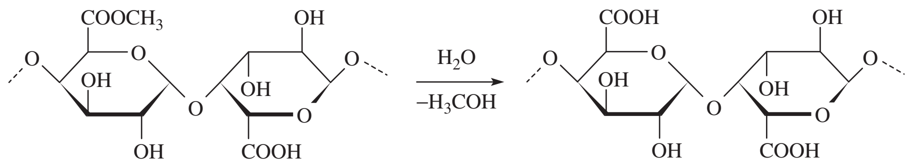

Figure 4.20 Reaction catalysed by pectinesterases.

lead to spontaneous gelling (in fruit juices) or hardening (in the processing of potatoes or cauliflower). Pectinesterases are present in various fruits and vegetables and are particularly active in cherries, citrus fruits, tomatoes and carrots. Also described are pectinacetylesterases splitting off acetyl groups in the smooth regions of pectin and rhamnogalacturonan acetylesterase that catalyses the same reaction in areas of branching. Together with rhamnogalacturonase, the latter enzyme also splits oligosaccharides containing rhamnose.

Enzymes hydrolysing glycosidic bonds (pectin depolymerases) are glycosidases and lyases. Glycosidases, termed polygalacturonases or poly-α-1,4-D-galacturonid glycanohydrolases, hydrolyse α-(1→4) glycosidic and ester bonds. Exoenzymes split off monomers from the end of the chain, while endoenzymes operate within the chain. The products of hydrolysis are either monomers or oligomers with variable chain lengths. Polymethylgalacturonases cleave highly esterified pectins; polygalacturonases break down completely (or almost completely) deesterified pectins (Figure 4.21). These enzymes are found in higher plants and microorganisms.

Pectate lyases (poly-α-1,4-D-galacturonid lyases) are also divided into exo- and endoenzymes. They degrade esterified or non-esterified pectins by a different mechanism to glycosidases, which is known as β-elimination (Figure 4.22). Pectate lyases are typical bacterial enzymes. Pectin lyases (poly-α-1,4-D-methoxygalacturonid lyases) cleave the glycosidic bond between esterified galacturonic acids by β-elimination (Figure 4.23). Only fungi produce pectin lyases.

Pectolytic enzymes usually act in combination. The enzyme exhibiting the activities of pectinesterase and polygalacturonase is sometimes referred to as pectinase. Industrially used pectinases are of bacterial origin, and often also have the activity of lyase, protease, cellulase and of other glycosidases.

Pectin is relatively stable under acidic conditions and its stability is highest in the pH range of 3–4. Hydrolysis of methoxyl and acetyl groups and hydrolysis of glycosidic bonds occurs in strongly acidic solutions. Free D-galacturonic acid can degrade to furan-2-carbaldehyde and other products. At elevated temperatures, hydrolysis of pectin occurs even in weakly acidic solutions (pH > 5); the polysaccharide chain is cleaved by β-elimination.

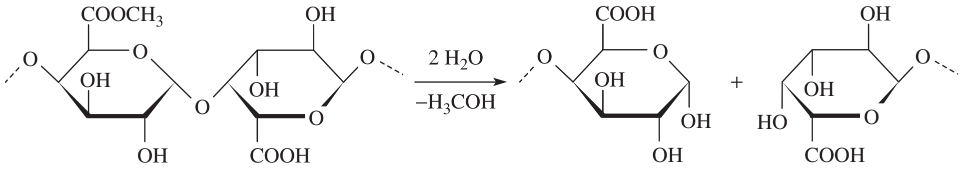

Figure 4.21 Reaction catalysed by polygalacturonases.

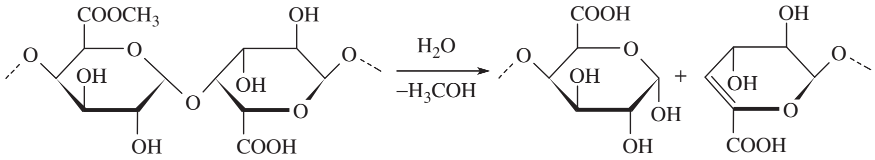

Figure 4.22 Reaction catalysed by pectate lyases.

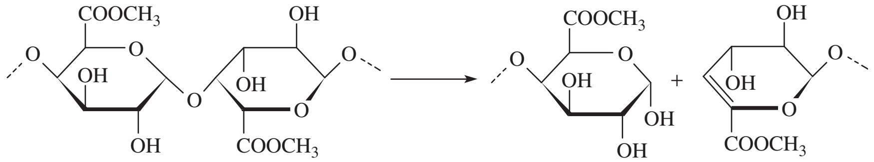

Figure 4.23 Reaction catalysed by pectin lyases.

This reaction is also important in alkaline solutions, where ester bonds are mainly hydrolysed and this reaction is accompanied by depolymerisation of the polysaccharide chains (β-elimination). The depolymerisation reaction occurs at the glycosidic bond of the non-reducing methoxylated galacturonic acid residue (Figures 4.22 and 4.23). Pectic acids are not depolymerised.

Treatment of a suspension of pectin in ethanol with ammonia yields **amidated pectin** that contains $-CONH_2$ functional groups. The degree of amidation is around 20%. Amidated pectin has a higher affinity for calcium ions in comparison with low esterified pectins.

4.5.6.6.4 Physiology and nutrition

Pectin belongs to the polysaccharides that form dietary fibre, which affects glucose metabolism and decreases the amount of cholesterol in the blood serum. Pectin, with a higher content of methoxyl groups, is more effective.

4.5.6.6.5 Significance and use

Insoluble pectic substances produce the hardness and strength of immature fruits and vegetables. During maturation, post-harvest storage and processing, these substances are subject to enzymatic and non-enzymatic degradation, which results in softening of fruits and the loss of the gelling ability of pectin. Pectins are released from complex polysaccharides that form the cell walls and this process continues after harvest during storage. Fruits containing active *endo*-polygalacturonases and pectinmethylesterases soften significantly and so quickly that this process often becomes an economic problem (e.g. in pears, cherries, kiwi and tomatoes). Softening is less pronounced in fruits containing only *exo*-polygalacturonases (apples, peaches). Changes during processing are suppressed by heat inactivation of pectolytic enzymes and by the addition of monovalent (softening) or bivalent (texture hardening) cations. Bivalent ions (such as Ca^{2+} ions) protect pectins against depolymerisation, which results in a firmer texture of the tissues; monovalent cations displace divalent ions, which have the opposite effect.

Pectins are also responsible for the consistency of sterilised fruits and vegetables, for the pressability of oilseeds, the filterability of fruit juices and the formation of hazes in fruit juices. Some manufacturing processes, for example in the canning industry, use pectolytic enzymes of microbial origin to increase the yield in the production of fruit juices and to maintain their clarity. Pectolytic preparations have also found use in the oenological industry, sugar industry and other sectors.

In industrial practice, pectins are mostly extracted from citrus fruit peels (their albedo), which contain about 20–40% of pectin. Another source of pectin is apple pomace, containing about 10–20% pectin. The isolation of pectin is based on extraction from an acidified aqueous slurry (pH 1.5–3) at temperatures of 60–100 °C. The extracts are then concentrated by evaporation or dried. Commercial pectin products are obtained by precipitation using metal ions that form insoluble salts with pectin (e.g. Al^{3+}), or by precipitation of pectin solutions with alcohols (ethanol or propan-2-ol).

4.5.6.7 Accompanying substances

Cellulose and other structural polysaccharides of cell walls are associated with different polymeric non-sugar materials that fix and firm the cell walls and also form their outer hydrophobic layers, which are impermeable to water. In nutrition, they are classified as dietary fibre. According to their chemical composition, substances accompanying polysaccharides are classified as lignin, phenolic compounds (tannins), proteins or lipids.

4.5.6.7.1 Lignin

Occurrence

The structural polymer lignin is a major component of wood, where it makes up to about 25% of the biomass. Shelled nuts also have a similar amount of lignin. In lower amounts, lignin is a constituent of the dietary fibre of fruits, vegetables and cereals (Table 4.20). Primary cell walls are virtually free of lignin. A high content of lignin is found in lignified secondary cell walls, such as aleurone and subaleurone cells of cereals (in bran), which contain around 8% lignin. Lignin occurs in small amounts (tens to hundreds of mg/l) in spirits aged in oak barrels, where it is extracted from wood.

Lignin is a copolymer of phenylpropanoid units known as **monolignols**, which may include, according to the type of plant, 4-coumaryl alcohol, coniferyl alcohol (also known as ferulyl alcohol), 5-hydroxyconiferyl alcohol and sinapyl alcohol (**4-158**). These fenylpropanoid units (dominating structures are *trans*-isomers) are bound irregularly into three-dimensional structures by ether bonds (C–O–C) or bonds between two carbon atoms (C–C) and form the corresponding types of lignin (4-hydroxycoumaryl lignin, guaiacyl lignin, 5-hydroxyguaiacyl lignin and syringyl lignin). Also involved in the lignin biosynthesis are monolignol glucosides,

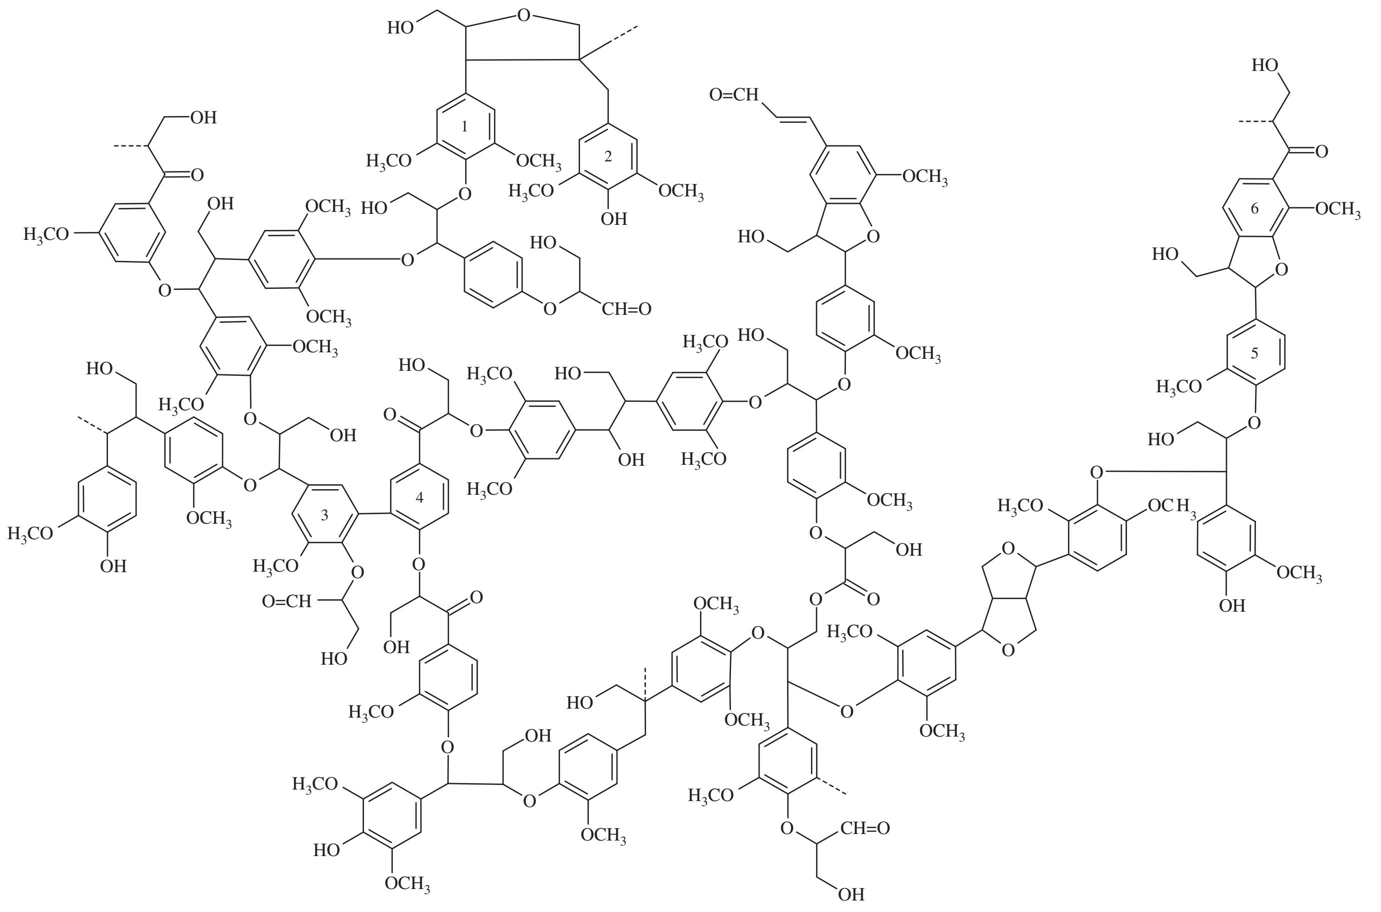
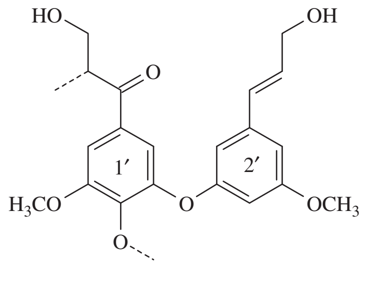
4-159, monolignol glucosides

coniferin, R = H
syringin, $R = OCH_3$

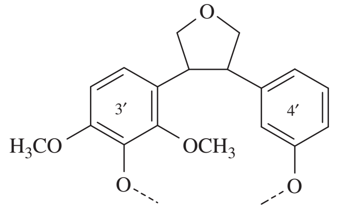


4-160, basic structure of lignin

aldehydes derived from monolignols and glucosides of these aldehydes. The most common monolignol glucosides are 4-*O*-β-D-glucopyranoside of (*E*)-coniferyl alcohol, known as coniferin, and 4-*O*-β-D-glucopyranoside of sinapyl alcohol, or syringin (**4-159**). The structure of birch wood lignin is given as an example (**4-160**). Dilignols 1′-2′ (**4-161**), 3′-4′ (**4-162**) and 5′-6′ (**4-163**) can replace the corresponding structural units 1-2, 3-4 and 5-6 with an incidence of 40, 50 and 10%.



4-161, alternative structures 1-2 in lignin (see **4-160**)



4-162, alternative structures 3-4 in lignin (see **4-160**)

Physiology and nutrition

The digestive system does not decompose lignin, and only cleaves the bonds between lignin and other polymers.

Use

During maturation of wines and spirits in oak barrels, lignin is decomposed to phenolic compounds that act as significant flavour-active components of these commodities. Phenolic components are also formed by pyrolysis of lignin in wood that is used in the process of smoking, and therefore are also found in smoked meat products and other smoked foods as well as in liquid smoke used for both food preservation and flavouring.

4.5.6.7.2 Other polymers

In addition to lignin, plants also contain structurally similar types of phenolic polymers, which are classified as **tannins** (see Section 8.3.6).

The best known structural protein of cell walls of plants is **extensin**, which is present in cells at levels of about 0.5–5%. Extensin is a glycoprotein with an unusual amino acid composition. It contains about 40% hydroxyproline and a large proportion of lysine and serine. Octasaccharides and decasaccharides composed of arabinose and galactose are bound through hydroxyamino acids, and phenolic compounds are bound through tyrosine molecules forming cross-links in the extensin molecule. Other structural proteins are present in smaller quantities, but may have an important function in building cell walls, as a connecting material with lignin.

Further components of dietary fibre are lipidic materials on the surface of cell walls that are composed of **waxes**, **cutin** (a cross-linked hydroxy fatty acid polyester) and **suberin** (a polyester composed of higher ω-hydroxy acids, α,ω-dicarboxylic acids, fatty acids and fatty alcohols, which also contains ferulic acid).

4.5.6.8 Plant gums and mucilages

Plant exudates, known as **vegetable gums**, are usually sticky juices flowing spontaneously from plant tissues as a result of different stress factors, especially the attack of microorganisms and injury. They eventually solidify in a solid gummy mass on contact with air. **Mucilages** are slimy secondary metabolites occurring in different parts (such as the fruits and seeds) of some plants. The basic chemical composition of gums and mucilages of some plants is shown in Table 4.34.

The polysaccharides of most important vegetable gums and mucilages are acidic polysaccharides. According to their primary structure, they may be divided into:

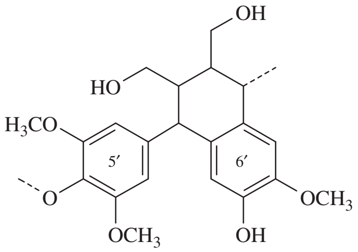
- substituted **arabinogalactans** (gum arabic, larch gum)
- mixed **arabinogalactans** and **glycanogalacturonans** (gum tragacanth)
- **glycanorhamnogalacturonans** (gum karaya)
- **glycanoglucuronomannoglycans** (ghatti gum)
- **glycanorhamnogalacturonans** (okra).

Vegetable gums and mucilages are highly hydrophilic, water-soluble polysaccharides. They are significantly polydisperse, branched and of very non-uniform structure. They are ranked among the hydrocolloids, but the low molecular weight fractions form true solutions. Dispersions or solutions are viscous, and in some cases gels may also arise. Plant gums often include non-starch storage polysaccharides of some seeds and tubers, such as guar, locust, tamarind and konjac gums.

4.5.6.8.1 Gum arabic

Occurrence

Gum arabic (also called acacia gum) is hardened exudate from acacia tree species, in particular from *Acacia senegal* and *Acacia seyal* (Fabaceae), growing mainly in Senegal, Nigeria and West African countries. There are over 100 different acacia gums, but the structural differences between them are small.



4-163, alternative structures 5-6 in lignin (see **4-160**)

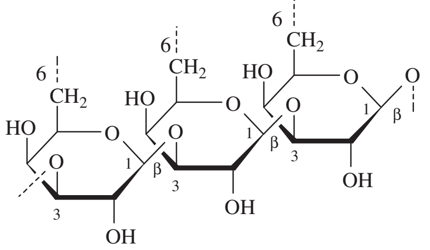
4-164, basic structure of gum arabic

Structure

Gum arabic is a substituted acid arabinogalactan. The basic building units are β-D-galactopyranose (the side chains also contain α-D-pyranose in small amounts), L-arabinose (α-furanose with small amounts of β-pyranose) and α-L-rhamnopyranose. β-D-Glucuronic and 4-*O*-methyl-β-D-glucuronic acids are present at lower levels. The gum from *A. senegal* contains around 44% galactose, 27% arabinose, 13% rhamnose and about 16% uronic acids (glucuronic and 4-*O*-methylglucuronic acids). In various types of acacia (*A. senegal*, *A. seyal*, *A. arabica*, *A. drepanolobium*, *A. karroo* and *A. sieberana*), the individual sugars are present over a relatively wide range of concentrations (Table 4.34).

The main polysaccharide chain consists of β-D-galactopyranose units linked by (1→3) glycosidic bonds. Side chains, often repeatedly branched like amylopectin, occur in all residues of β-D-galactopyranoses of the main chain. β-D-Galactopyranose, linked to the main chain by β-(1→6) bonds and mutually by β-(1→6) and β-(1→3) bonds, predominates in the side chains. The abbreviated notation of a segment of gum arabic molecule originating from the plant *A. senegal* is given in formula **4-164**, which represents one of many possible structures. Some major segments of the molecule are shown in formulae **4-165** to **4-167**.

The relative molecular weight ranges from about 260 to 1200 kDa, but there are also polymers with molecular weights of several tens to 2 300 kDa. Molecules are spherical globules with a twisted main chain. Associated with the gum is a protein (1.5–3%), containing as the main amino acids hydroxyproline, serine and proline, bound by covalent bonds through arabinose in the side chain to hydroxyproline hydroxyl group.



→ 3)-β-D-Galp-(1→3)-β-D-Galp-(1→3)-β-D-Galp-(1→

4-165, main chain fragment of gum Arabic

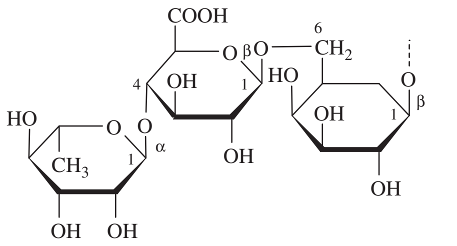
4-166, secondary chain fragment of gum arabic



α-L-Rhap-(1→4)-β-D-GlcpA-(1→6)-β-D-Galp-(1→

4-167, secondary chain fragment of gum arabic

Properties

The advantage of gum arabic is its very good solubility in water to dispersions of low viscosity. Dispersions containing 40% gum behave as Newtonian fluids, and dispersions of higher concentration of gum behave as pseudoplastic systems (due to aggregation of the molecules). Viscosity is, as in all other polyelectrolytes (acidic polysaccharides), strongly influenced by the pH of the medium and the presence of electrolytes (salts). Maximum viscosity is achieved at pH 4.5–8.0, but the presence of electrolytes decreases the viscosity. In the presence of sugar, concentrated solutions (approximately 40–50%) of gum arabic form soft gels; however, gels are not formed at commonly used concentrations.

Use

The ability of gum arabic to form concentrated dispersions (up to 50%), without significantly increasing their viscosity, is used for stabilising and emulsifying various food systems. The gum stabilises emulsions of oil-in-water as it is firmly adsorbed on oil droplets due to proteins bound to polysaccharides. In ice cream, gum arabic helps to maintain a smooth consistency (formation of small crystals), and in confectionery it prevents the crystallisation of sugars and wetting of icings. Gum arabic can also be combined well with other gums, starches, gelatine and sugars.

4.5.6.8.2 Larch gum

Occurrence

An industrial source of larch gum is the western larch (*Larix occidentalis*, Pinaceae), native to the mountains of western North America, whose wood contains up to 35% galactoarabans; these are obtained by extraction with hot water. Some other types of larch trees (*L. lyallii*, *L. sibirica*, *L. laricina* and *L. leptolepis*) have similar gums. Some species of pines, firs and other conifers may also be alternative sources.

Structure

Larch gum resembles the composition of gum arabic (arabinose content is usually 10–20%), but contains a lower amount of uronic acids. It consists of two fractions of nearly neutral arabinogalactans of different relative molecular weights (about 16 and 100 kDa). The main chain consists, as in gum arabic, of D-galactopyranose units linked by β-(1→3) bonds. The C-6 positions contain short side chains composed of arabinose and galactose (**4-168**).

Properties

Larch gum forms highly concentrated aqueous solutions (60%). It is stable in the pH range of 1.5 to 10.5, even in the presence of electrolytes.

Use

Larch gum is used in the food industry as a substitute for gum arabic. It is used also as a thickener and surfactant.

4.5.6.8.3 Tragacanth

Occurrence

The sources of tragacanth (also referred to as traganth, tragakanth, gum bassora or bassorin) are shrubs of the genus *Astragalus* (the common name milkvetch includes most species) belonging to the legume family Fabaceae. The most important plants are *A. gummifer*, *A. microcephalus* and *A. kurdicus*, growing in dry mountainous areas of Iran and Turkey.

Structure

Except for small amounts of starch and proteins (1.0–3.6%), tragacanth consists of two groups of polysaccharides. The first group is characterised by neutral arabinogalactans (so-called tragantin or tragacanthin), which represent about 60–70% of gum weight. Their structure is similar to that of larch gum. The main chain consists of units of D-galactopyranose linked by β-(1→4) bonds. Side chains

contain other units of D-galactopyranose linked by β-(1→6) bonds with terminal arabinose units attached to β-D-galactopyranose through (1→2), (1→3) and (1→5) bonds.

The second group of acidic polysaccharides of the pectin type (so-called tragacanthic acid or bassorin) consist of α-D-galacturonic acid (or its potassium salt) units linked by (1→4) bonds. Tragacanthic acid also contains small amounts of α-L-rhamnopyranose. Units of the main chain are either unsubstituted or substituted by β-D-xylanopyranose residues, or by short chains formed by xylose and β-D-galactopyranose that can be replaced by α-L-fucose (**4-169**). The side chain also contains D-glucuronic acid. Some sugars are acetylated and α-D-galacturonic acid is methylated analogously to pectin. The average molecular weight is 840 kDa.

Properties

The neutral fraction of tragacanth is soluble in water; acidic fractions only swell and form a thick slime or gel in the presence of Ca^{2+} ions. The viscosity of sols is high even at low concentrations, where the dispersion behaves as a Newtonian fluid (in the concentration range of from 0.3 to 0.5%). The pH value of solutions has little effect on viscosity and viscosity does not change under acidic conditions and even at pH 7–10. An important feature of tragacanth is its resistance to hydrolysis and mechanical stress.

Use

Tragacanth is used as a thickening agent, emulsifier and stabiliser in salad dressings, ice creams, pastry fillings and other products.

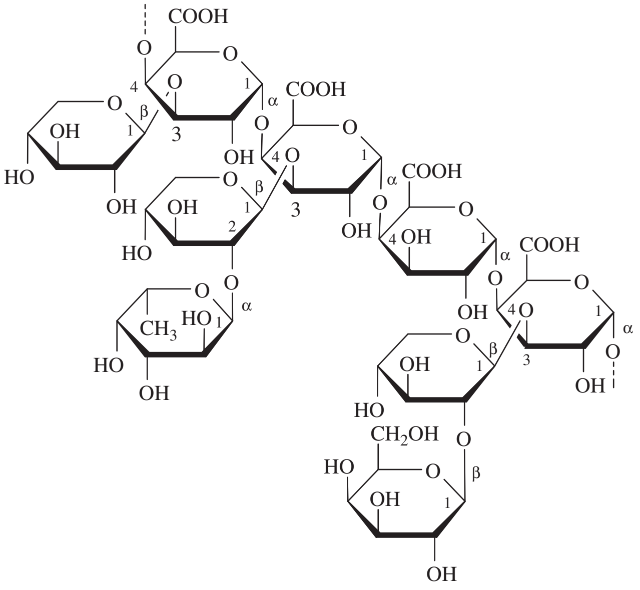
4.5.6.8.4 Gum karaya

Occurrence

Gum karaya (sometimes referred to as Sterculia gum) is a bark exudate of trees of the genus *Sterculia* (Sterculiaceae), mainly of *S. urens*, growing on the plateaus of central and northern India. Similar properties are found in some other species of the genus Sterculia, for example *S. setigera*, *S. caudata* and *S. villosa* or some species of the genus *Cochlospermum* of the Cochlospermaceae family.

Structure

Gum karaya is glycanorhamnogalacturonan. The main polysaccharide chain consists of alternating units of L-rhamnopyranose and D-galacturonic acid, which are connected by α-(1→4) and α-(1→2) glycosidic bonds. Units of the main chain are substituted by β-D-galactopyranose and β-D-glucuronic acid or remain unsubstituted. The end units are rhamnose, galactose and glucuronic acid; some units are partially acetylated (**4-170**). Gum karaya contains



··· →4)-α-D-Gal*p*A-(1→4)-α-D-Gal*p*A-(1→4)-α-D-Gal*p*A-(1→4)-α-D-Gal*p*A-(1→ ···

4-170, basic structure of gum karaya

calcium and magnesium ions bound to the carboxylic acid groups of glycuronic acids.

Properties

Gum karaya is very slightly soluble. At very low concentrations (<0.02% in cold water and 0.06% in hot water) it forms true solutions. Dispersions of a concentration of 0.3–0.5% show behaviour of newtonian liquids as well as dispersions of tragacanth, guar and locust gums. At higher concentrations (up to 5%), gum karaya forms viscous colloidal dispersions, which behave as non-Newtonian liquids.

Use

Gum karaya is used as a thickener for soups, sauces, ketchups and mayonnaise, as a substance that increases water binding capacity in processed cheese and meat products and for stabilisation of foams produced from proteins (egg white whipped cream or whipped cream). It is also used in the pharmaceutical industry.

4.5.6.8.5 Ghatti gum

Occurrence

Ghatti gum (also known as gum ghati or Indian gum) is an exudate of *Anogeissus latifolia* trees (Combretaceae) growing in arid regions of India, Ceylon and Africa (Ghana). The gum of *A. leiocarpus* has similar properties. Ghatti gum is not very significant commercially.

Structure

The molecule of glycanoglucuronomannoglycan (formerly called ghattic acid) is formed by periodically repeating residues of α-D-mannose and β-D-glucuronic acid, which are linked in the main chain through (1→4) and (1→2) bonds. The side chain contains mannose, to which is linked α-L-arabinofuranose by (1→6) bonds, and by (1→3) bonds β-L-arabinopyranose to which β-D-glucuronic acid or β-D-galactopyranose is bound (**4-171**). The average molecular weight is about 12 kDa. The gum of the *A. leiocarpus* tree contains two mutually different polysaccharides of similar composition. The minor component is leiocarpan A and the major component is leiocarpan B.

Y = β-D-GlcpA-(1→6)- or β-D-Galp-(1→6)-[β-D-Galp]$_n$-(l→···

3 ↑ X

4-171, basic structure of ghatti gum

Properties

The functional properties of ghatti gum are more similar to those of gum arabic than to viscous gums tragacanth and karaya. Ghatti gum has low solubility in water and does not form a gel. At concentrations lower than 5% it forms true solutions, and at higher concentrations viscous colloidal dispersions result.

Use

Ghatti gum, thanks to its higher viscosity, has found use as a stabiliser of emulsions and suspensions.

4.5.6.8.6 Okra and other plant mucilages

Plant mucilages are used in many eastern Mediterranean, West Asian and African countries, and are popular in Indian, Pakistani, Chinese, Malaysian, Japanese, Caribbean and many other cuisines as ingredients in soups and sauces, to which they give their characteristic mucilaginous consistency. The main representative of this group of polysaccharides is **glycanorhamnogalacturonan** that

comes from unripe fruits of edible hibiscus (*Abelmoschus esculentus*) of the mallow family (Malvaceae), which is known as **okra** (also bamie or gombo), and commonly known in many English-speaking countries as lady's fingers.

The basic structural unit of the main okra chain is acidic disaccharide →4)-α-D-Gal*p*A-(1→2)-α-L-Rha*p*-(1→. Side chains contain the disaccharide D-galactobiose, β-D-Gal*p*-(1→4)-β-D-Gal*p*-(1→, that is linked by (1→4) bound to about one half of the α-L-rhamnopyranose residues.

Okra polysaccharides are already viscous in diluted solutions (0.5%), and the viscosity increases rapidly with increasing concentration. Heating increases their solubility, but after some time leads to irreversible loss of viscosity caused by hydrolysis. The maximum viscosity is achieved at pH 6–9. Okra mucilage is a typical polyelectrolyte. It has hypoglycaemic effects.

Other acid mucilages of composition similar to that of okra (glycanorhamnogalacturonans) are **junsai**, originating from the leaves and stems of plant *Brasenia schreberi* (Cabombaceae), **baobab mucilage**, obtained from the leaves of baobab *Adansonia digitata* (Malvaceae) and **ruredzo** from the plant *Dicerocaryum zanguebarium* (Pedaliaceae). Slimy substances are produced by many other plants, but these mucilages are usually important locally and are not used commercially.

4.5.7 Seaweed polysaccharides

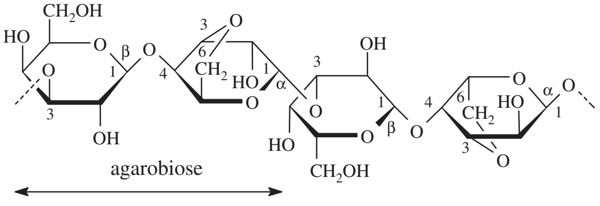
The most important representatives of this group of polysaccharides are:

- **agar**
- **carrageenans** and **furcellaran**
- **alginates** (alginic acid salts).

4.5.7.1 Agar

Agar forms an intracellular matrix of a number of species of red seaweed (Rhodophyceae) that plays a similar role in algae as cellulose does in higher plants. Algae, which are a source of agar (agarophytes), come mainly from the Gelidaceae, Gracilariaceae and Pterocladiaceae families, which grow on the coast of Portugal, South Africa, India, Japan, Mexico, Chile and New Zealand. Agarophytes are usually wild algae and are only grown in marine farms in Chile. Agar is obtained from algae usually by extraction with hot neutral, acidic or alkaline water (at a temperature higher than the melting point of the agar gel). Gels obtained from extracts are dried. Alkaline solutions cause partial hydrolysis of the sulfate groups, which results in modified agar properties.

The building units of linear polysaccharides agars are β-D-galactopyranose and 3,6-anhydro-α-L-galactopyranose alternately linked by glycosidic (1→3) and (1→4) bonds. The basic neutral polysaccharide is often still called **agarose** (by analogy with starch amylose). Its building block is disaccharide agarobiose, 4-*O*-β-D-galactopyranosyl-3,6-anhydro-α-L-galactopyranose (**4-172**). The structure of agars is in fact much more complex. Some polysaccharide fractions contain α-L-galactose instead of 3,6-anhydro-α-L-galactose. Hydroxyl groups at C-6 of β-D-galactose or at C-2 of α-L-galactose can be partially methylated. Hydroxyl groups at C-4 of β-D-galactose and at C-6 of α-L-galactose are esterified with sulfuric acid (the SO_4^{2-} ion concentration is up to about 7% w/w). These fractions also contain bound pyruvic acid (as acetal in positions C-4 and C-6 of β-D-galactose) in 4,6-*O*-(1′-carboxyethylidene)-D-galactose, the concentration of which is 0.02–1%. These fractions also contain about 1% of D-galacturonic acid. Previously, these acidic agar fractions were known as **agaropectin** (by analogy with amylopectin). According to recent studies, up to 18% of total sugars in some agars represent D-xylopyranose molecules substituted in some units of the main chain.



·· →3)-β-D-Gal*p*-(1→4)-α-L-Gal*p*3,6An-(1→3)-β-D-Gal*p*-(1→4)-α-L-Gal*p*3,6An-(1→ ··

4-172, agarose

Agars are largely polydisperse polysaccharides whose molecular weight ranges from 80 to 420 kDa. These molecules, similarly to other algal polysaccharides, form organised structures (double right-handed helices).

Agars are soluble in hot water at 85 °C and at higher temperatures and the dispersion yields gel by cooling. Commonly used concentrations range from 0.5 to 2.0%, but gels are formed even in 0.04% solutions. The sol–gel transition and the reverse process show a hysteresis. The melting point temperature of the gel (at temperatures up to 95 °C) is higher than the temperature at which the gel forms. During aging, agar gels are subject to syneresis. Their resistance to deformation is improved when combined with vegetable gums, such as locust gum. Agars are polysaccharides of low acidity and, unlike carrageenans, the gel formation does not require the presence of neutralising cations.

The use of agar in food production is based on its ability to bind water and form thermoreversible gels. Its gelling properties depend on the proportion of the agarose fraction present. Owing to the high melting point of gels, agar is mainly used in bakery products, as well as in the production of jams and jellies, confectionery products, dairy products, meat, fish and poultry products and beverages. In some Asian countries (e.g. in Japan), agar is used not only as a food additive, but also as a separate food (in various types of flavoured gels or in edible packagings).

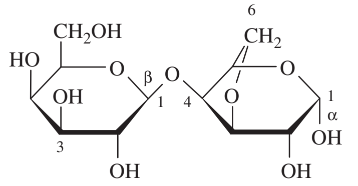
4.5.7.2 Carrageenan

Carrageenan is an extract from red seaweed (Rhodophyceae), especially of the genera *Chondrus* and *Gigartina*. Carrageenans differ in their structure, which is largely related to their origin.

Seaweed algae of the genus *Euchema* (*E. cottonii* and *E. spinosum*) are fibrous shrubs of about 0.5 m in height, which grow on coral reefs along the Philippines, Indonesia and other tropical regions of the Pacific Ocean. They are also grown on marine farms. The algae *Chondrus crispus* (also known as Irish moss) are small, dark red shrubs growing to a height of about 0.1 m along the coast of the North Atlantic, particularly in Canada, the British Isles and France. Algae of the genus *Gigartina* grow to a height of up to 5 m in the cool coastal waters of South America (Chile).

Carrageenans are mainly extracted as sodium salts using alkaline hot water (Na_2CO_3 or NaOH solutions). On acidification (HCl) carrageenans are obtained. The final materials are produced by drying or by precipitation with solvents (such as propan-2-ol).

Carrageenans are linear polysaccharides with a structure similar to the structure of agars but, unlike agars, the structural unit is only D-galactopyranose and not L-galactopyranose. The structure is a repetitive sequence of β-D-galactopyranose and 3,6-anhydro-α-D-galactopyranose, a disaccharide, known as carabiose (**4-173**). In fact, the primary structures of carrageenans are much more complex. They can be expressed by notation ⋯ → 3)-β-A-(1→4)-α-B-(1→3)-β-A-(1→4)-)-α-B-(1→ ⋯ , where A and B are units of D-galactose; its derivatives are listed in Table 4.35. For comparison, the structure of polysaccharide agarose is also given.



β-D-Gal*p*-(1→4)-α-D-Gal*p*3,6An

4-173, carabiose

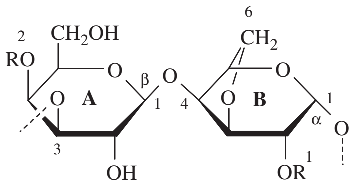
Sequences of at least eight types of monomers in the carrageenan molecules are known. They are indicated with lower case Greek letters: β (beta), θ (theta), ι (iota), κ (kappa), λ (lambda), μ (mu), ν (nu) and ξ (xi). The same names are used for the individual carrageenans if these sequences predominate in their primary structures. In the food industry, attention is devoted to just three dominant species, known as ι-carrageenan (its precursor is ν-carrageenan), κ-carrageenan (its precursor is μ-carrageenan) and λ-carrageenan. These three carrageenans are highlighted in bold in Table 4.35.

Carrageenans obtained from algae are predominantly complex mixtures of polysaccharides. They can be fracionated by precipitation with potassium salts (a KCl solution of concentration 0.25 mol/l), which separates the two main components, insoluble κ-carrageenan and soluble λ-carrageenan. The potassium salt of κ-carrageenan is insoluble in cold water, whereas the potassium salt of ι-carrageenan is slightly soluble in cold water, but soluble at temperatures above 60 °C, and λ-carrageenan is soluble in the form of any salt. Virtually pure carrageenans can also be obtained from certain species of algae; for example, ι-carrageenan from *Euchema cottonii* algae, κ-carrageenan from *E. spinosum algae* and λ- carrageenan from *Chondrus crispus* algae.

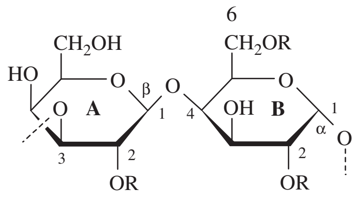
Table 4.35 Basic structure of carrageenans.

Polysaccharide	Building unit A	Building unit B
Agarose	**β-D-Galactose**	**3,6-Anhydro-α-L-galactose**
β-Carrageenan	β-D-Galactose	3,6-Anhydro-α-D-galactose
κ-Carrageenan	**β-D-Galactose-4-sulfate**	**3,6-Anhydro-α-D-galactose**
ι-Carrageenan	**β-D-Galactose-4-sulfate**	**3,6-Anhydro-α-D-galactose-2-sulfate**
μ-Carrageenan	β-D-Galactose-4-sulfate	α-D-Galactose-6-sulfate
θ-Carrageenan	β-D-Galactose-2-sulfate	3,6-Anhydro-α-D-galactose-2-sulfate
ξ-Carrageenan	β-D-Galactose-2-sulfate	α-D-Galactose-2-disulfate
ν-Carrageenan	β-D-Galactose-4-sulfate	α-D-Galactose-2,6-disulfate
λ-Carrageenan	**β-D-Galactose-2-sulfate**	**α-D-Galactose-2,6-disulfate**

The structure of the repeating units A and B in κ-carrageenan ($R^1 = H$, $R^2 = SO_3^-$), ι-carrageenan ($R^1 = R^2 = SO_3^-$) and λ-carrageenan ($R = SO_3^-$) are provided in formulae **4-174** and **4-175**, respectively. In addition to sulfate groups, and similarly to agar, carrageenan macromolecules also contain other functional groups (methoxyl groups or pyruvic acid bound as acetal).



4-174, basic structure of κ- and ι-carrageenans



4-175, basic structure of λ-carrageenan

The average molecular weights of all three very polydisperse polymers ranges from 100 to 1 000 kDa. In the sequence shown in Table 4.35, the sulfate group contents of the polysaccharides

increase, which is associated with conformations of the molecules and the carrageenan properties. In the same way as agar molecules, molecules of κ-carrageenan and ι-carrageenan form double helices, but molecules of λ-carrageenan occur in a zigzag conformation due to sulfuric acid bound at C-2 and C-6 of the B unit (disulfate is primarily found in the $^4C_1$ conformation, but the formation of helical structures needs a $^1C_4$ conformation of the 3,6-anhydro derivative). Gelling properties can be improved by intramolecular substitution of sulfate group at C-6 of the B units in alkaline solution, which yields 3,6-anhydrogalactose-2-sulfate (θ-carrageenan).

Carrageenans are anionic hydrophilic colloids. Solubility in water depends on the type of carrageenan, ions present, temperature and pH. The ratio of hydrophilic hydroxyl and sulfate groups and hydrophobic 3,6-anhydro-D-galactose residues also affects the solubility. Highly sulfated λ-carrageenan is very soluble and forms viscous dispersions (but does not form gels). κ-Carrageenan containing higher amounts of hydrophobic and less hydrophilic groups is less soluble, and the solubility of ι-carrageenan is between the solubility of κ-carrageenan and λ-carrageenan. Carrageenans are stable in solutions of pH 5–10, but in more acidic solutions (pH < 4) they are hydrolysed and the viscosity of dispersions decreases.

An important feature is the formation of gels. They are formed, like agar gels, by cooling dispersions of κ- or ι-carrageenans of even 0.5%, where intermolecular associations of double helices lead to the formation of superhelical structures (Figure 7.28). κ-Carrageenan forms a firm, brittle gel that undergoes syneresis, ι-carrageenan provides flexible and cohesive thixotropic gels, where syneresis does not occur. The formation of strong but brittle gels requires the presence of neutralising ions (e.g. potassium or ammonium ions, but not sodium ions in κ-carrageenan or calcium ions in ι-carrageenan).

An important property is the ability of carrageenans to form complexes with milk proteins (caseins). They can also be combined with modified starches.

Commercial carrageenan is a mixture of all three types of carrageenans in which κ-carrageenan (gelling) mostly prevails over λ-carrageenan (non-gelling) in a ratio of about 3 : 2. Carrageenan is used as a thickener, gelling agent, stabiliser and emulsifier in the production of dairy desserts, milk drinks and ice creams, and in the manufacture of canned meat. It also finds applications in cosmetics, for stabilisation of industrial suspensions and in the production of various pigments.

4.5.7.3 Furcellaran

Furcellaran is obtained mainly from red algae of the genus *Furcellaria* (*F. lumbricalis* and *F. fastigiata*). Sometimes it is also known as Danish agar, because its source is predominantly along the coast of Denmark. Furcellaran is a sulfated polysaccharide consisting of D-galactose units (46–53%), 3,6-anhydro-D-galactose (30–33%) and their sulfates (16–20%). Its structure and properties are similar to κ-carrageenan, and it is therefore often considered one of the carrageenans. The difference between furcellaran and κ-carrageenan lies in the fact that κ-carrageenan has a sulfate group linked to every second sugar unit, while in furcellaran it is to every third unit.

Furcellaran is soluble in warm water and forms soft, flexible and thermoreversible gels. The addition of sugar positively affects the strength of the gel. Furcellaran forms very strong gels in the presence of K^+ and $NH_4{}^+$ ions the same as κ-carrageenan, the presence of Ca^{2+} ions has less effect and with Na^+ ions it does not produce gels. It is used in the production of milk puddings and desserts.

4.5.7.4 Algin

4.5.7.4.1 Occurrence

Algin is the name used to cover **alginic acid** and its salts, **alginates**. Algin is an intercellular matrix (a gel containing ions of Na, Ca, Mg, Sr and Ba) in the brown seaweed family Phaeophyceae growing off the coast of the North Atlantic, especially in the United States, Norway, France and Great Britain. The main industrial sources are algae *Macrocystis pyrifera*, *Laminaria hyperborea* and algae of the genus *Ascophyllum* and *Sarrgasum*. Alginate makes up about 40% of dry matter of algae.[8]

Algin, like agar and carrageenan, is obtained as the sodium salt (alginate) by extraction of algae with alkaline aqueous solutions (NaOH or Na_2CO_3). The extract is precipitated as calcium salts by adding $CaCl_2$ or as alginic acid by acidification using HCl. The calcium salt is converted into alginic acid, from which the final commercial product (sodium salt) is obtained by neutralisation with Na_2CO_3. A significant portion of native polysaccharides are hydrolysed during the isolation of alginates.

4.5.7.4.2 Structure

Alginates are linear copolymers of non-branched β-D-mannuronic acid (M) and α-L-guluronic acid (G) linked by (1→4) glycosidic bonds (**4-176**). Residues of mannuronic acid are in the $^4C_1$ conformation, while residues of guluronic acid are in the $^1C_4$ conformation. The chain contains alternating sections of different

[8]A range of extracellular bacterial polysaccharides of the genera *Azotobacter* (*A. vinelandii* and *A. crococcum*) and *Pseudomonas* (*P. aeruginosa*, *P. putida*, *P. mendocina*, *P. Fluorescens* and *P. syringae*), known as bacterial alginates, have similar compositions and properties. They are almost exclusively polymannuronans. Some bacteria are considered as a future potential industrial source of bacterial alginate, which could replace production from algae.

M−M−M−M−G−M−G−G−G−G−G−M−G−M−G−G−G−G−G−G−G−M−M−G−M−G−M−G−G−M

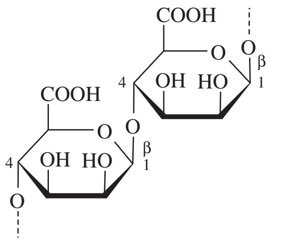
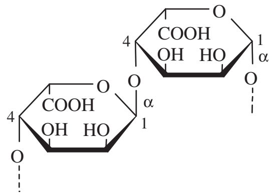
4-176, basic ctructuru of alginates (M = β-D-mannuronic acid, G = α-L-guluronic acid)

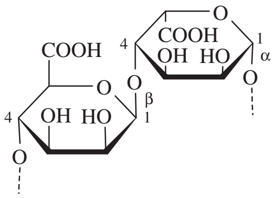
lengths containing only molecules M, sections formed exclusively of molecules G and mixed sections G-M. Representation and alternation of both components is particularly variable, depending mainly on the origin of the alginate. The mannuronic acid content is usually 22–90%, and that of guluronic acid varies between 10 and 78%. The structures of alginate sections M-M, G-G and M-G are shown in formulae **4-177** to **4-179**.



4-177, structure of alginate section M-M



4-178, structure of alginate section G-G



4-179, structure of alginate section M-G

4.5.7.4.3 Properties

Alginates of alkali metals, ammonium salts, amine salts and magnesium salts are soluble, while calcium salts are insoluble. Solubility is affected by pH, ionic strength and ion type. Alginic acid is precipitated in acidic solution and slow acidification gives a precipitate rather than a gel. Solutions of alkali metal alginates are highly viscous and behave as pseudoplastic systems. Viscosity is strongly dependent on ionic strength (they are polyelectrolytes); as the ionic strength increases the viscosity decreases. By heating and in the presence of reducing agents (such as ascorbic acid), the polymers are degraded and viscosity decreases.

An important property of alginates is the formation of gels and heat-resistant films that easily form on addition of calcium ions to sodium alginate dispersions. In the binding of calcium ions, not only do electrostatic forces participate, but their chelation is also involved. The binding zones are the G sections that contain at least four units of guluronic acid. This creates a structure called the egg-box structure (Figure 7.31), as in pectin. Depending on the guluronic acid concentration (the amount in the binding zones), the formed gels have different properties. The relative molecular weight of alginates is 32–200 kDa and the chains (spiral to almost linear) contain 180–930 sugar units.

4.5.7.4.4 Use

Alginates are used, in concentrations ranging from 0.25 to 0.5%, as thickeners, stabilisers and emulsifiers to improve the consistency of bread, sauces, dressings, ice creams, fruit juices and many other foods. Their gelling properties are employed in the production of fruit and dessert jellies, puddings and reconstituted fruit prepared from fruit pulp. With highly esterified pectins thermoreversible gels are formed. Alginates also readily react with protonised amino acid residues in proteins to form precipitates, and may therefore also be used to remove proteins, for example from beer. Besides the native alginates, alginates modified by propylene oxide (propylene glycol alginates) are also used.

4.5.8 Polysaccharides of microorganisms and higher fungi

Microorganisms and higher fungi produce two basic types of polysaccharides:

- **extracellular**
- **intracellular** (structural and storage polysaccharides).

Extracellular polysaccharides of bacteria are accumulated in the form of capsules, which remain part of the cell wall or as an amorphous mucilaginous material surrounding the outer cell wall, and diffuse into the growth medium. These **mucilages**, also known as **bacterial gums**, apper to have a barrier function to protect cells from infection by bacterial viruses (bacteriophages), prevent dehydration and fix microorganisms to the environment (e.g. to soil particles). Bacterial gums have unique properties for which they find use in the food industry, pharmaceutical industry and elsewhere. The most important bacterial extracellular hydrocolloid used for food purposes is **xanthan** (**xanthan gum**), while on a smaller scale **gellan** (gellan gum) is used. In addition to xanthan and gellan, a number of other bacterial polysaccharides are obtained, but for various reasons (e.g. low production, high cost and better resources) they are use only sporadically. Dextran and curdlan, for example, have limited uses. Bacteria of the genus *Azotobacter* are a potential source of bacterial alginates.

Yeasts, moulds and higher fungi produce a large variety of extra- and intracellular polysaccharides. Certain applications have been found for glucans as hydrocolloids in the food industry, especially α-glucans with multiple α-(1→4), α-(1→3) bonds and also some β-glucans with combined β-(1→3) and β-(1→6) bonds. Extracellular (excreted as mucilages) and intracellular (structural polysaccharides of cell walls) polysaccharides, which are commonly called **β-glucans**, or more precisely **β-(1→3)-D-glucans**, have unique properties. They are produced by some yeasts, moulds and higher fungi. Their antibacterial, antiviral, anticoagulant and

anticarcinogenic effects are mainly exploited by the pharmaceutical industry and in human medicine.

4.5.8.1 Xanthan

The extracellular polysaccharide xanthan (xanthan gum) is produced by bacteria of the genus *Xanthomonas* (industrially those most commonly used are the bacteria *X. campestris*).

The main xanthan chain consists of β-D-(1→4) glucose units that also occur in cellulose. Side chains (usually trisaccharides) consist of a D-glucuronic acid residue and two D-mannose residues (**4-180**). To the terminal D-mannose unit of the side chain is attached to β-D-glucuronic acid through β-(1→4) glycosidic bond. Glucuronic acid is further linked to α-D-mannose by a (1→2) bond. The structure is further complicated by the presence of pyruvic acid linked, as an

HOOC CH$_3$

4-180, basic structure of xanthan

acetal, at positions C-4 and C-6 of the terminal β-D-mannose unit, which is 4,6-*O*-(1′-carboxyethylidene)-β-D-mannopyranose. The internal mannose unit in the side chain is acetylated in position C-6 (6-*O*-acetyl-α-D-mannopyranose). The structure may also vary in the degree of substitution depending on the bacterial strain used in the production. The relative molecular weight is about 15 000 kDa. Xanthan molecules form single or double helices stabilised by side chains.

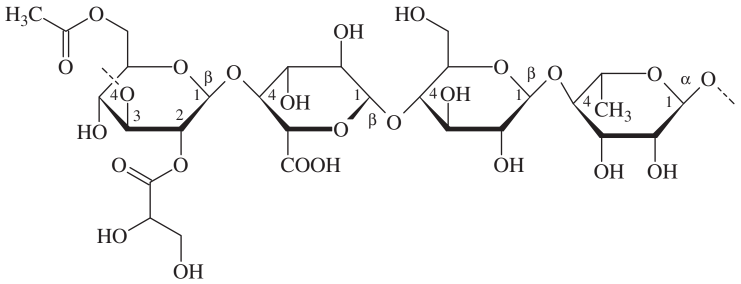
Xanthan gum is water soluble; its dispersions are highly viscous and even at low concentrations show thixotropic behaviour. The viscosity is strongly dependent on temperature. During heating, viscosity decreases at first, but then increases again with changes in the conformation of the molecules. Xanthan dispersions are stable in acidic and alkaline conditions and at elevated temperature (80 °C). In the presence of guar gum, the viscosity of dispersions increases, which is utilised in products that require a stable viscosity over a wide range of salt concentrations, pH and temperatures.

Xanthan does not form gels, but thermoreversible gels are formed in mixtures with some polysaccharides, such as galactomannans (locust gum), glucomannans (konjak gum) and κ-carrageenan. Gel formation requires the interaction of xanthan molecules (arranged in a double helix) with the unbranched part of another polysaccharide molecule (with its binding zone). Better, elastic, cohesive gels are formed from deacetylated xanthan.

Xanthan gum is used primarily as a thickener, emulsion stabiliser and in combination with other hydrocolloids as a gelling agent. The thermostability of xanthan is typically exploited in the preparation of instant soups, sauces and as binders in various canned foods.

4.5.8.2 Gellan

Gellan (gellan gum) is an extracellular polysaccharide produced commercially by aerobic submerged fermentation from bacteria *Sphingomonas elodea* (previously called *Pseudomonas elodea*). The gellan chain contains tetrasaccharide repeating structures β-D-Glc*p*-(1→4)-β-D-Glc*p*A-(1→4)-β-D-Glc*p*-(1→4)-α-L-Rha*p*-(1→3) consisting of β-D-glucose esterified at position C-6 by acetic acid (the degree of substitution is about 50%) to which is bound L-glyceric acid at C-2 and D-glucuronic acid. D-Glucuronic acid is bound to the second molecule of D-glucose by a β-(1→4) bond, which is connected with α-L-rhamnose by a (1→4) bond (**4-181**).



···· →3)-β-D-Glc*p*6Ac-(1→ 4)-β-D-Glc*p*A-(1→ 4)-β-D-Glc*p*-(1→ 4)-α-L-Rha*p*-(1→ ····
2
↑
L-glyceric acid

4-181, basic structure of gellan

Gellan can occur also in a branched form, known as **welan**. The molecular weights range from thousands to tens of thousands of kilo daltons. Gellan gum forms coaxial triangular three-fold double helices from two left-handed chains coiled around each other, with the acetate residues on the periphery and glyceryl groups stabilising the interchain associations. The molecule is further stabilised by hydrogen bonds.

Gellan dissolves in water to form highly viscous solutions even at low concentration. The gelling properties depend on the degree of acetylation. The native acetylated product forms soft, elastic gels, whereas gellan produces hard and brittle gels. Gellan is an acidic polysaccharide and in the presence of cations, even at low (0.1% w/w) to very low (0.005% w/w) concentrations forms thermoreversible gels on cooling at about 50 °C. Gelatinisation depends on the cation type and its valence. Divalent cations form stronger and more elastic gels than monovalent cations.

Depending on their structure (degree of deacetylation), gellan gels form in either cold or warm water and are thermoreversible or thermoirreversible, which means they are perfect as broad spectrum gelatinisation agents that find use in many food and non-food applications (texture modification and stabilisation of foams and emulsions). They are used mainly in Japan. Gellan is used also in combination with other hydrocolloids, for example xanthan gum, locust gum and gelatine. In microbiology it is used as an alternative to agar gels due to its thermal stability (up to temperatures of 120 °C) and is particularly suitable for the cultivation of thermophilic microorganisms.

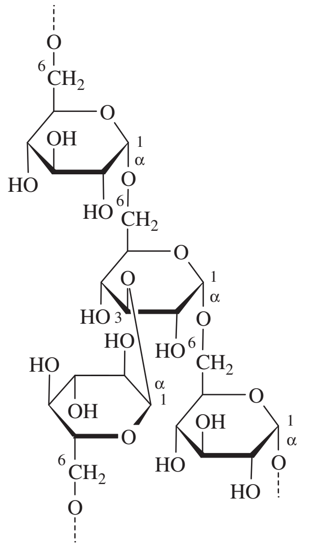
4.5.8.3 Dextran

The extracellular polysaccharide dextran is produced by the bacteria *Leuconostoc mesenteroides*, *Streptobacterium dextranicum*, *Streptococcus mutans* and some other bacteria. A dextran molecule consists of about 95% of α-(1→6) linked D-glucose units. The remainder are D-glucose molecules linked by α-(1→3) bonds that form side chains (**4-182**). Some dextrans contain side chains in which D-glucose molecules are also partly bound by α-(1→4) and α-(1→2) bonds. The type and number of these glycosidic bonds depends on the origin of the dextran. The relative molecular weight of dextran is usually 60–90 kDa.

Dextran is soluble in water, but water-insoluble dextrans also exist. Dextran dispersions have lower viscosity in comparison with xanthan dispersions, but are relatively resistant to hydrolysis.

In food applications, dextrans (*Leuconostoc mesenteroides* strains product) have been used, usually in combination with other polysaccharides such as gum arabic, for purposes similar to other hydrocolloids. They are highly effective emulsifiers and stabilisers of emulsions of oil in water. They bind water and inhibit the crystallisation of saccharose. Much more extensive use has been found for dextran in pharmacy and medicine (replacement of blood plasma) and in analytical chemistry as a chromatographic material for gel filtration and other applications.

Dextran naturally forms in contaminated sugar beet and juice, where higher viscosity can cause problems in sugar beet processing.



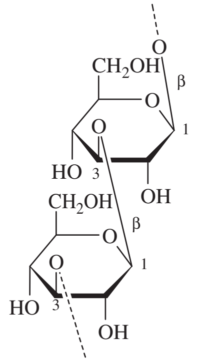
····→6)-α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→ ····
3
↑
1
···· →6)-α-D-Glc*p*

4-182, basic structure of dextran

4.5.8.4 Curdlan

Curdlan is an extracellular polysaccharide produced by the bacterium *Alcaligenes faecalis* var. *myxogenes*. It is also found in many yeasts and fungi as a component of cell walls or as a storage polysaccharide.

Curdlan is a linear polymer of glucose units linked by β-(1→3) bonds (**4-183**). The basic unit is actually disaccharide laminaribiose. It can be partially esterified by succinic acid. The relative molecular weight of curdlan is 44–77 kDa.



···· →3)-β-D-Glc*p*-(1 →3)-β-D-Glc*p*-(1→ ····

4-183, basic structure of curdlan

Curdlan swells in water and after heating to 80 °C forms a turbid gel that is stable over a wide range of temperatures and pH values. Gel strength can be influenced by the addition of sugars.

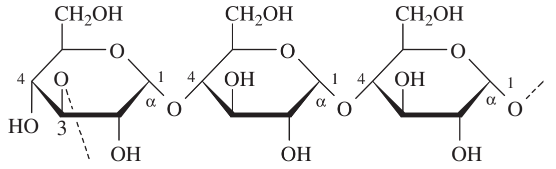
Curdlan serves as a gelling agent, thickener and stabiliser, it improves water binding capacity, viscoelasticity, masks various

odours and has an excellent ability to form films, which are insoluble in water, impermeable to oxygen and are biodegradable. It is mainly used in Japan.

4.5.8.5 Elsinan

Elsinan is an exocelullular glucan produced by the fungus *Elsinoe lencospila*, which forms white patches on the leaves of tea plants (*Camellia sinensis*, Theaceae), whose leaves and leaf buds are used to produce Chinese tea.

The elsinan chain is composed of D-glucose units linked by approximately 70% of α-(1→4) bonds and by about 28% of α-(1→3) bonds (**4-184**).



···· →3)-α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→ ····

4-184, basic structure of elsinan

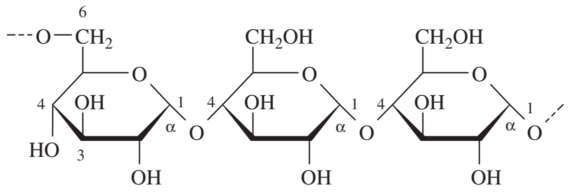
Elsinan is soluble in hot water. It is stable over a wide range of pH values and in the presence of salts, it can be hydrolysed by some amylolytic enzymes (e.g. by α-amylase), can form highly viscous solutions even at low concentrations and at concentrations higher than 5% it forms a gel. An important feature is the formation of strong, flexible films that are formed during evaporation of elsinan solutions.

Elsinan is used as low energy filler. Films made from elsinan are suitable as edible food packagings that are impermeable to oxygen.

4.5.8.6 Pullulan

Extracellular polysaccharide pullulan is produced by the fungus *Aureobasidium pullulans* (syn. *Pullularia pullulans*). The molecule consists of D-glucopyranose units linked alternately by two α-(1→4) and one α-(1→6) bonds (**4-185**). The molecular weight varies widely, from 1.5 to about 800 kDa, according to origin of the fungus and cultivation conditions.

Pullulan is soluble in water. The pressed polysaccharide has similar properties to polystyrene. When mixed with sorbitol or glycerol, pullulan forms translucent films that are impermeable to oxygen and fats.



···· →6)-α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→ ····

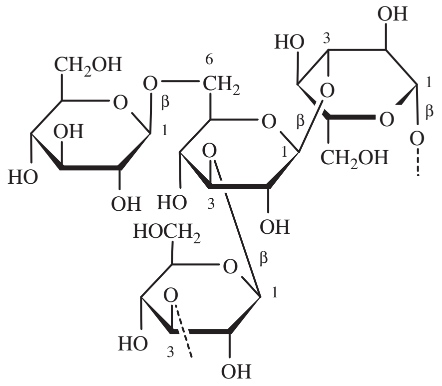
4-185, basic structure of pullulan

It is not used for food purposes. The most widespread applications of pullulan are in medicine (infusion solutions), pharmacy (coated tablets) and in the paper industry (adhesives).

4.5.8.7 Scleroglucan

Scleroglucan is the capsular polysaccharide excreted by some lower fungi of the genus *Sclerotium*. The fungi *S. glucanicum* and *S. roefsii* serve as an industrial source. Other sources are fungi of the genera *Sclerotinia*, *Corticium*, *Botrytis* and *Stromatinia* that produce polysaccharides similar to scleroglucan. Similar polysaccharides are also cell wall components and storage polysaccharides of yeasts and higher fungi.

Scleroglucan produced by *P. glucanicum* has a linear chain composed of D-glucose residues linked by β-(1→3) bonds, with side glucose residues linked with β-(1→6) bonds that occur on approximately every third glucose unit of the main chain (**4-186**). The polymers contain between one hundred and several hundred molecules of glucose.



···· →3)-β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→ ····

6
↑
1

β-D-Glc*p*

4-186, basic structures of scleroglucan, schizophyllan and lentinan

Scleroglucan is soluble in water and forms highly viscous dispersions that are stable over a wide range of pH values and at higher temperatures. Dispersions of concentrations higher than 1.5% form gels. In combination with glycerol, scleroglucan forms a strong and flexible film and emulsions with vegetable oils.

The food use of scleroglucan is minimal; greater use is made in cosmetics, pharmaceuticals and in the manufacture of porcelain, paper and paints.

4.5.8.8 Other glucans

Polysaccharides structurally related to scleroglucan, which are β-glucans with glucose units in the main chain linked by (1→3) bonds and side chains attached by (1→6) bonds, are produced

as structural and storage (extra- and intracellular) polysaccharides by many yeasts, moulds and higher fungi. For example, yeast *Saccharomyces cerevisiae* contain as the major polysaccharides β-glucan with (1→6) bonds in the main chain and (1→3) bonds in the side chains and α-mannan with (1→6) bonds in the main chain and (1→2) and (1→3) bonds in the side chains. Cultivated yeast strains produce only β-glucan with (1→3) bonds in the main chain and (1→6) bonds in the side chains.

Polysaccharides composed of glucose units are also known as β-(1→3)-D-glucans. Individual polysaccharides differ in substitution of the main chain and the number of glucose units in the side chains. The chains form triple helices. β-(1→3)-D-Glucans are mostly isolated from so-called club fungi, belonging to the phylum Basidiomycota, and from so-called sac fungi of the phylum Ascomycota. Examples of these polysaccharides are given in Table 4.36.

The most important properties of β-(1→3)-D-glucans are their ability to strengthen the immune system and to inhibit tumour growth. Their activity depends on the molecular weight, frequency of branching and conformation of molecules. The highest efficiency reported is shown by β-D-glucans with a degree of branching of 0.20–0.33 and higher relative molecular weight (100–200 kDa). Some β-D-glucans (Table 4.36), for example schizophyllan (extracellular polysaccharide of Basidiomycota fungi) and lentinan (structural cell wall polysaccharide of Oomycota fungi) are used in clinical medicine as immunotherapeutic agents in the treatment of cancer diseases, often in combination with radiotherapy. Schizofyllan also protects against bacterial infections. Lentinan is used against viral diseases. The structure of both compounds is similar to the structure of scleroglucan (**4-186**) and differs only in the level of substitution of the main chain and the degree of polymerisation.

Schizofyllan is a product of phytopathogenic fungus *Schizophyllum commune* (Table 4.36), which produces three types of β-(1→3)-D-glucans with molecular weights 10, 20–80 and 200 kDa. The first two types contain disaccharide laminaribiose in the side chains. Glucans with a relative molecular weight of 200 kDa show the highest antitumor and cytotoxic activities. Their side chains contain trisaccharide β-D-Glc*p*-(1→3)-β-D-Glc*p*-(1→3)-β-D-Glc*p*.

4.5.9 Animal polysaccharides

Among the polysaccharides of animal origin, the storage homopolysaccharide **glycogen** and structural homopolysaccharide **chitin** are important. In addition to these homopolysaccharides, animal tissues contain many other heteropolysaccharides, which have structural, protective and other functions.

4.5.9.1 Glycogen

The primary structure and function of glycogen resembles the starch component amylopectin and therefore glycogen is also called animal starch. Glycogen is the main utilisable source of glucose (energy) present in all animal cells, but also found in cells of bacteria, moulds and higher fungi.

4.5.9.1.1 Structure and nomenclature

Glycogen is an α-glucan that contains more than 10^6 D-glucose residues linked by α-(1→4) bonds. In every 8–12 glucose residues, side chains of other α-(1→4) glucans are bound, attached by α-(1→6) bonds, similar to as in amylopectin, but the glycogen molecule is more branched and structurally more compact. Glycogen contains also phosphoric acid in small amounts.

4.5.9.1.2 Occurrence

In mammals, glycogen is found mainly in the liver and muscles. The liver cells, hepatocytes, contain glycogen at a level of 2.9–8.1% of their weight (in total 100–120 g in adults). It occurs in the form

Table 4.36 Some β-D-(1→3)-glucans with important anticarcinogenic activity.

of granules in the cell cytoplasm. Approximately 1–2% of glycogen is also present in the skeletal muscles of animals (*in vivo*), but his total amount is higher than the content in the liver. Meat contains only about 0.15–0.18% of glycogen, with the exception of horse meat, which contains 0.9% glycogen.

Glycogen plays an important role in post-mortem changes in muscle. Anaerobic glycolysis transforms glycogen into L-lactic acid, which lowers the pH of the meat, increases its fragility during ripening and has antimicrobial effects, thereby extending the shelf life of meat during storage. The level of glycogen in the muscle of animals, poultry and fish prior to slaughter has a major impact on the quality of meat during further processing (see Section 2.4.5.1.5). In fish, glycogen is present at levels of up to 0.3%. It is also found in higher fungi, moulds, yeasts and bacteria. Higher fungi contain 5–10% glycogen. From a nutritional point of view, glycogen has little significance.

4.5.9.1.3 Properties

Glycogen is more soluble than starch and does not form gels.

4.5.9.1.4 Physiology and nutrition

The large number of non-reducing ends of the glycogen molecule play an important role in biochemical processes, as they allow rapid mobilisation of glucose during biodegradation of glycogen. In cells, glycogen is degraded for metabolic purposes by glycogen phosphorylase that splits α-(1→4) bonds from the non-reducing end of the molecule with the formation of glucose 1-phosphate. Glucose 1-phosphate is transformed into glucose 6-phosphate, which produces glucose via the process of glycolysis (with the catalytic action of hexokinase) or other sugar phosphates. The α-(1→6) bonds are cleaved by α-(1→6)-glucosidase (isomaltase).

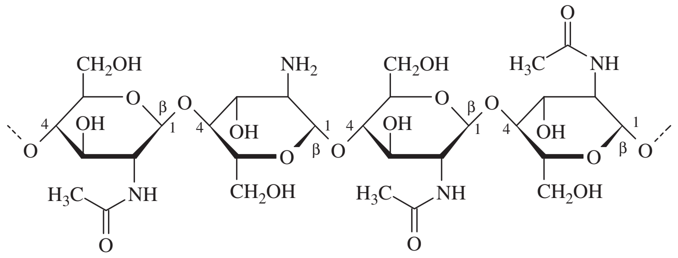
Glycogen is a utilisable polysaccharide. In food, it is hydrolysed by hydrolases (α-amylase and β-amylase) in the same way as starch. The branched dextrins formed are further broken down by isoamylase to maltose and glucose.

4.5.9.2 Chitin

4.5.9.2.1 Structure and nomenclature

Chitin is an almost linear copolymer of *N*-acetyl-β-D-glucosamine (70–90%) and β-D-glucosamine (10–30%), in which both monomers are bound to each other by β-(1→4) glycosidic bonds (**4-187**). The basic building block of chitin is disaccharide **chitobiose**, composed of two molecules of *N*-acetyl-β-D-glucosamine (also known as chitosamine). Its relative molecular weight is about 1000 kDa.

The chains are coiled along the longitudinal axis into a helix at certain distances (1–1.5 nm) and are oriented parallel or antiparallel. The most common conformation is an α-conformation in which the individual chains are arranged antiparallel. In the less frequent β-conformation, the chains are oriented in parallel.



····→4)-β-D-Glc*p*NAc-(1→4)-β-D-Glc*p*N-(1→4)-β-D-Glc*p*NAc-(1→4)-β-D-Glc*p*NAc-(1→····

4-187, chitin

4.5.9.2.2 Occurrence

Chitin is the second most abundant organic compound in nature after cellulose. It is found mainly in the animal kingdom, where it is the main structural polysaccharide in the exoskeleton (shells) of crustaceans, insects and other invertebrates. It also occurs in some algae, fungi, yeasts and bacteria, usually associated with proteins. Naturally occurring chitin is consumed only rarely. Some beetles and sea foods with shells (such as crabs and snails) are eaten as delicacies, and are largely made of chitin. The chitin content in the exoskeleton of crabs is 61–77%.

The main sources of chitin in the diet are mainly the higher fungi that contain about 1% of chitin, such as cultivated common mushrooms (*Agaricus bisporus*) (1.3–8.0% of dry matter) and shiitake mushrooms (*Lentinula edodes*) containing 3.6–8.1% chitin in dry matter. Fermented soybeans and fermented rice used in the preparation of oriental foods contain chitin derived from moulds (*Aspergillus oryzae* and *A. sojae*). Fungi contain up to 42% chitin (e.g. *A. niger*). Baker's yeast (*Saccharomyces cerevisiae*) contains around 2.9% chitin, which becomes part of the baked products.

4.5.9.2.3 Properties

Chitin is insoluble in water and barely soluble in acidic media (forming ammonium salts). Heating in acid or alkaline solutions leads to the hydrolysis of bound *N*-acetyl-D-glucosamine with the formation of D-glucosamine and acetic acid. Heating under acidic conditions causes partial depolymerisation of chitin through the hydrolysis of β-glycosidic bonds. In alkaline solutions, depolymerisation occurs to a lesser extent.

The enzyme lysozyme cleaves β-(1→4) glycosidic bonds between *N*-acetylglucosamine and D-glucosamine. The more chitin is acetylated, the faster the reaction. The ability to decompose chitin is based on the antimicrobial effects of lysozyme. Some bacteria produce chitinases known as chitodextrinases or poly[β-1,4-(2-acetamido-2-deoxy-D-glucosidases)] and chitosanase (chitosan-*N*-acetylglucosamine hydrolases), which cleave chitin chains to form *N*-acetylglucosamine.

Chitin forms complexes with most transition metals. Copper ions form one of the strongest complexes. The rates of formation

and stability of the metal complexes depend on the temperature, the solubility of ions, their type, pH, degree of acetylation of chitin and other factors. Complexes with toxic metals (mercury or lead) can cause poisoning, because they break down in the digestive tract.

4.5.9.2.4 Physiology and nutrition

Chitin is virtually indigestible, because no human intestinal microflora contains the chitin cleaving enzymes. Chitin is only partially hydrolysed by saliva (by lysozyme) and in the stomach (by lysozyme and hydrochloric acid). A significant proportion of chitin can be utilised by some animals (e.g. by fish, fowl and rabbits).

4.5.9.2.5 Use

Chitin is obtained industrially mainly from the shells of marine molluscs. The technology involves the removal of accompanying proteins in dilute sodium hydroxide, calcium carbonate and hydrochloric acid. Partial alkaline hydrolysis of acetyl groups using sodium hydroxide is used for the preparation of modified chitin, which is called **chitosan**.

Chitosan

Chitosan contains 5–25% of *N*-acetylglucosamine and 75–95% of D-glucosamine units. Although the structures of chitin and chitosan differ only slightly, chemical reactivity and physical properties of these two polysaccharides are quite different. Chitosan is soluble in water, acids and organic solvents and insoluble in neutral and alkaline solutions (it is a stronger base than chitin). Chitosan molecules are polycations and coagulate when molecules or particles carrying negative charge (e.g. sodium alginate, sulfates, phosphates and proteins) are added to chitosan solutions. Dispersions of chitosan are highly viscous.

Chitosan is, like chitin, hydrolysed by acids, alkalis or enzymes and forms complexes with metals. Unlike chitin, chitosan reacts with aldehydes to form imines. It is also indigestible, but significantly reduces the cholesterol level in the blood serum and liver. The mechanism of this effect is not fully understood yet. Apparently, coagulation and flocculation of chitosan play an important role. Bile acids form micelles containing cholesterol, which are absorbed through the intestinal wall. Chitosan forms a gummy coagulate that captures and binds these micelles, which reduces the level of emulsified cholesterol. In the colon, chitosan blocks the conversion of cholesterol into coprostanol, which increases faecal excretion of cholesterol and reduces its transfer into the blood serum. Chitosan also forms salts with fatty acids, which do not dissociate even in acidic gastric juice. These salts bind lipids (triacylglycerols), which are thus excluded from the body.

Chitosan is used as an emulsifier (for margarine) and an emulsion stabiliser (it is added to hamburgers, ice creams and cheeses), thickener (viscosity increases), foam stabiliser, gelling agent, clarification agent for fruit juices and also in the pharmaceutical industry and in cosmetics.

4.6 Complex saccharides

In animal and plant tissues and in cells of microorganisms, saccharides are often part of more complex structures containing, simultaneously, proteins, peptides, lipids and other non-saccharide components. These saccharides are called **conjugated** or **complex** saccharides.

Peptides and proteins form a wide range of conjugated compounds with carbohydrates. Carbohydrates are present mostly as linear or branched oligosaccharides. In some conjugated compounds the properties of peptide (protein) predominate, therefore these complex saccharides include:

- **glycopeptides**
- **glycoproteins**.

In other complex carbohydrates the properties of saccharides predominate, and then these compounds are divided into:

- **peptidoglycans** (also known as **mucopeptides**)
- **proteoglycans** (also known as **mucoproteins**).

The linear polysaccharide components of peptidoglycans of bacterial cell walls, known as **mureins**, are made up of alternating units of *N*-acetyl-D-glucosamine and *N*-acetylmuramic acid that are linked by β-(1→4) glycosidic bonds. The residue of lactic acid in *N*-acetylmuramic acid is linked by an amide bond to L-alanine in tetrapeptide Ala-D-isoGlu-L-Lys-D-Ala. Saccharides in proteoglycans of higher animals are predominantly linear polymers, so-called **mucopolysaccharides**, composed of aldoses (D-galactose), glycuronic acids (D-glucuronic or L-iduronic acids), amino sugars (*N*-acetyl-D-glucosamine and *N*-acetyl-D-galactosamine) and their sulfates.

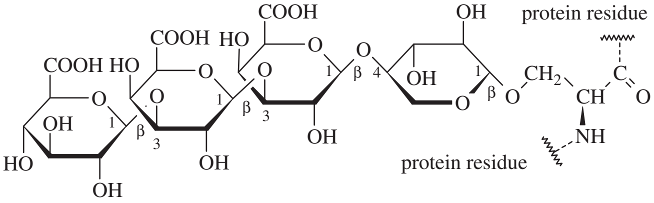
Saccharides also form a very diverse range of compounds with lipids. These compounds are categories of homolipids, heterolipids and complex lipids. Glycolipids are homolipids that include naturally occurring esters of higher fatty acids (e.g. glycoglycerolipids such as diacylgalactosylglycerol), synthetic sugar esters (e.g. esters of sucrose) and various sugar derivatives (such as glucitol esters). Heterolipids include some phospholipids (phosphatides, such as phosphatidylinositol) and lipamides (e.g. lipamide glycosides called cerebrosides). For example, complex lipids include mucolipids and gangliosides.

4.6.1 Mucopolysaccharides

Mucopolysaccharides, also known as **glycosaminoglycans**, are acidic linear polysaccharides composed of repeating disaccharide units. Mucopolysaccharides are sugar components of proteoglycans, peptidoglycans and also of glycoproteins and glycopeptides. Proteoglycans are essential components of the extracellular parts of the epithelial and connective tissues (skin, tendons, blood vessels, cartilages and bones) and also have protective functions in cells.

Glycoproteins are slimy and gelatinous substances in the synovial fluids of joints, liquids of eye sockets and in various secretions, such as respiratory tract mucus. They also occur in saliva, egg white and other viscous materials.

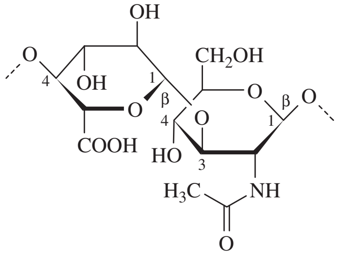
Glycosaminoglycans are covalently bound to proteins through a tetrasaccharide bound to the serine residue (**4-188**). Elongation of this tetrasaccharide (consecutive addition of sugar units to gluconic acid), esterification with sulfuric acid and various other reactions yield the individual glycosaminoglycans.



β-D-Glc*p*A-(1→3)-β-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-β-D-Xyl*p*-(1→

4-188, binding region of glycosaminoglycans

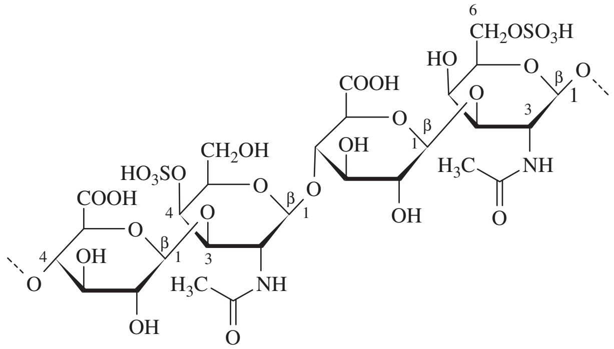
Hyaluronic acid is a common glycosaminoglycan that is not esterified with sulfuric acid. It consists of 250–25 000 alternating units of D-glucuronic acid and *N*-acetyl-D-glucosamine linked to each other by β-(1→3) glycosidic bond (**4-189**). Hyaluronic acid is present in the skin (which prevents penetration of bacteria into the tissues), in cartilage and the aqueous humour of the eyes resulting in the lubrication properties of synovial fluid. The properties are attributed to the formation of hydrogen bridges between the chains and their high degree of hydration. The enzyme hyaluronidase, hydrolysing β-(1→3) bonds, occurs in animal tissues, in bacteria (which is probably responsible for their invasiveness) and in snake and insect poisons.



… →4)-β-D-Glc*p*A-(1 →3)-β-D-Gal*p*N-(1→ …

4-189, basic structure of hyaluronic acid

There are two types of sulfated glycosaminoglycans. The first type includes galactosaminoglycans, known as chondroitin sulfate and dermatan sulfate, the second type are glucosaminoglycans, referred to as heparin sulfate and heparin. An example of a commonly occurring galactosaminoglycan is chondroitin sulfate, which contains alternating units of D-glucuronic acid and *N*-acetyl-D-galactosamine. The units of D-glucuronic acid can be esterified with sulfuric acid at position C-2, the units of *N*-acetyl-D-galactosamine are esterified at positions C-4, C-6 or they are

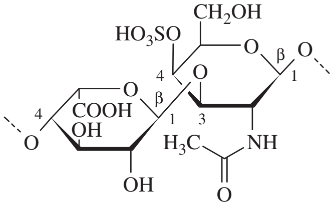


….→4)-β-D-Glc*p*A-(1→3)-β-D-Gal*p*NAc4SO_3-(1→4)-β-D-Glc*p*A-(1→3)-β-D-Gal*p*NAc6SO_3^-(1 →..

4-190, basic structure of chondroitin sulfate

non-esterified (**4-190**). Chondroitin sulfate connects cells in animal tissues (mainly in epithelial and connective tissues).

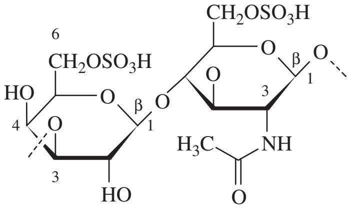
Dermatan sulfate differs from chondroitin sulfate as some units of D-glucuronic acid are replaced by L-iduronic acid units (**4-191**), or by its 2-sulfate and *N*-acetyl-D-galactosamine is esterified in position C-4 or C-6 (monoesters), simultaneously at C-4 and C-6 (diesters) or it is not esterified. Dermatan sulfate is found mostly in the skin (also in the blood vessels and tendons).



….→4)-β-L-Ido*p*A-(1→3)-β-D-Gal*p*NAc4SO_3^--(1→….

4-191, basic structure of dermatan sulfate

Instead of *N*-acetyl-D-galactosamine, keratan sulfate (kerato sulfate, **4-192**) contains *N*-acetyl-D-glucosamine and instead of D-glucuronic acid it contains D-galactose esterified at C-6 with sulfuric acid. *N*-Acetyl-D-glucosamine can also be esterified at C-6 with sulfuric acid. Other sugars are also present in small amounts, such as L-fucose, which is found in type II keratan sulfate. Keratan sulfate is part of cartilages and the cornea.



…. →3)-β-D-Gal*p*-(1 →4)-β-D-Glc*p*NAc6SO_3^--(1 → ….

4-192, basic structure of keratan sulfate

A related acidic heteropolysaccharide is heparin. It consists primarily of D-glucuronic acid (and also contains L-idurono-2-sulfate) and *N*-acetyl-D-glucosamine, which can be esterified with sulfuric acid at nitrogen, C-6, or both places simultaneously. These basic units are joined by α-(1→4) glycosidic bonds. Heparin does not occur in connective tissues, but is found in granular form in specific cells (particularly cells of the liver, lungs and skin) and is a part of the bloodstream. It has anticoagulant properties (prevents blood clotting). A very similar polysaccharide is heparan sulfate, which contains predominantly D-glucuronic acid (or L-iduronic acid and L-idurono-2-sulfate) and *N*-acetyl-D-glucosamine (or its sulfates as heparan). D-Glucuronic acid is linked by β-(1→4) glycosidic bonds with *N*-acetyl-D-glucosamine (its sulfates), which is linked with an additional unit of D-glucuronic acid by an α-(1→4) glycosidic bond. Disaccharide units are organised into sulfate and non-sulfate domains.

4.6.2 Proteoglycans

Mucopolysaccharides are covalently and non-covalently bound to various proteins to form macromolecules called proteoglycans or mucoproteins. The basis of the molecule of proteoglycans is a linear molecule of hyaluronic acid, to which are non-covalently attached proteoglycan subunits through the globular *N*-terminus. The subunits are composed of proteins covalently bound to mucopolysaccharides, mainly to chondroitin sulfate and keratan sulfate through serine and threonine hydroxyl groups or amide group of asparagine and the hemiacetal hydroxyl groups of *N*-acetyl-D-glucosamine or *N*-acetyl-D-galactosamine.

4.7 Reactions

4.7.1 Monosaccharides and oligosaccharides

The forms of sugars with free carbonyl groups and the cyclic forms are in equilibrium, and therefore most of the reactions of sugars involve the reactive carbonyl group and the anomeric hydroxyl group. Some reactions also involve primary and secondary hydroxyl groups of the chain (salt formation, formation of complexes with metals and other reactions). The presence of the hydroxyl groups allows carbohydrates to interact with the aqueous environment and to participate in non-bonding interactions.

Sugars in the enzymatically active food materials become often substrates for various enzymes that catalyse oxidoreduction reactions of sugars (oxidoreductases), their hydrolysis (hydrolases) and a range of other reactions.

The aldehyde group of aldoses is easily oxidised, yielding sugar acids (glyconic acids) that eliminate water and form lactones. Aldoses and ketoses isomerise under the catalysis of bases and break down to lower sugars and other compounds. Reduction of aldoses and ketoses yields sugar alcohols. In aqueous solutions (of pH 3–7) and in diluted solutions of acids, monosaccharides are relatively stable at normal temperatures. At higher temperatures, to a small extent, intermolecular condensation leads to disaccharides and higher oligosaccharides. The long-term effect of diluted acids or concentrated acids results in hydrolysis of polysaccharides and oligosaccharides, and monosaccharides undergo dehydration to furan and pyran derivatives. In alkaline solutions, monosaccharides are unstable and even at normal temperature they undergo isomerisation and elimination reactions and rearrangements, their carbon chain splits and recombines again. At higher temperatures, sugars decompose to low molecular weight products. Chemical reactions of monosaccharides are shown schematically in Figure 4.24.

Reactions of sugars in foods are generally complex biochemical (enzymatic) and chemical (non-enzymatic) reactions. All the functional groups of sugar molecules participate in these reactions, which are influenced by pH, temperature, water content and depend on many other factors, especially on the presence of other food components. In this respect, reactions of sugars themselves and reactions of sugars with other food components that result in the formation of brown pigments are generally classified as **non-enzymatic browning reactions**. The most important reaction is the reaction of reducing sugars with proteins, the **Maillard reaction**.

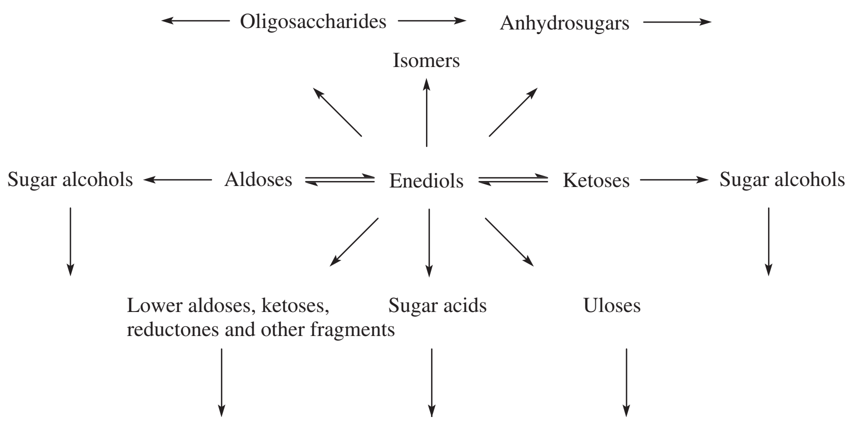


Figure 4.24 Main reactions of monosaccharides.

4.7.1.1 Reactions in acid media

4.7.1.1.1 Formation and hydrolysis of glycosides

Hemiacetal hydroxyl groups of pyranoses and furanoses are more acidic in comparison with other hydroxyl groups due to the negative inductive effect (–I effect) of the ring oxygen atom. Therefore, sugars tend to split these reactive hydroxyl groups in acidic media with the formation of mesomeric carbenium cations (Figure 4.25). This reaction is reversible. The existence of this cation explains a number of reactions that proceed on anomeric carbon, especially the formation and hydrolysis of glycosides.

A typical example is the formation of oligosaccharides from monosaccharides in acidic solutions. The reaction is called **reversion**. Its mechanism is opposite to the hydrolysis of oligosaccharides, which is **inversion**. The main products of D-glucose reversion are (1→6) disaccharides isomaltose and gentiobiose because the primary hydroxyl group on the C-6 carbon is more reactive than the secondary hydroxyl groups. Of the total products of glucose reversion, isomaltose amounts to about 68–70% and the gentiobiose to 17–18%. Minor reaction products are (1↔1), (1→2), (1→3) and (1→4) disaccharides and some higher oligosaccharides. Reversion products are commonly found in hydrolysates of saccharose, starch and other polysaccharides and arise also during caramelisation of sugars. For example, the reversion products in hydrolysates of starch are about 5–6%.

Glycosides have the typical properties of acetals. They are generally stable in alkaline solutions, but are hydrolysed in acidic solutions to the parent sugar and aglycone. Hydrolysis of glycosides by acids starts with protonation of the aglycone oxygen atom (Figure 4.25). Hydrolysed β-glycosides are generally hydrolysed faster than α-glycosides; the reaction rate depends considerably on the sugar moiety substituents. Hydrolysis of glycosides containing a 2-deoxysugar with hydrogen as a C-2 substituent is relatively rapid. For sugars containing either the electronegative hydroxyl group (which the majority of important sugars have) or the protonated amino group (in 2-amino-2-deoxysugars) in position C-2 hydrolysis is much slower.

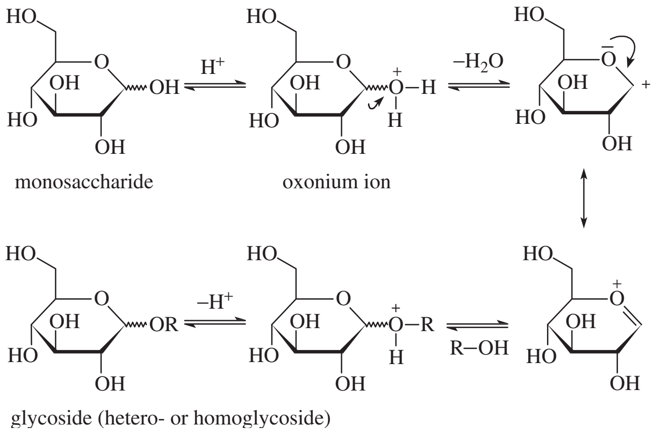

Figure 4.25 Mechanism of glycoside formation and hydrolysis.

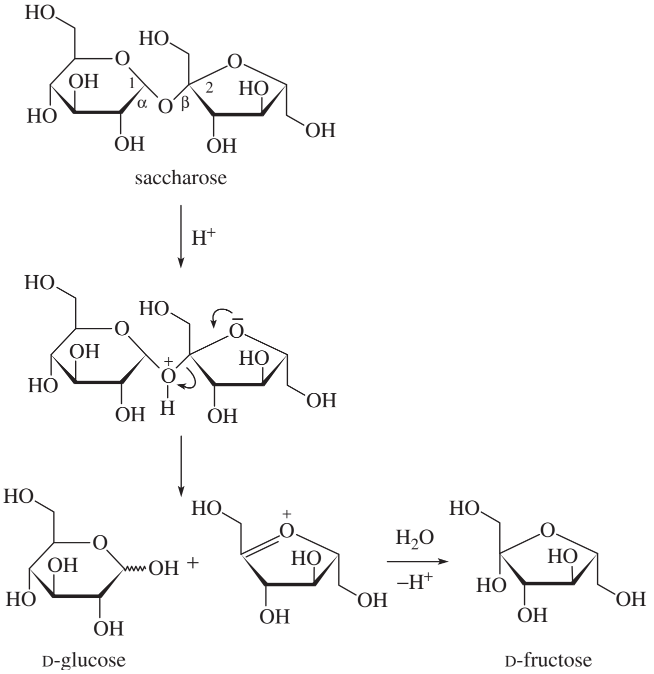

Figure 4.26 Mechanism of saccharose hydrolysis.

One of the most stable disaccharides is α,α-trehalose that contains two C-2 hydroxyl groups and is therefore about ten times more stable than maltose or lactose. Increased stability determines, in particular, the negative inductive effect of the hydroxyl groups at C-2. The hydrolysis rate of the galactose-*O*-glucose bond in raffinose, and also of the glucose-*O*-fructose bond in the reducing disaccharide turanose (Table 4.14), is comparable to the hydrolysis rate of maltose or lactose.

Hydrolysis (inversion) of saccharose to glucose and fructose is about 10^3 times faster than hydrolysis of other disaccharides, such as maltose and lactose (the rate constant of this first-order reaction in solutions of pH 1–3 at 100 °C is approximately $1\times10^{-3}\ s^{-1}$). Hydrolysis of saccharose takes place even at low temperatures, in the presence of diluted mineral or organic acids and in the presence of even small amounts of water. The glycosidic bond in glucose-*O*-fructose in raffinose, which yields melibiose (Table 4.16), is hydrolysed at a similar rate as saccharose. The reason is that the mechanism of hydrolysis of saccharose is somewhat different from the mechanism of hydrolysis of other glycosidic bonds (such as glucose-*O*-glucose or galactose-*O*-glucose). It is assumed that the resulting cation is degraded to glucose and a stable five membered cation of fructose. The reaction of this cation with water forms fructose (Figure 4.26).

4.7.1.1.2 Formation of anhydrosugars

In addition to extramolecular condensation to homoglycosides, aldohexoses also undergo intramolecular condensation of the hemiacetal and other hydroxyl groups to form the corresponding anhydrosugar (sugar anhydride). In addition to the main

reaction product, 1,6-anhydropyranose, small amounts of 1,6-anhydrofuranoses and other anhydrosugars may also form.

In acidic solutions D-glucose yields about 1% of 1,6-anhydro-β-D-glucopyranose known as β-glucosan or laevoglucosan. It is also produced under partial polymerisation to branched polysaccharides when glucose syrup is heated to temperatures higher than 100 °C, and by pyrolysis of glucose, starch and cellulose. Acids hydrolyse β-glucosan to D-glucose. The mechanism of formation of anhydrosugars from D-glucose is shown in Figure 4.27. Under similar conditions D-mannose yields 1,6-anhydro-β-D-mannopyranose (β-mannosan) and D-galactose yields 1,6-anhydro-β-D-galactopyranose (β-galactosan). The pyranose ring of 1,6-anhydrosugars is fixed in the $^1C_4$ conformation. Anhydrosugars of those monosaccharides that have a higher number of equatorial hydroxyl groups with appropriate conformation, such as β-D-idopyranose, are formed in larger amounts.

Ketoses do not form monomeric anhydrides, but intermolecular reactions yield tricyclic compounds. Heating of D-fructose (and also heating of saccharose or inulin) gives rise to various dianhydrides of the corresponding furanoses and pyranoses. Examples of these intermolecular anhydrides formed from fructose are the 1,2′:1′,2-dianhydride of α-D-fructofuranose with α-D-fructofuranose (**4-193**) and 1,2′:1′,2-dianhydride of α-D-fructopyranose with β-D-fructopyranose (**4-194**). Anhydrides are also formed by dehydration of disaccharides and sugar alcohols.

4-194, (α-D-fructopyranose)-(β-D-fructopyranose)-1,2′:1′,2-dianhydride

4.7.1.1.3 Formation of furan and pyran derivatives

The main reaction of monosaccharides under strongly acidic conditions is dehydration, associated with the loss of 1–3 molecules of water and the formation of furan and pyran derivatives. Both types of compounds are also formed during caramelisation of sugars. In practice, dehydration of monosaccharides and formation of furan and pyran derivatives also occurs in slightly acidic solutions, such as during long-term storage of fruit compotes, especially at elevated temperatures. Higher levels of furans and pyrans are formed during hydrolysis of starch, and significant amounts of these compounds arises in the production of acid protein hydrolysates that are used as seasonings for soups, sauces, gravies, snacks, meat and other products.

The reaction mechanism of the formation of furans and pyrans from D-glucose and D-fructose (ketoses are more reactive than aldoses) is shown in Figure 4.28. The intermediate product of dehydration of both sugars is 1-ene-1,2-diol (1-ene-1,2-diolate) stabilised by hydrogen bonds (Figure 4.29). The formation of 1-ene-1,2-diolate is known as **1,2-enolisation**. The reaction involves acid/base catalysis, so endiolates are common products of acid catalysed dehydration as well as isomerisation, saccharinic acid re-arrangement and fragmentation of sugars in alkaline media. All these reactions are often collectively called Lobry de Bruyn–Alberda van Ekenstein transformations of aldoses and ketoses.

The elimination of one molecule of water from D-glucose or D-fructose produces 3-deoxy-D-2-glycos-2-ulose, also known under the systematic name 3-deoxy-D-*erythro*-hexos-2-ulose (or

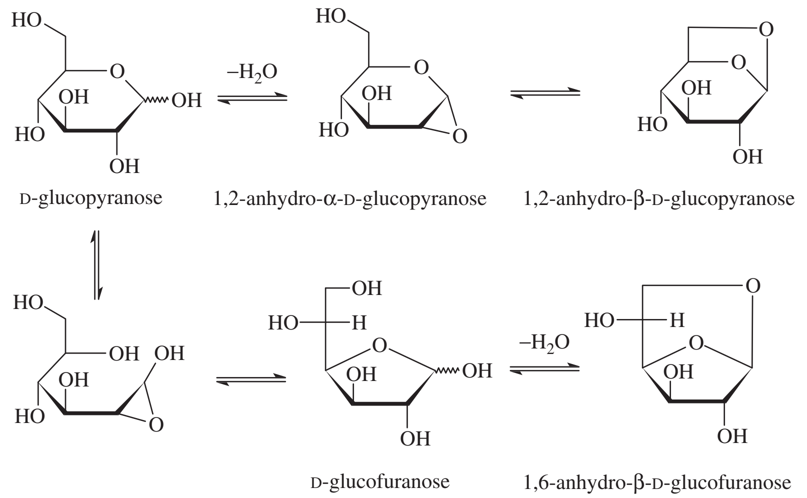

Figure 4.27 Formation of glucose anhydrides.

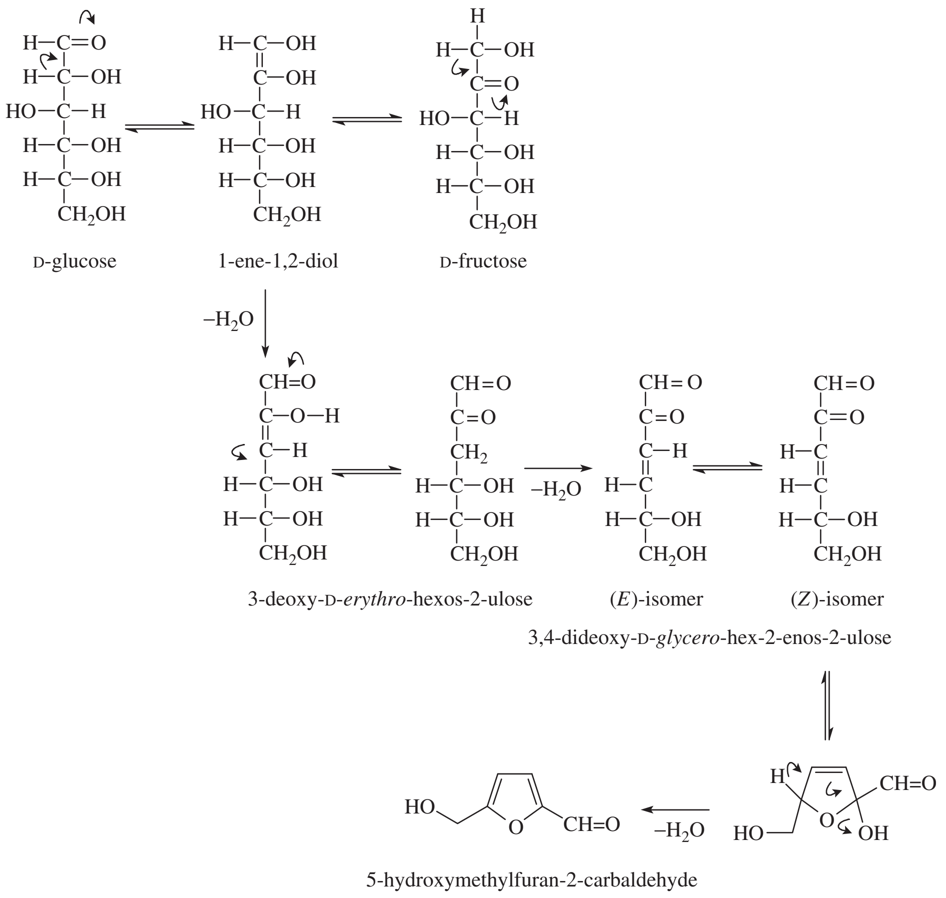

Figure 4.28 Dehydration of glucose and fructose.

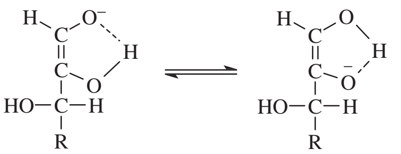

Figure 4.29 Structure of (*Z*)-1-ene-1,2-diolate.

by older name 3-deoxy-D-glucosone). In analogy, 3-deoxy-D-*threo*-hexos-2-ulose (3-deoxy-D-galactosone) results from D-galactose in milk products. Loss of the second water molecule creates 3,4-dideoxy-D-*glycero*-hex-3-enos-2-ulose (3,4-dideoxy-D-glucosulos-3-ene). The elimination of the third water molecule then yields 5-hydroxymethylfuran-2-carbaldehyde that can further decompose to laevulinic and formic acids. 5-Hydroxymethylfuran-2-carbaldehyde is one of the most common products of the dehydration of hexoses. It is virtually absent in fresh and untreated foods, but occurs in many carbohydrate-rich processed foods. For example, the concentrations of 5-hydroxymethylfuran-2-carbaldehyde in honeys were 3.3–26.3 mg/kg, in apple juices 2.9–3.5 mg/kg, in orange juices 2.7–10.6, in jams 2.7–15.9 mg/kg, in orange marmalade 47.1 mg/kg, in toasts 41.7–591 mg/kg and in roasted coffee 113–1093 mg/kg. When heated with hydrochloric acid, as in the production of acid hydrolysates of proteins (hydrolysis is performed at a temperature of 100–120 °C in about 20% acid), hexoses yield 5-chloromethylfuran-2-carbaldehyde (about 1–2 mg/kg) as a minor product.

The formation of 5-hydroxymethylfuran-2-carbaldehyde from saccharose proceeds via hydrolysis to fructofuranosyl cation and glucose (Figure 4.26). Elimination of a proton and two molecules of water from the fructofuranosyl cation yields 5-hydroxymethylfuran-2-carbaldehyde. Under dry pyrolytic conditions and at temperatures above 250 °C, 90% of 5-hydroxymethylfuran-2-carbaldehyde originates from the fructose moiety and only 10% originates from glucose. Pentoses and L-ascorbic acid dehydrate in the same way as hexoses under acidic conditions yielding furan-2-carbaldehyde (via reactive 3-deoxy-L-*threo*-pentos-2-ulose and 3,4-dideoxypentosulos-3-ene) as the main product (see Section 5.14.6.1.5). 6-Deoxyhexoses, such as L-rhamnose, yield, analogously, 5-methylfuran-2-carbaldehyde (**4-195**).

3-Deoxy-D-*erythro*-hexos-2-ulose occurs mainly as α- or β-pyranose in aqueous solutions. Owing to the presence of a keto group at C-2, other cyclic forms may also be present, such as furanoses (shown in Figure 4.30). In weakly acidic and neutral solutions, 3-deoxy-D-*erythro*-hexos-2-ulose eliminates water and yields γ-lactone of metasaccharinic acid and other products

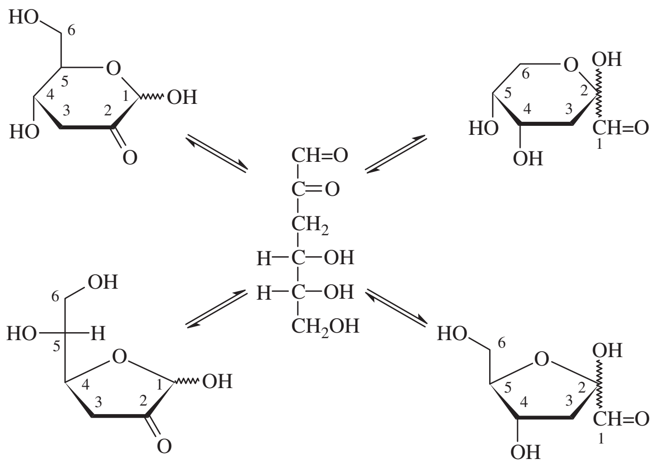

Figure 4.30 Cyclic forms of 3-deoxy-D-*erythro*-hexos-2-ulose in solutions.

5-chloromethylfuran-2-carbaldehyde, R = CH_2Cl

(Figure 4.31). Metasaccharinic and other sugar acids are, however, formed, preferably in alkaline solutions. Pyranoses also dominate in (*Z*)-3,4-dideoxy-D-*glycero*-hex-3-enos-2-ulose (**4-196**) solutions. The existence of a six-membered ring in (*E*)-3,4-dideoxy-D-*glycero*-hex-3-enos-2-ulose is not possible; therefore in aqueous solutions this isomer occurs as a straight chain form or as its hydrate (**4-197**), respectively.

5-Hydroxymethylfuran-2-carbaldehyde is the main reaction product of glucose and fructose in strongly acidic solutions, but fructose degradation also produces some other furan derivatives. Enolisation of D-fructose may continue along the chain and isomerisation via 2-ene-2,3-diol leads to a wider range of products than in the case of glucose. This isomerisation is known as **2,3-enolisation**. Splitting of the hydroxyl group at C-4 probably yields, by a sequence of isomerisation and dehydration reactions via 4-deoxy-D-*glycero*-hexo-2,3-diulose, another important degradation product of fructose 2-hydroxyacetylfuran, also known as furyl hydroxymethyl ketone (Figure 4.32). Via 1-deoxy-D-*erythro*-hexo-2,4-diulose (an isomerisation product of 1-deoxy-D-*erythro*-hexo-2,3-diulose, Figure 4.36) and 1,4-dideoxy-D-*glycero*-hexo-2,3-diulose (a product of oligosaccharides degradation, see also Figure 4.95) another dehydration product of sugars 2-acetylfuran is formed. The reactivity of sugars in 2-acetylfuran formation decreases

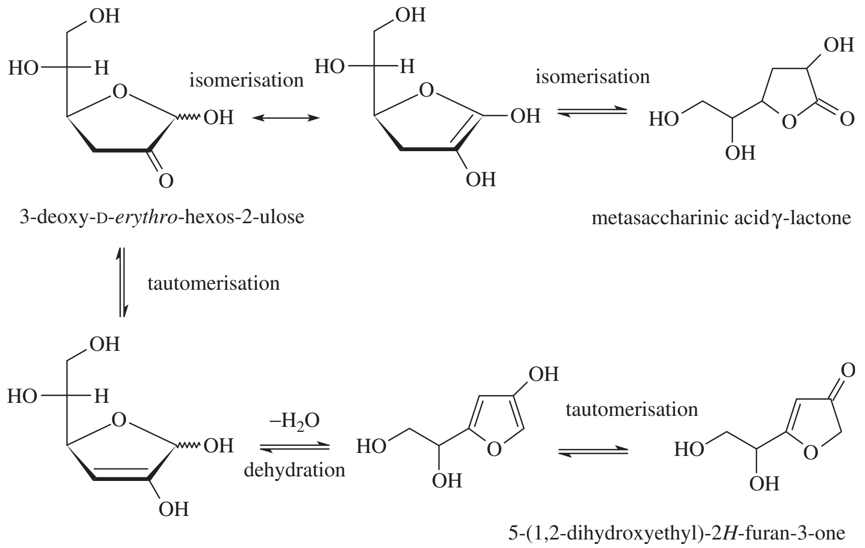

Figure 4.31 Formation of metasaccharinic acids and furan-3-ones from 3-deoxy-D-*erythro*-hexos-2-ulose.

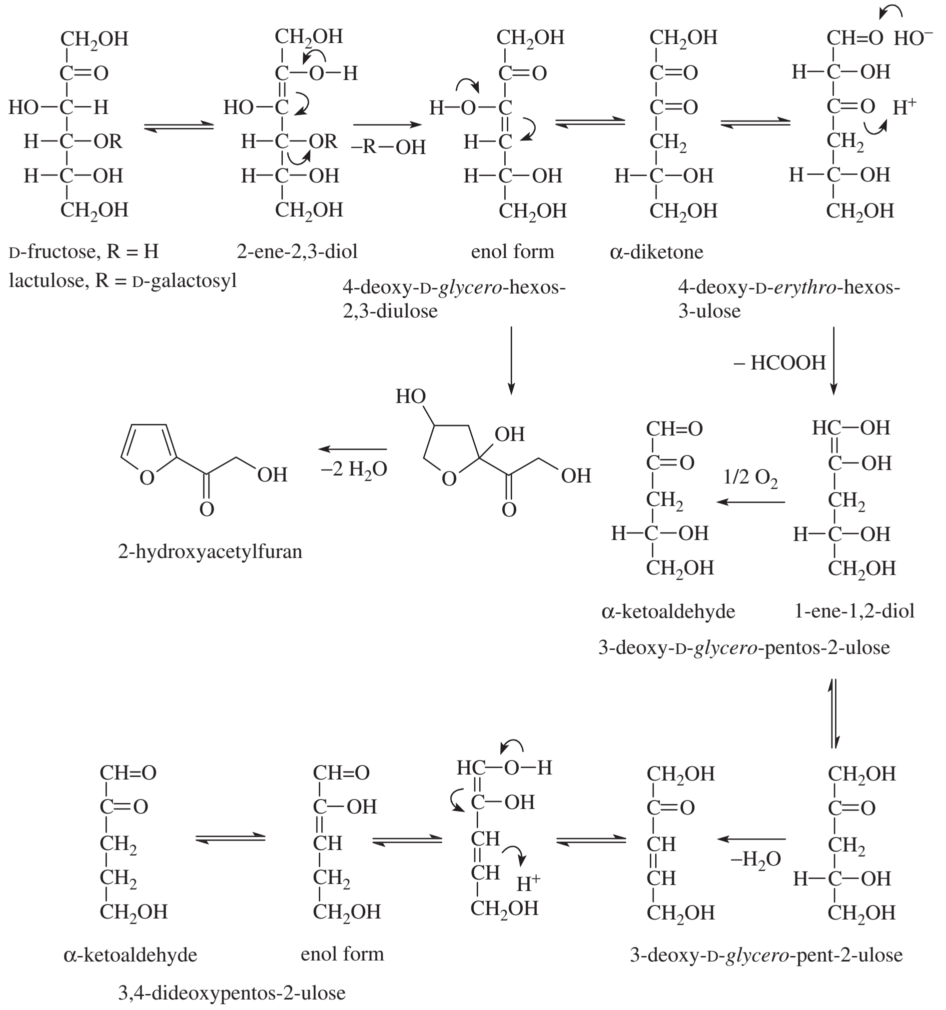

Figure 4.32 Formation of 2-hydroxyacetylfuran and 3-deoxy-D-*glycero*-pent-2-ulose from fructose and lactulose.

in the order ribose, fructose, glucose, rhamnose and sucrose. 1-Deoxy-2,3-diulose derived from ribose (and ascorbic and dehydroascorbic acids) reacts with formaldehyde (formed, for example, in the Strecker degradation of glycine) before forming a six-carbon unit – 1-deoxy-D-*erythro*-hexo-2,4-diulose – leading to 2-acetylfuran (Figure 4.33).

4-Deoxy-D-*glycero*-hexo-2,3-diulose is a typical product of degradation and 4-*O*-substituted derivatives of fructose (e.g. lactulose, which arises by isomerisation of lactose). 1,2-Enolisation of 4-deoxy-D-*glycero*-hexo-2,3-diulose yields, via the appropriate 1-ene-1,2-diol, unstable 4-deoxyhexos-3-ulose, which splits into formic acid and 1,2-enediol of 3-deoxy-D-*glycero*-pentulose in neutral or alkaline solutions by a reverse Claisen condensation mechanism. This sugar can be oxidised to 3-deoxy-D-*glycero*-pentos-2-ulose or may dehydrate to form 3,4-dideoxypentosulose (Figure 4.32). Other reaction products are isosaccharinic acids.

Splitting of the hydroxyl group at C-1 of fructose yields a key intermediate 1-deoxy-D-*erythro*-hexo-2,3-diulose (Figure 4.34). In addition to the straight chain form, the corresponding furanoses and pyranoses also form in solution (Figure 4.35). Isomerisation of 1-deoxy-D-*erythro*-hexo-2,3-diulose along the chain yields other important intermediates: 1-deoxy-D-*erythro*-hexo-2,4-diulose, 1-deoxy-D-*erythro*-hexo-3,4-diulose, 1-deoxy-D-*erythro*-hexo-3,5-diulose, 1-deoxy-D-*erythro*-hexo-4,5-diulose and 1-deoxy-D-*ribo*-hexo-4,6-diulose (Figure 4.36). 1-Deoxy-D-*erythro*-hexo-2,3-diulose is considered a precursor of many important furanones and pyranones that arise particularly in weakly acidic and neutral solutions. For example, this diulose is the precursor of 3-hydroxy-2-methylpyran-4-one, which is trivially termed maltol, and of its isomer 2-acetyl-3-hydroxyfuran, known as isomaltol (Figure 4.37). Maltol and isomaltol have the characteristic and intense caramel odour and taste.

In comparison with hexoses, higher quantities of maltol and isomaltol are produced from 4-*O*-substituted glucose derivatives, such as from maltose and lactose. For example, in malt coffee (coffee substitutes), maltol occurs at a level of 300 mg/kg, in chocolates at approximately 3 mg/kg and in dark beers up to 3 mg/kg. The mechanism of degradation of 1-deoxyglycodiuloses derived from disaccharides is somewhat different from that of 1-deoxyglycodiuloses arising from monosaccharides (Figure 4.38). Elimination of the hydroxyl group in position C-5 of the cyclic diulose (pyranose) yields pyran-3-one. This compound,

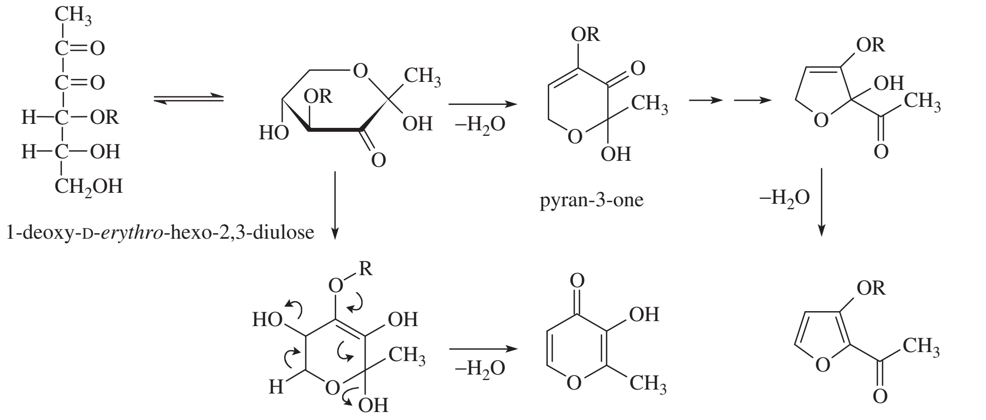

Figure 4.38 Formation of maltol and isomaltol from disaccharides.

which was also found in heat-treated milk (R = β-D-galactosyl), is the key intermediate of the degradation of disaccharides. The fate of this intermediate depends on the properties of glycosidically bound sugar. If that sugar is β-galactose (in the case of lactose), the main reaction product is galactosylisomaltol. If that sugar is glucose (in the case of maltose), maltol and glucosylisomaltol are formed only in trace amounts. For example, glucosylisomaltol was determined in prebaked bread (heated at 190 °C for 30 min), where its amount increased from non-detectable to 20.9 mg/kg after 30 min of baking.

A compound with similar organoleptic properties to those of isomaltol or maltol is 2,4-dihydroxy-2,5-dimethyl-2*H*-furan-3-one, the cyclic form of so called diacetylformoin. Diacetylformoin arises from 1-deoxy-D-*erythro*-hexo-2,3-diulose (Figure 4.39) via 1,6-dideoxy-D-*glycero*-hexo-2,4,5-triulose (acyclic form of diacetylformoin) and other intermediates (Figure 4.40). Diacetylformoin is considered a precursor of other important furans and pyrans and of many low molecular weight degradation products. In addition to diacetylformoin, hexoses (cyclic forms of 1-deoxy-D-*erythro*-hexo-2,3-diulose) also give rise to 4-hydroxy-5-hydroxymethyl-2-methyl-2*H*-furan-3-one and to isomeric 5,6-dihydro-3,5-dihydroxy-2-methyl-4*H*-pyran-4-one (Figure 4.39). 5,6-Dihydro-3,5-dihydroxy-2-methyl-4*H*-pyran-4-one is typically formed in thermally processed foods and its presence indicates the extent of non-enzymatic browning reactions. This dihydropyranone is related to maltol, but maltol is not produced from this compound under the conditions of the Maillard reaction. Along with 5,6-dihydro-3,5-dihydroxy-2-methyl-4*H*-pyran-4-one, its unstable isomer, the corresponding pyran-3-one is also formed, but this compound rearranges to lactic acid ester.

The reaction product of pentoses, hexoses (e.g. D-fructose via 1-deoxy-D-*erythro*-hexo-2,3-diulose) or alduronic acids is 4-hydroxy-5-methyl-2*H*-furan-3-one, which is known as norfuraneol (Figure 4.39). Norfuraneol can also be formed from hexoses via 4-hydroxy-2-hydroxymethyl-5-methyl-2*H*-furan-3-one by splitting off formaldehyde. 6-Deoxyhexoses (methylpentoses) produce, analogously, 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one, which is known as furaneol (Figure 4.39). An alternative reaction

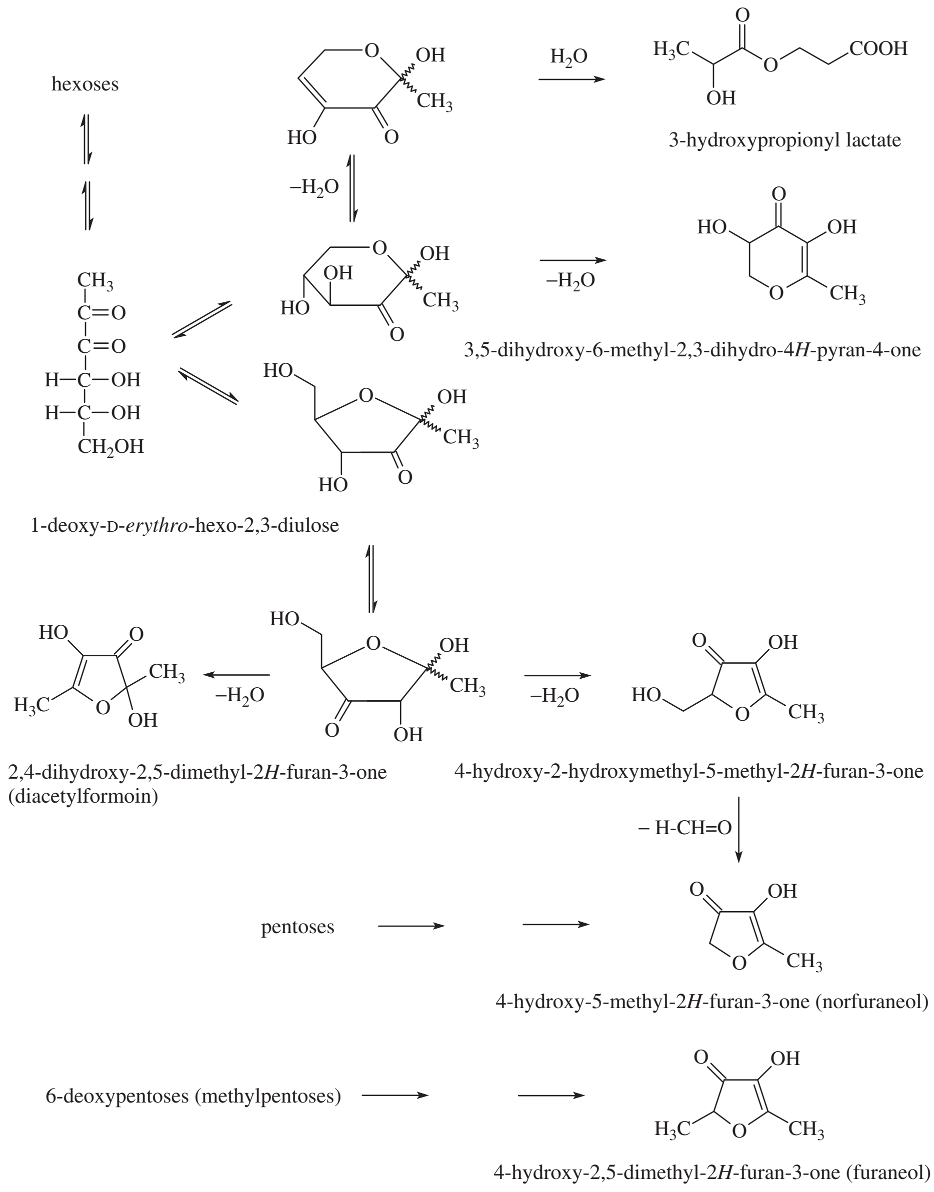

Figure 4.39 Formation of furan-3-ones and pyran-4-ones.

pathway to 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one is a reaction of methylglyoxal with hydroxyacetone (1-hydroxypropan-2-one) (Figure 4.41). Furaneol occurs as a racemic mixture because of its configurational instability (keto–enol tautomerism).

Furaneol and norfuraneol are significant sensorially active substances with low threshold concentrations. They are synthesised and added to numerous aroma compositions with a pleasant sugary, jammy, fruity and caramel flavour reminiscent of cooked strawberries and pineapple, which is where furaneol was identified for the first time (see Section 8.2.11.1.1).

4.7.1.1.4 Subsequent reactions of furans and pyrans

Under acidic conditions, 5-hydroxymethylfuran-2-carbaldehyde partially decomposes to laevulinic (4-oxopentanoic) acid and formic acid (Figure 4.42). Both acids are, for example, important components of acid protein hydrolysates. Laevulinic acid content in acid protein hydrolysates can be up to about 2% w/w. Its cyclisation product, α-angelica lactone, was identified in acid hydrolysates of proteins, extracts from vanilla pods, raisins, bread and other products.

All derivatives of furan-2-carbaldehyde are reactive substances. They are easily oxidised by oxygen to the corresponding acids, which, together with the appropriate alcohols, are also formed from furan-2-carbaldehyde derivatives by Cannizzaro reaction. Derivatives of furan-2-carbaldehyde condense together or with other carbonyl compounds and enter into non-enzymatic browning reactions. Oxidation of 5-hydroxymethylfuran-2-carbaldehyde, for example, yields 5-hydroxymethylfuran-2-carboxylic acid (**4-198**). Condensation

of two molecules of this aldehyde form the corresponding ether (**4-199**) and condensation with 3,4-dideoxy-D-*glycero*-hex-3-en-2-ulose (2-hydroxy-6-hydroxymethylpyran-3-one) yields the corresponding dimer and other compounds (Figure 4.43). The dehydration product of fructose 2-hydroxyacetylfuran gives a coloured trimer with furan-2-carbaldehyde by aldolisation (**4-200**). Condensation products are also formed in reactions of 4-hydroxy-5-methyl-2*H*-furan-3-one (**4-201**) or 3,5-dihydroxy-2-methyl-4,5-

dihydropyran-3-one (**4-202**) with aliphatic aldehydes and similar products arise with other furans and pyrans. Some of these products are coloured, and uncoloured compounds produce coloured polymers by condensation reactions.

4.7.1.1.5 Formation of reductones

Some of the degradation products of 1-deoxyhexo-2,3-diuloses are reductones, compounds that have the enediol group adjacent to a carbonyl group. In solutions of pH < 6, reductones (like enediolates) occur as monoanions (Figure 4.44) stabilised by resonance. In media of higher pH value, reductones form unstable dianions. In foods, reductones act as antioxidants as in acidic solutions they can reduce a number of organic compounds and metal ions. Their oxidation yields triuloses (Figure 4.45).

Reductones with six carbon atoms in the molecule, formed in acidic solutions, include aliphatic compounds that form as intermediates in the transformation of 1-deoxy-D-*erythro*-hexo-2,3-diulose (Figure 4.37). Diacetylformoin is also one such reductone

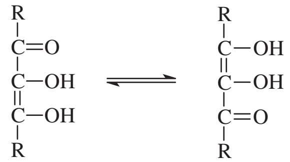

Figure 4.44 Structure of reductones.

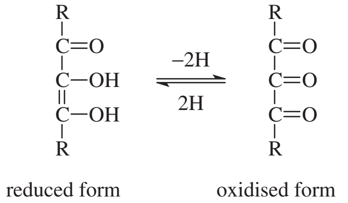

Figure 4.45 Oxidation and reduction of reductones.

(Figure 4.40); another naturally occurring reductone is L-ascorbic acid. In alkaline media, aliphatic reductones with four and three carbon atoms in the molecule, such as *C*-methyltriosoreductone and alicyclic triosoreductone, form by fragmentation of sugars. Reductones containing nitrogen in the molecule are formed as products of the Maillard reaction.

4.7.1.2 Reactions in basic media

4.7.1.2.1 Isomerisation

Enolisation of acyclic forms of reducing monosaccharides occurring in neutral and weakly alkaline media proceeds by a similar mechanism as to their dehydration in acidic solutions. Enolisation of D-glucose or D-fructose produces 1-ene-1,2-diol (enediol anion species 1-ene-1,2-diolates). Enolisation is a reversible reaction, therefore D-glucose, its epimer D-mannose and D-fructose produce a mixture of all three sugars as the main products (Figure 4.46). For example, an aqueous solution of D-glucose of pH 10 is still dominated by D-glucose after 10 days of heating to 35 °C and contains 63.5% D-glucose, 31% D-fructose and 2.5% D-mannose. Isomerisation of glucose to fructose is also known as **aldose–ketose isomerisation** and the change of configuration on carbon C-2 is

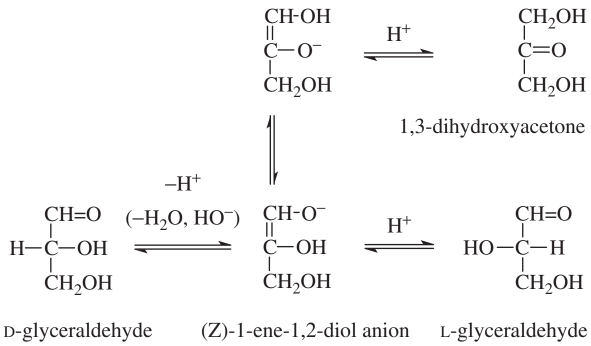

Figure 4.47 Isomerisation of trioses.

called **epimerisation** or **aldose–aldose** isomerisation. The corresponding pairs of aldoses (e.g. glucose and mannose) are called **epimers**. D-Fructose further produces a small amount of D-psicose by 2,3-enolisation. Enolisation can continue along the chain and a small amount of D-sorbose is produced by 3,4-enolisation of fructose, while glucose can yield traces of D-allose and D-mannose gives rise to small amounts of D-altrose.

Isomerisation of pentoses, tetroses, trioses as well as isomerisation of disaccharides takes place analogously. For example, D-ribose produces ketose D-ribulose as the major product and a smaller amount of aldose D-arabinose, glyceraldehyde yields ketose 1,3-dihydroxyacetone (Figure 4.47), the major product of disaccharide lactose is lactulose, which is accompanied by smaller amount of epilactose.

4.7.1.2.2 Rearrangement to acids

When sugars are heated in the solid state (caramelisation) or in alkaline solutions, enolisation precedes the parallel irreversible

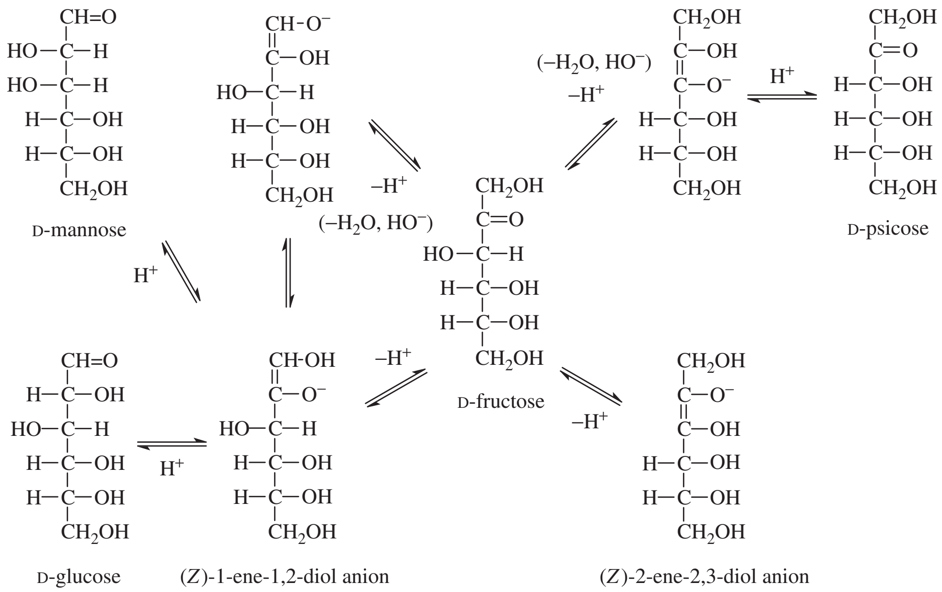

Figure 4.46 Isomerisation of glucose.

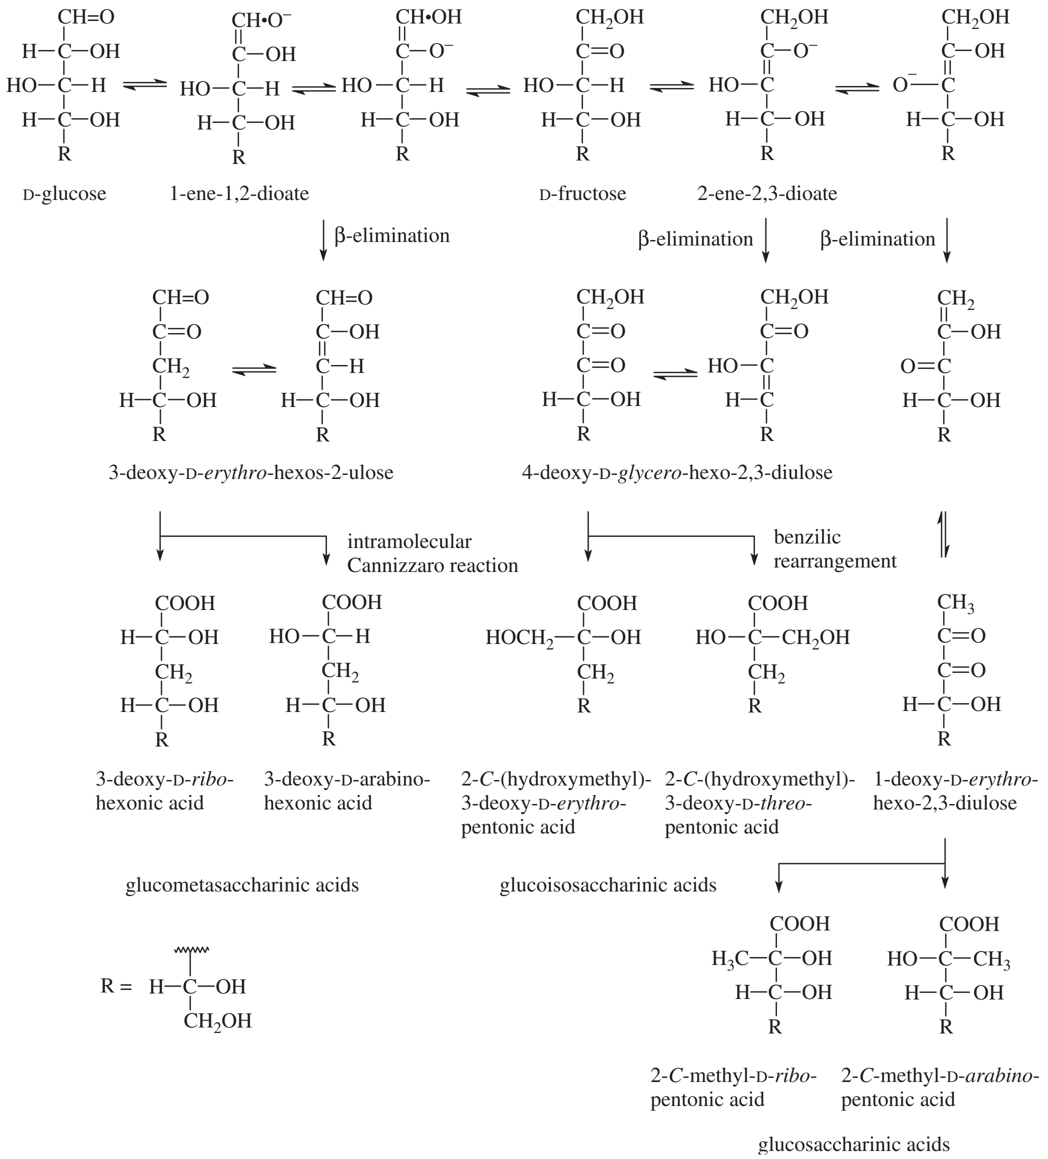

Figure 4.48 Formation of saccharinic acids from glucose and fructose.

rearrangement to sugar acids. The mechanism of this reaction is, using the example of D-glucose and D-fructose, shown in Figure 4.48. The 1-ene-1,2-diolate eliminates the hydroxyl group at C-3 producing the reactive α-dicarbonyl compound (or 2-oxoaldehyde) 3-deoxy-D-*erythro*-hexos-2-ulose. Isomers of **metasaccharinic acids**, such as 3-deoxy-D-*ribo*-hexonic acid (3-deoxy-D-gluconic acid) and 3-deoxy-D-*arabino*-hexonic acid (3-deoxy-D-mannonic acid), are formed from 3-deoxy-D-*erythro*-hexos-2-ulose by intramolecular Cannizzaro reaction. Branched acids, called **isosaccharinic acids**, such as 2-*C*-(hydroxymethyl)-3-deoxy-D-*erythro*-pentonic acid and 2-*C*-(hydroxymethyl)-3-deoxy-D-*threo*-pentonic acid, and also isomers of saccharinic (aldonic) acids (2-*C*-methyl-D-*ribo*-pentonic and 2-*C*-methyl-D-*arabino*-pentonic acids), are formed via 2-ene-2,3-diols by benzilic acid rearrangement of α-dicarbonyl intermediates (2,3-diuloses).

The reaction is generally acid–base catalysed and small amounts of saccharinic acids (their lactones) are formed even in an acidic solution. D-Glucose is the precursor, via 3-deoxy-D-gluconic acid, of the corresponding γ-lactone (Figure 4.31). In the case of 3-*O*-substituted D-glucose, 4-*O*-substituted D-glucose and 1-*O*-substituted D-fructose (and the corresponding disaccharides), the reaction mechanism is analogous and the reaction products are again isosaccharinic and saccharinic acids. The formation of isosaccharinic acids from lactose is shown in Figure 4.49 as an example.

The reaction of trioses takes place in a similar manner (Figure 4.50). D-Glyceraldehyde or 1,3-dihydroxyacetone dehydration yields 1,2-diulose methylglyoxal (also known as pyruvic acid aldehyde or pyruvaldehyde) and the intramolecular Cannizzaro reaction of methylglyoxal yields lactic acid (racemate).

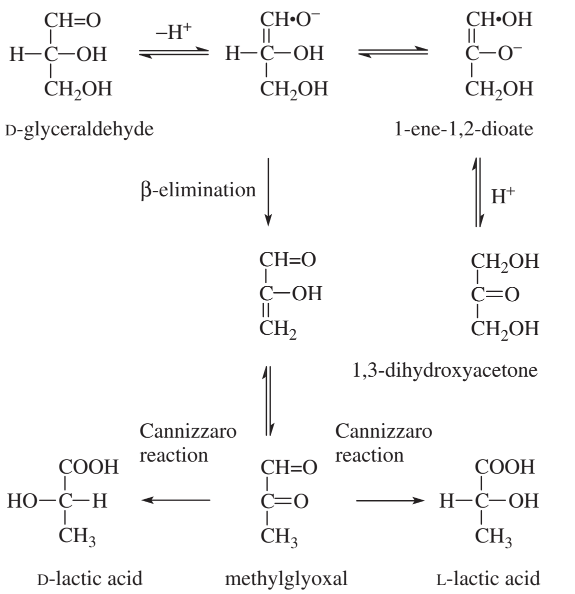

Figure 4.50 Formation of methylglyoxal and lactic acid from trioses.

4.7.1.2.3 Fragmentation and reactions of fragments

Fragmentation

Another important reaction in alkaline media is monosaccharide splitting into fragments with fewer carbon atoms. The cleavage occurs by oxidation of the molecule (after previous isomerisation and dehydration) or by retroaldolisation (opposite reaction to aldolisation). The main products are acids and highly reactive carbonyl, hydroxycarbonyl and dicarbonyl compounds, from which a large number of secondary products result from subsequent reactions such as isomerisation, aldolisation, Cannizzaro reaction and other reactions. Some of these products may be the final reaction products, while others subsequently enter into other reactions, for example with amino acids or proteins.

An example of a degradation product of sugars with one carbon atom in the molecule is formaldehyde. Acetaldehyde, glyoxal and glycolaldehyde have two carbon atoms, while glyceraldehyde, 1,3-dihydroxyacetone (1,3-dihydroxypropan-2-one), hydroxyacetone (1-hydroxypropan-2-one and also known as acetol), lactaldehyde (2-hydroxypropanal or lactic acid aldehyde), methylglyoxal (pyruvaldehyde) and hydroxymethylglyoxal are all examples of products with three carbon atoms. The four carbon fragment is hydroxybiacetyl (1-hydroxybutan-2,3-dione) and aldose D-erythrose, and the five carbon atom fragments are pentoses, such as D-arabinose. At the same time, aliphatic three and four carbon reductones are produced, such as the so-called triosoreductone, *C*-methyltriosoreductone and alicyclic reductones. Monosaccharides produce more fragments than disaccharides, and glucose gives more fragments than fructose. Fragmentation of monosaccharides is illustrated by the fragmentation of D-glucose (Figure 4.51) and D-fructose (Figure 4.52).

Formation of carboxylic acids

Fragmentation of sugars and glycosuloses leads not only to reactive α-dicarbonyl and α-hydroxycarbonyl products, but also to carboxylic acids. Carboxylic acids with short chains can be formed by several mechanisms. Acetic acid is a major degradation product of sugars, especially in neutral and alkaline solutions. As a product of degradation of hexoses, acetic acid is almost exclusively produced from C-1/C-2 atoms of their transformation products, 1-deoxy-2,3-diuloses. The most common pathway is the isomerisation of the reactive α-dicarbonyl intermediate to

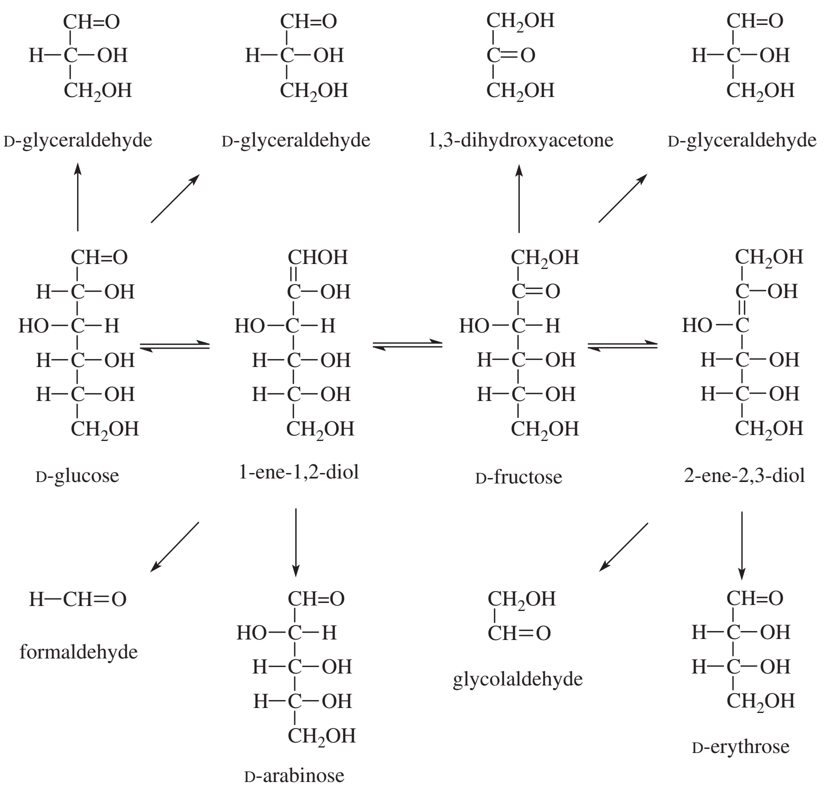

Figure 4.51 Fragmentation of glucose and fructose.

β-dicarbonyl compounds, followed by hydrolytic (β-dicarbonyl) cleavage (reverse Claisen condensation). For example, 1-deoxy-D-*erythro*-hexo-2,3-diulose, via 1-deoxy-D-*erythro*-hexo-2,4-diulose and after nucleophilic attack of hydroxyl anion to the C-2 carbonyl group and subsequent protonisation of C-4 carbonyl group, yields acetic acid and an 1-ene-1,2-diol intermediate, which isomerises to yield either C_4 ketose D-erythrulose or C_4 aldoses D-erythrose and D-threose (Figure 4.53). Oxidative (α-dicarbonyl) cleavage of 1-deoxy-D-*erythro*-hexo-2,4-diulose yields acetic acid and D-tetronic acids (D-erythronic and D-threonic acids). Hydrolytic cleavage of 1-deoxy-D-*erythro*-hexo-2,4-diulose leads to D-glyceric acid and hydroxyacetone (acetol). Oxidative cleavage of the 1-ene-1,2-diol intermediate leads to the formation of D-*glycero*-tetros-2-ulose and dehydration of the 1-ene-1,2-diol yields 3-deoxytetros-2-ulose and (after isomerisation) 1-deoxytetro-2,3-diulose. Another possibility is the formation of acetic acid from carbons C-3/C-4 of 1-deoxy-D-*erythro*-hexo-2,4-diulose by hydrolytic cleavage of 1-deoxytetro-2,3-diulose (Figure 4.54). To a lesser extent acetic acid results from carbons C-5/C-6 after dehydration of 1-deoxy-D-*erythro*-hexo-2,4-diulose to diacetylformoin and its hydrolytic β-cleavage.

Similar mechanisms, cleavage of C-1/C-2 bonds of 1-amino-1,4-dideoxyhexo-2,3-diulose, lead to the formation of formic acid and 3-deoxypentos-2-ulose. 1-Amino-1,4-dideoxy-D-*glycero*-hexo-2,3-diulose arises almost exclusively by transformation of oligosaccharides, such as maltose, linked by a (1→4) glycosidic bond and hydrolysis of the bound amino compound yields 1,4-dideoxy-D-*glycero*-hexo-2,3-diulose (see Section 4.7.5.3.3).

In addition to formic, acetic and glyceric acids, the transformation of sugars yields a number of other acids, from C_2 (glycolic acid) to C_6 acids. Acids are formed at higher temperatures, especially in alkaline media and in the presence of oxygen. To a lesser extent, acids may arise from α-dicarbonyl intermediates by oxidative cleavage. When oxygen binds to one of the carbonyl group carbons, electron transfer (Baeyer–Villiger rearrangement) and hydrolysis of the product yield two molecules of carboxylic acids (Figure 4.55). The options also include oxidation of the terminal aldehyde groups of sugars by molecular oxygen, which produces carboxylic acids occurring in acidic solutions in the form of lactones.

Reactions of fragments with water

Carbonyl compounds with electron-withdrawing groups on C_α carbon can be hydrated in aqueous solution. Carbonyl compounds and their hydrates are in equilibrium with each other and most hydrates (as well as hemiacetals) are known to decompose spontaneously to the corresponding carbonyl compounds (Figure 4.56). For example, formaldehyde in dilute aqueous solutions is almost completely hydrated, acetaldehyde is hydrated to about 60%, while higher (fatty) aldehydes and acetone are not hydrated at all. The hydration of carbonyl compounds is the result of the positive inductive effect of alkyl substituents. In addition to the hydrate (methyleneglycol), concentrated solutions of formaldehyde also contain a series of oligomeric hydrates of general formula H–(O–CH_2)$_n$–OH. In neutral and especially in acidic

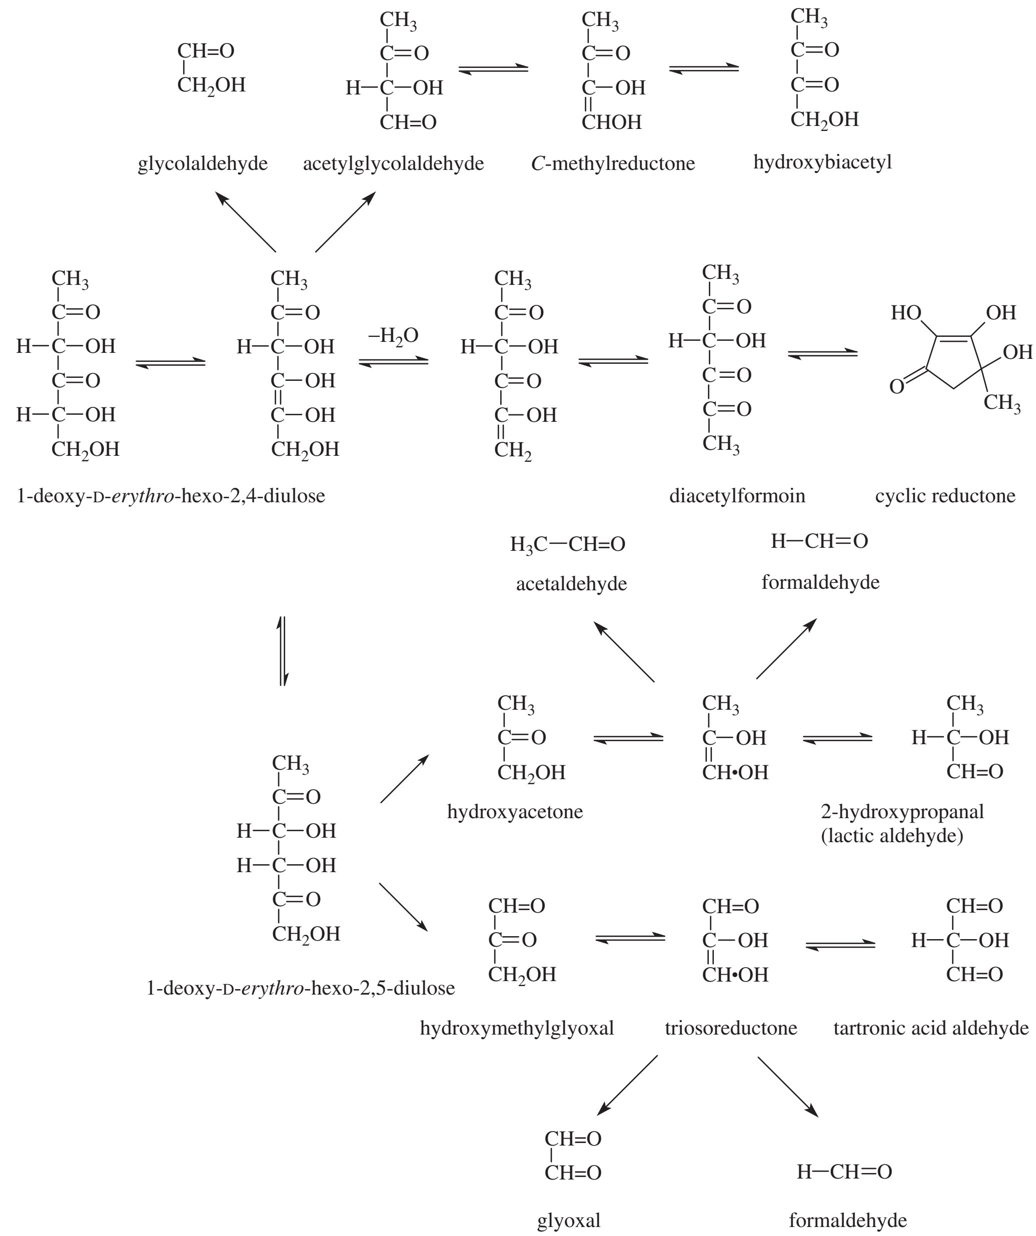

Figure 4.52 Formation of fragments and reductones from fructose 2,3-enolisation products.

solutions, formaldehyde also forms a cyclic trimer, 1,3,5-trioxan, and polymeric hydrates known as paraformaldehyde (Figure 4.57). A cyclic trimer, 2,4,6-trimethyl-1,3,5-trioxan (paraldehyde, **4-203**), is formed in acidic solutions from acetaldehyde.

The product of microbial transformation of glycerol, 3-hydroxypropionaldehyde, undergoes a reversible dimerisation and hydration (Figure 4.58), which results in an equilibrium of 3-hydroxypropionaldehyde, 1,1,3-trihydroxypropane (3-hydroxypropionaldehyde hydrate) and 2-(2-hydroxyethyl)-4-hydroxy-1,3-dioxane (3-hydroxypropionaldehyde dimer). Hydrates also form from α-hydroxycarbonyl compounds, such as glycolaldehyde, glyceraldehyde and 1,3-dihydroxyacetone, and α-dicarbonyl compounds, such as glyoxal, methylglyoxal and related substances (Figure 4.59). These hydrates are spontaneously transformed into various cyclic dimers with 1,4-dioxolane rings. Hydrates similarly form some higher α-hydroxycarbonyl and α-dicarbonyl compounds, such as L-dehydroascorbic acid (Figure 5.27) and 2,3-dioxo-L-gulonic acid.

The hydrates of most carbonyl compounds, such as methylglyoxal hydrate (Figure 4.60), are unstable and exist only in solutions. Hydrates that are stable in the solid state arise, for example, from (*E*)-3,4-dideoxy-D-*glycero*-hex-3-enos-2-ulose. Oligomers that are stable in the solid state are also formed from hydrates of glycolaldehyde (**4-204**) or glyoxal (**4-205**) and thermal degradation of these hydrates produces a number of different products. For example, glyoxal hydrate trimer produces the corresponding dimer, monomer,

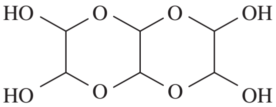
carbon dioxide and formic acid[9] when heated to 250 °C. Methylglyoxal hydrate yields about 40 different compounds during heating to 100 °C. The main decomposition products are acetic acid (30%), propane-1,2-diol (18%), hydroxyacetone (acetol, 7%) and 2,4-dimethyl-1,3-dioxolane, which is a cyclic acetal of formaldehyde and propane-1,2-diol (7%). Other products are formed in smaller quantities, for example 2-hydroxypropanal (lactic aldehyde) and formic acid. Dehydration of hydroxyacetone yields acrolein (Figure 4.60).



4-205, glyoxal hydrate trimer

[9]Formic acid is a common degradation product of sugars and also the oxidation product of formaldehyde. It is effective as a specific reagent for reductive amination of imminium ions to give secondary amines in the Maillard reaction. The reaction is known as a Wallach or Leuckart reaction (reactions of formates or formamide): $R^1R^2N^+{=}CH{-}R + H{-}COOH \rightarrow R^1R^2N{-}CH_2{-}R + CO_2$.

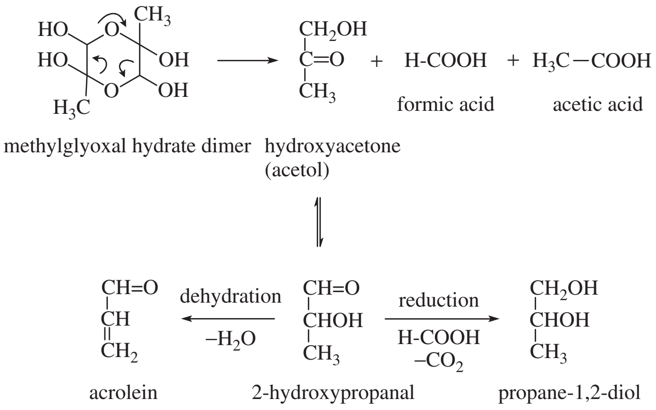

Figure 4.60 Degradation of methylglyoxal and hydroxyacetone.

Other reactions of fragments

Sugar fragments isomerise in alkaline solutions just like the original sugars. Glyceraldehyde, for example, isomerises to 1,3-dihydroxyacetone (Figure 4.47), hydroxyacetone isomerises to lactic aldehyde, hydroxymethylglyoxal to triosoreductone and *C*-methyltriosereductone to 3-oxobutanal (Figure 4.52).

Sugar fragments can also be rearranged into acids. For example, dehydration of glyceraldehyde and 1,3-dihydroxyacetone yields methylglyoxal, which is rearranged to lactic acid (Figure 4.50). Aldehydes and ketones that have at least one hydrogen on the C_α carbon undergo aldolisation in alkaline solutions. The reaction of formaldehyde with the reactive degradation sugar product glycolaldehyde yields glyceraldehyde that isomerises to 1,3-dihydroxyacetone and then reacts, in the rate-determining step, with another molecule of formaldehyde. The reaction of formaldehyde in alkaline earth hydroxide solutions, leading to a mixture of optically inactive sugars (so-called formose), is called the formose reaction. Originally it was assumed that glycolaldehyde, which catalyses this reaction, arises from formaldehyde. It was later shown that formaldehyde contained trace amounts of glycolaldehyde as an impurity. The formed tetroses break down relatively quickly by retroaldolisation to glycolaldehyde, and the cycle is repeated. In subsequent steps, tetroses can react with formaldehyde or to yield pentoses to hexoses with branched or straight chains. At the level of hexoses, the reaction virtually stops because hexoses are relatively stable compounds that react slowly with formaldehyde (Figure 4.61).

The main aldolisation products from the reaction of glycolaldehyde with D-glyceraldehyde are D-arabinose and D-xylose. Similarly, D-glyceraldehyde and 1,3-dihydroxyacetone aldolisation produce a mixture of D-fructose and D-sorbose. The reaction is highly stereoselective as a diol arrangement of *threo*-configuration and not of *erythro*-configuration results on carbons C-3 and C-4. A similar highly selective aldol reaction of 1,3-dihydroxyacetone phosphate is catalysed by the enzyme aldolase. Branched sugar D-dendroketose is formed as one of the minor products.

The mutual condensation of some degradation products of sugars yields important alicyclic substances called cyclopentenolones, which are characterised by a caramel flavour similar to maltol, and other secondary reaction products of sugars. For example, condensation of hydroxyacetone with lactic aldehyde yields the basic member of the homologous series 2-hydroxy-3-methylcyclopent-2-en-1-one, which is known as cyclotene (Figure 4.62). In aqueous solutions, cyclotene exists partly as the corresponding hydrate.

Condensation of sugar degradation products in alkaline, neutral and weakly acidic media or a sequence of isomerisation, dehydration and oxidation/reduction reactions of sugars can lead to aromatic compounds such as phenols. For example, minor degradation products of D-glucose and D-fructose in neutral media are catechol and pyrogallol (**4-206**), but products with a higher number of carbon atoms can also be formed, such as 3,4-dihydroxybenzaldehyde, 3,4-dihydroxyacetophenone (**4-207**) and 3-hydroxy-6-hydroxymethylchrom-2-one (**4-208**). Phenolic compounds play an particularly important role in the non-enzymatic browning reactions of cellulose and cellulose products, which results in yellowing of paper and cotton textile products, because phenolic compounds are easily oxidised to coloured quinones that further react with the original phenols or amino compounds with the formation of coloured reaction products. Quinones also react with sugars and may form *C*-glycosides (**4-209**). During thermal processing of foods, *C*-glycosides are produced with reducing sugars, as are flavonoids such as flavan-3-ols (catechins). Reaction of maltose with (+)-catechin yields, for example, (+)-catechin-6-*C*-β-D-glucopyranosyl-(4→1)-*O*-α-D-glucopyranose (**4-210**). Carbonyl and dicarbonyl sugar transformation products form addition compounds with tannins and other naturally occurring phenolic substances even under physiological

conditions. An example is the reaction of the main component of tea leaves (−)-epigallocatechin-gallate (see Section 8.3.6.2.1) with methylglyoxal (Figure 4.63).

4.7.1.3 Oxidations and reductions

4.7.1.3.1 Oxidation by oxygen, peroxides and peroxyl radicals

An aldehyde group is oxidised to a carboxyl group enzymatically during caramelisation and by common oxidising agents in basic and acidic media. The oxidation by atmospheric oxygen, called autoxidation, is slow under neutral conditions and faster in alkaline media. During autoxidation, D-glucose and D-fructose produce unstable hydroperoxides via 1-ene-1,2-diol. Their decomposition yields arabinonic and formic acids (Figure 4.64). Glucose and fructose are also oxidised in the presence of transition metal ions, such as Cu^{2+} and Fe^{3+}, via enediol complex with metal and oxygen, to D-*arabino*-hexos-2-ulose, which can be further oxidised with decomposition and reduction of metal ions.

Similar products are formed by oxidation with hydrogen peroxide in alkaline media. Hydrogen peroxide is also formed by

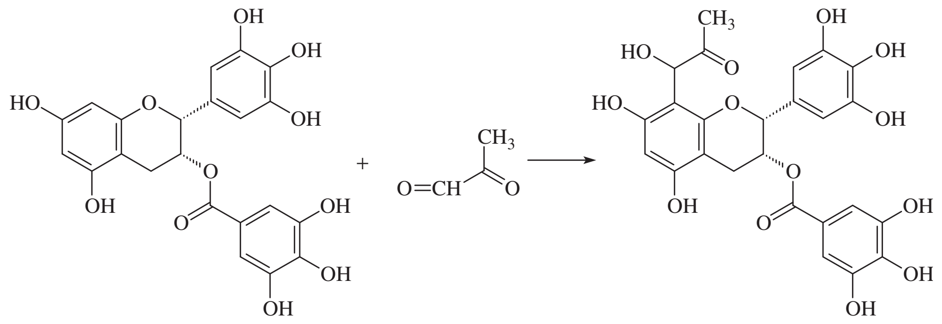

Figure 4.63 Reaction of methylglyoxal with epigallocatechin gallate.

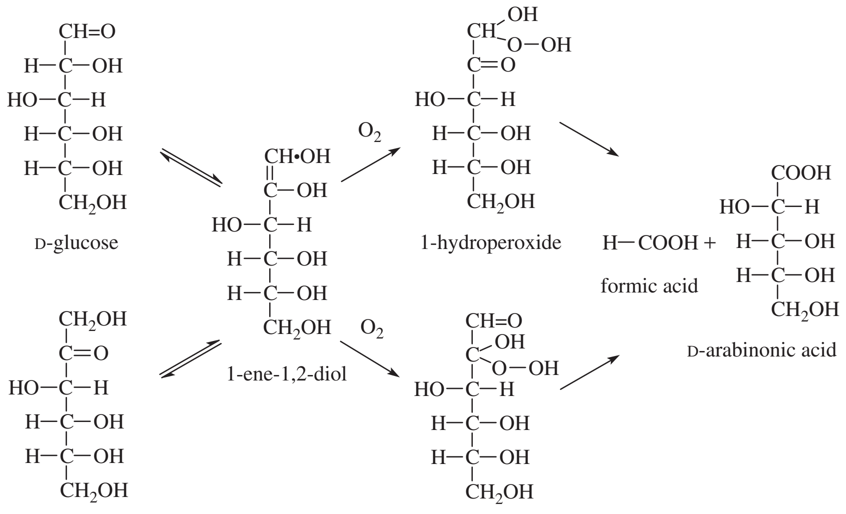

Figure 4.64 Autoxidation of glucose and fructose.

decomposition of the sugar enediol complex with metal and oxygen. In neutral and weakly acidic solutions, hydrogen peroxide itself is a weak oxidising agent. However, in the presence of Fe^{2+} ions, the decomposition of hydrogen peroxide generates free radicals (hydroxyl radicals $^•OH$), which also oxidise sugars to glycosuloses (Figure 4.65).

The mechanism of oxidation by lipid peroxyl radicals involves C–H bond cleavage at carbon C-2. The radical that is produced reacts with oxygen with the formation of a peroxyl radical that spontaneously decomposes to the corresponding glycosulose radical and hydrogen peroxide (Figure 4.66). This hydrogen peroxide radical, after disproportionation to hydrogen peroxide and oxygen ($2\,HOO^• \rightarrow H_2O_2 + O_2$), may act in other oxidation reactions. The formation of a hydrogen peroxide radical ($HOO^•$) by this mechanism, which assumes transfer of hydrogen in the five membered intermediate structure, is not the only possibility for the oxidation of sugar by peroxyl radicals. An alternative reaction is decomposition with hydrogen transfer in the intermediate six-membered structure. This generates lower aldonic acids (such as tetronic acid), hydrogen peroxide and glyoxal (Figure 4.67).

4.7.1.3.2 Cannizzaro reaction

A special case of an oxidation–reduction (redox) reaction catalysed typically by alkalis (in some cases the reaction also takes place in acidic solutions) is a Cannizzaro reaction. It occurs in aldehydes that do not have a hydrogen atom on the C_α carbon, which means that the usual aldol condensation cannot take place. One molecule of aldehyde is oxidised with the simultaneous reduction of the second molecule and the reaction product is a mixture of acid and primary alcohol (Figure 4.68). A Cannizzaro reaction of formaldehyde yields formic acid and methanol; furan-2-carbaldehyde gives rise to furan-2-carboxylic acid (also known as 2-furoic acid or pyromucic acid) and 2-furfuryl alcohol (2-furylmethanol or 2-hydroxymethylfuran).

Formaldehyde, as the most reactive aldehyde, undergoes Cannizzaro reaction even with aldehydes that have a hydrogen atom at the C_α carbon. Formaldehyde also reacts to some extent with aldoses that are reduced to sugar alcohols (alditols) and formaldehyde is oxidised to formic acid (Figure 4.69). Reaction of formaldehyde with D-glucose yields D-glucitol, reaction with D-glyceraldehyde

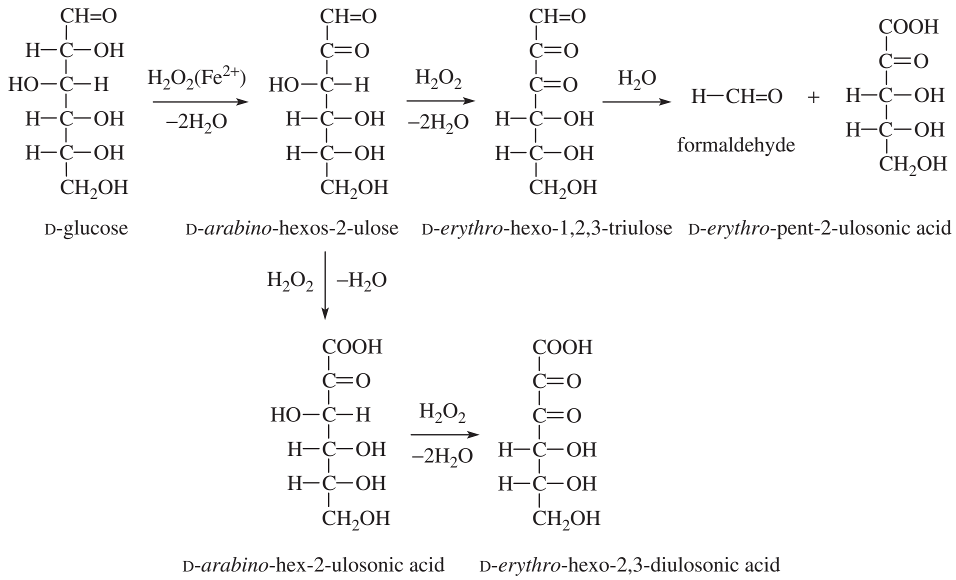

Figure 4.65 Oxidation of glucose to glycosulosonic acids by hydrogen peroxide in the presence of Fe^{2+} ions.

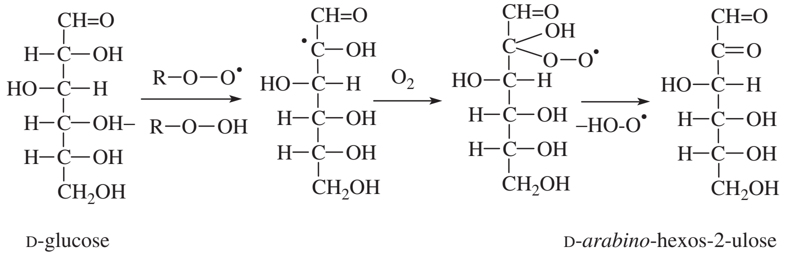

Figure 4.66 Oxidation of glucose to glycosulose by peroxyl radicals.

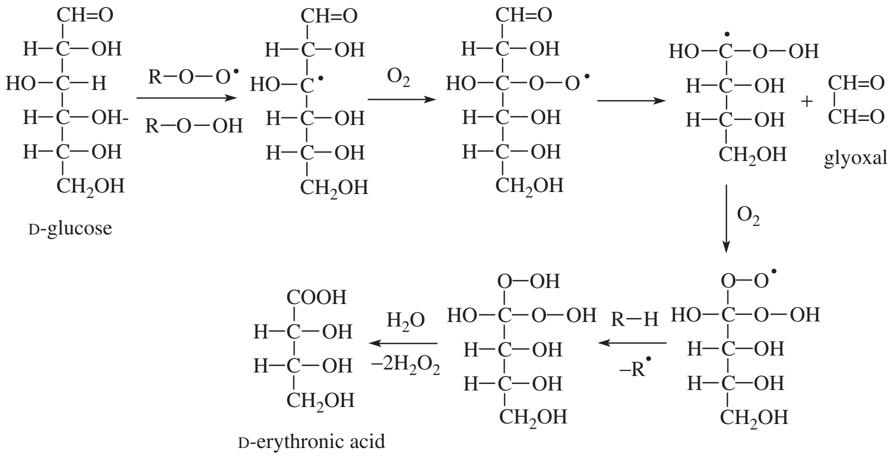

Figure 4.67 Oxidation of glucose to aldonic acid and glyoxal by peroxyl radicals.

yields glycerol and reaction with glycolaldehyde gives ethane-1,2-diol (ethylene glycol).

With glyoxal, methylglyoxal and other α-dicarbonyl compounds, the Cannizzaro reaction is an intramolecular redox reaction, which yields 2-hydroxy acids (Figure 4.70). Glycolic acid results from glyoxal and lactic acid is produced from methylglyoxal.

4.7.1.3.3 Disproportionation of α-hydroxycarbonyl and α-dicarbonyl compounds

Enediol forms of α-hydroxycarbonyl compounds react with α-dicarbonyl compounds through interconversion, in which α-hydroxycarbonyl compounds are transformed into α-dicarbonyl compounds and vice versa (Figure 4.71).

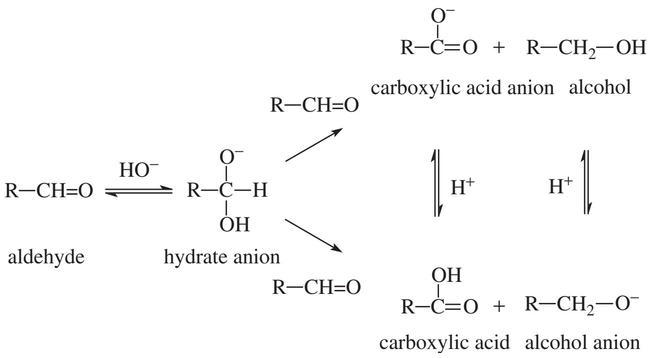

Figure 4.68 General mechanism of Cannizzaro reaction.

4.7.1.3.4 *Disproportionation of α-hydroxycarbonyl and α-dicarbonyl compounds*

Enediol forms of α-hydroxycarbonyl compounds react with α-dicarbonyl compounds with interconversion, in which α-hydroxycarbonyl compounds are transformed into α-dicarbonyl compounds and vice versa (Figure 4.66). The reaction explains a number of oxidation–reduction reactions that occur in degradation products of sugars and in the Maillard reaction. The transfer of two protons takes place within the complex of the α-dicarbonyl compound, with the endiol in either the basic energy singlet state or in the excited triplet state, through the more advantageous biradical mechanism.

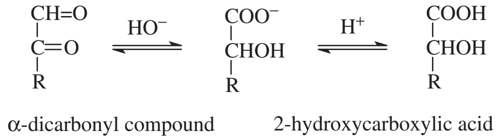

Figure 4.70 Cannizzaro reaction of α-dicarbonyl compounds.

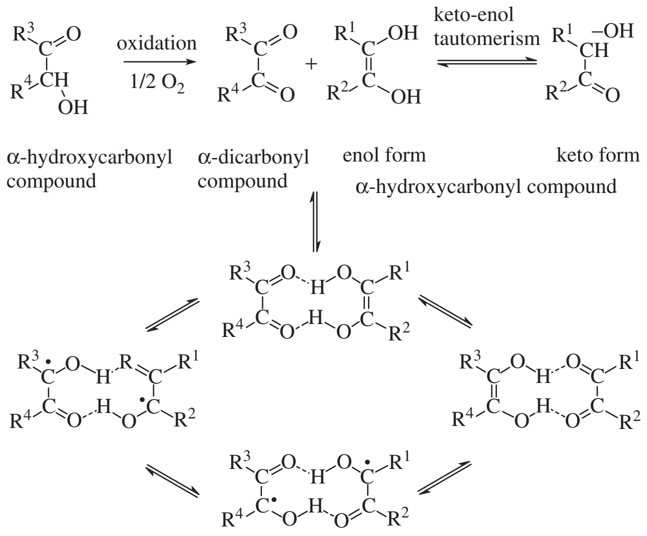

Figure 4.71 Disproportionation of α-hydroxycarbonyl and α-dicarbonyl compounds.

4.7.2 Derivatives of monosaccharides

The chemical reactions of polyols are similar to reactions of the hydroxyl groups of monosaccharides. For example, glycerol yields a mixture of different products containing diglycerol, oligoglycerols and polyglycerols. Alditols can dehydrate to form monoanhydro and dianhydro derivatives in acidic solutions. Acid catalysed dehydration of D-glucitol yields a mixture of cyclic anhydrides that are used as emulsifiers. Oxidation of the secondary alcoholic group of D-glucitol on C-2 or C-5 by the microorganisms *Acetobacter xylinum* or *Gluconobacter oxydans* produces L-sorbose, an intermediate used in the synthesis of L-ascorbic acid. Alditols, as well as cyclitols, are virtually stable during food storage and processing.

4.7.3 Oligosaccharides

The properties and reactivity of reducing oligosaccharides are comparable to the properties and reactivity of monosaccharides, non-reducing oligosaccharides behave and react similarly to glycosides of monosaccharides.

Acids hydrolyse oligosaccharides to monosaccharides under simultaneous intramolecular dehydration that produces small amounts of anhydrosugars as by-products. The rate of hydrolysis (inversion) depends on the acidity and temperature, but also on other factors related to the structure of the oligosaccharides, such as inductive and steric effects. The hydrolysis of α-anomers of disaccharides is easier than hydrolysis of β-anomers, pyranosides are more stable than furanosides and non-reducing oligosaccharides are more stable than the reducing sugars. The mechanism of hydrolysis of most disaccharides is similar to the mechanism of hydrolysis of *O*-glycosides. The hydrolysis of higher sugars takes place via disaccharides and other lower oligosaccharides. The α- and β-glycosidic bonds are also cleaved enzymatically under the action of α- and β-glycosidases, similarly to the case of heteroglycosides.

The opposite reaction to hydrolysis (inversion) is reversion, when di- and higher oligosaccharides are synthesised from

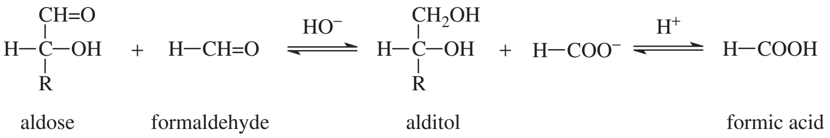

Figure 4.69 Cannizzaro reaction of formaldehyde with aldoses.

monosaccharides and lower oligosaccharides in acid solutions. Reversion often proceeds together with acid catalysed hydrolysis and the glycosidic bonds can isomerise simultaneously, so that, *O*-β-D-oligosaccharides are transformed into *O*-α-D-oligosaccharides and vice versa.

During heating in solution, fructooligosaccharides are less stable than glucooligosaccharides. For example, fructose decomposes already at 60 °C in neutral solutions, while glucose or saccharose solutions can be rapidly heated to temperatures up to 100 °C without decomposition. Hydrolysis of saccharose are undesirable reactions in the production of saccharose from sugar beet or sugar cane, which depends on the presence of hydrolases, pH, temperature, concentration of saccharose and other factors. Invertases, which catalyse saccharose hydrolysis during the diffusion process, have to be inactivated by heating the raw juice to temperatures up to 80 °C (see Section 4.4.2.1.2). At this temperature and with the relatively low pH of the juice (pH 5.2–5.8), however, chemical hydrolysis can cause significant loss of saccharose (e.g. in solutions of pH 5.2 and also at pH 11.4, saccharose loss is about 0.5% per hour) that can be prevented by an increase in pH through the addition of calcium hydroxide, as the rate of hydrolysis of saccharose is minimal in solutions of pH around 8.4. Alkaline pH, on the other hand, initiates non-enzymatic browning reactions of reducing monosaccharides. The main manifestation of these reactions is the formation of yellow, brown to black pigments called melanoidins, which, along with the pigments (known as melanins) derived from phenolic compounds in enzymatic browning reactions, cause discolouration of raw sugar and molasses.

Reducing oligosaccharides are somewhat more stable than monosaccharides in alkaline solutions. Under similar conditions as those for monosaccharides, isomerisation takes place of the sugar unit bound at the reducing end of the oligosaccharide, which leads to the formation of the corresponding epimer (isomerisation of the type aldose–aldose) and bound aldoses isomerise to bound ketoses (isomerisation of the type aldose–ketose).

4.7.4 Polysaccharides

Functional properties of polysaccharides (formation of viscous dispersions and gels) are associated with the mutual interactions of their chains and interactions with other food components (especially water, proteins and lipids).

The most important reaction of polysaccharides is hydrolysis. Hydrolysis by digestive enzymes of the digestive system or by colon microbial saccharases allows many polysaccharides, and especially starch, to be utilised. Spontaneous hydrolysis of polysaccharides by endogenous enzymes of food raw materials or microbial saccharases is an important reaction in many food technologies. It is related to the technological, functional and organoleptic characteristics of a number of food products (including production of bread, post-mortem changes in meat, fruit ripening and other processes). Hydrolysis of some polysaccharides (e.g. starch and inulin) is used to obtain monosaccharides, oligosaccharides and polysaccharide functional derivatives. Derivatives of some polysaccharides (e.g. starch and cellulose) are used as food additives (hydrocolloids).

4.7.5 Maillard reaction

Some of the most important and widespread chemical reactions occurring during storage and processing of food are reactions of reducing sugars with amino compounds. These reactions produce a number of highly reactive carbonyl compounds that react with each other and also with the amino compounds present. This series of reactions is generally known as the Maillard reaction,[10] the consequence of which is the formation of brown pigments called **melanoidins** and therefore these reactions belong to the group of **non-enzymatic browning reactions**. In addition to the Maillard browning reaction, two other major types of non-enzymatic browning reactions are recognised:

- **caramelisation**
- **reactions of proteins with oxidised lipids**.

The Maillard reaction can therefore be regarded as a special case of non-enzymatic browning reactions of sugars with proteins (amino acids).

Only a small number of compounds produced in these reactions have been characterised. These are mainly low molecular weight compounds, which are relatively stable during isolation and identification. Much less is known about the reactive intermediates that arise in very low concentrations and, moreover, are usually decomposed during isolation. Very little is known about the resulting free radicals. Knowledge of the structure of these compounds is very important because they play an important role in the formation of flavour-active substances, high molecular weight coloured pigments (melanoidins) and also in the reactions that occur *in vivo*.

The attention of food chemists has mainly been focused on the following.

- Formation of a brown colour, which may either be desirable as a manifestation of the Maillard reaction (such as the colour of bread crust, roasted coffee and fried onions) or may be a negative phenomenon (e.g. in the production of dried foods, especially milk, as well as fruits and vegetables).
- Formation of aromatic compounds and aromatic compounds with adverse organoleptic properties.
- Nutritional and physiological aspects of the Maillard reaction (reduction of the nutritional value of foods mainly due to the reaction of sugars and other carbonyl compounds with lysine, an essential and often limiting amino acid).
- Antioxidant activities of the reaction products (mainly reductones and coloured melanoidins).

[10]The reaction was named after the French chemist Louis Camille Maillard, who first described the formation of brown pigments formed during heating of glucose with glycine. The Maillard reaction has always attracted, and still attracts, the attention of many chemists. It has been studied for a century by food chemists, nutritionists, physiologists and physicians, but it is still impossible to present a complete reaction scheme due to its complexity.

- Toxicity of some products, especially mutagenic and carcinogenic substances.

The most important food saccharides involved in the Maillard reaction are the monosaccharides glucose and fructose, and in some cases ribose (e.g. in meat and meat products). The most important disaccharides are lactose (in milk and dairy products) and maltose (in cereal products, e.g.in malt). Saccharides linked by glycosidic bonds in glycoproteins, glycolipids, heteroglycosides and non-reducing sugars (such as saccharose) can participate in the Maillard reaction after hydrolysis to the parent monosaccharides.

Reaction partners of reducing sugars are mainly proteins and amino acids. Proteins react with reducing carbohydrates primarily through the ε-amino group of bound lysine. To a smaller extent α-amino groups of *N*-terminal amino acids and other amino acid functional groups, such as the mercapto group of cysteine and guanidyl group of arginine, are also involved in the Maillard reaction. In addition to proteins and amino acids, biogenic amines also contribute significantly to the Maillard reaction in some foods (e.g. in cheeses).

In addition to sugars and their degradation products and the degradation products of amino acids (amines, ammonia and aldehydes), these reactions also include carbonyl compounds already present in foods as primary substances (e.g. aldehydes and ketones occurring in essential oils), ascorbic acid and carbonyl compounds formed in foods from precursors other than carbohydrates (aldehydes resulting from fat oxidation), thereby the reactions become even more complex.

Owing to the complexity of the Maillard reaction, model systems containing only one reducing sugar and one amino acid are often chosen because they are simpler systems than foods. Research has shown that even in simple reaction systems, for example in glucose and glycine solutions, many tens of reaction products are formed. Therefore, even in such simple systems, the Maillard reaction mechanisms have not been fully elucidated and all the reaction products have still not been identified. The modified reaction schemes according to Hodge and Tressl[11] are given in Figure 4.72 and Figure 4.73, respectively.

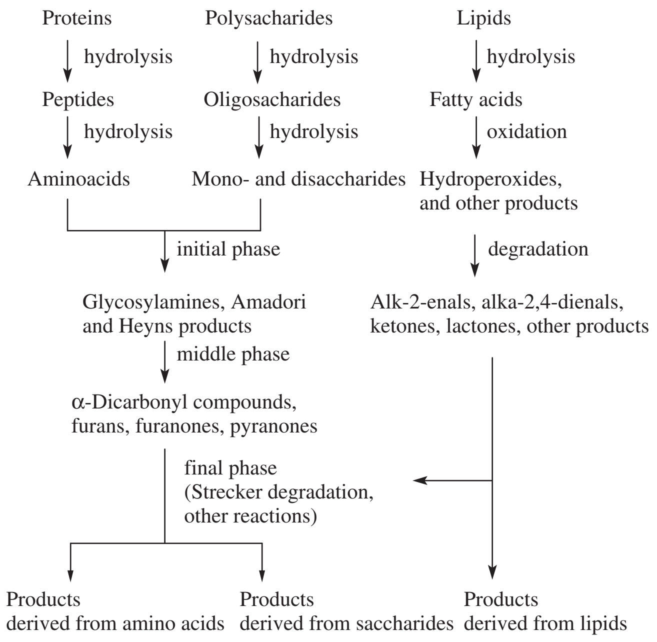

Figure 4.73 Schematic representation of the Maillard reaction according to Tressl.

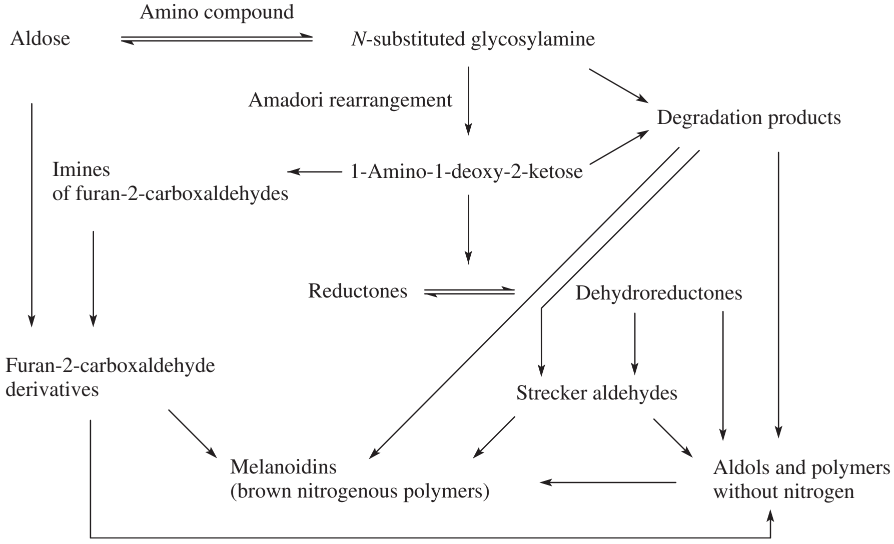

Figure 4.72 Schematic representation of the Maillard reaction according to Hodge.

[11]The classification of individual reactions taking place within the Maillard reaction was first described by John Edward Hodge in 1953, more than 50 years ago, and it is still the most concise description of the Maillard reaction. Exactly 40 years later Roland Tressl supplemented this scheme.

In the reaction of an aldose with an amino compound, such as the reaction of glucose with amino acids, three basic phases are recognised:

- the **initial phase** involves the formation of glycosylamine followed by Amadori rearrangement;
- the **middle phase** involves dehydration and fragmentation of saccharides and Strecker degradation of amino acids;
- the **final phase**, which includes reactions of intermediates leading to the formation of heterocyclic and other compounds, and are usually important as flavour-active compounds and coloured pigments called melanoidins that cause the yellow, brown or black colouration.

Ketoses may also enter into the reaction, and then the formation of glycosylamine is followed by Heyns rearrangement (Section 4.7.5.1). The reaction could also include not only carbonyl compounds derived from the degradation of sugars, but also Strecker aldehydes arising from amino acids and reactive aldehydes and other compounds produced as secondary decomposition products of fatty acid hydroperoxides in lipid peroxidation.

4.7.5.1 Formation of glycosylamines and rearrangement to aminodeoxysugars

The Maillard reaction starts by the addition of a non-protonated amino group of an amino compound (amine, amino acid or protein) to an electron deficient carbon atom of a polarised carbonyl group of a reducing sugar (acyclic form of an aldose or ketose). The resulting addition product, *N*-substituted hemiaminal (formerly also known as monotopic carbinolamine), dehydrates with the formation of an imine (formerly also known as azomethine or a Schiff base). The electron density on the carbonyl group carbon and thus the ease of addition is influenced by polar factors (mainly inductive effects of the carbonyl group substituents) and steric factors. Alkyl and aryl carbonyl group substituents have a positive inductive effect (electron repelling; +I). The most reactive substance is therefore formaldehyde, and less reactive compounds are higher aliphatic aldehydes. The introduction of the electronegative group exhibiting a negative inductive effect (electron attracting; –I) into the aliphatic substituent to a position adjacent to the carbonyl group, such as a hydroxyl group (in sugar) or other carbonyl group (in glycosuloses), decreases the electron density on the carbon of the carbonyl group, which results in a higher reactivity of such a derivative. The reactivity of carbonyl compounds, therefore, generally decreases in the following order:

- aldoses > ketoses
- trioses > tetroses > pentoses > hexoses > disaccharides
- α-dicarbonyl compounds > aldehydes > ketones > saccharides > oxoacids.

The reactivity of sugars is mainly determined by the amounts of acyclic forms present. The reactivity of amino compounds is closely related to their basicity and therefore falls in the following order:

- ammonia > amines > amino acids
- 6-amino acids > . . . > 3-amino acids > 2-amino acids.

Another very important factor influencing the reactivity of both reaction partners is pH. Protonisation of the carbonyl group in acidic solutions increases the reactivity of nucleophilic reagents, while protonised amino groups are less reactive as the nitrogen atom does not have a free electron pair (Figure 4.74). Acid–base properties of amino acids, peptides and proteins (formation of cations, amphions and anions) are described in Section 2.2.3.1.

The mutual reaction of a carbonyl compound with an amino compound is shown in Figure 4.75. The concentration of both reactants varies with pH value of the solution in the opposite direction (cation concentration of the carbonyl compound increases, while the concentration of the unprotonised amino compound decreases with decreasing pH) and the reaction rate reaches a maximum in slightly acidic solutions (e.g. in reactions of aldoses with amines) or in slightly basic solutions (in reactions of α-dicarbonyl compounds with amino acids). Schiff bases are usually unstable compounds that are stabilised by subsequent reactions. The exception is the Schiff base of an aromatic aldehyde with an aromatic amine, in which case the reaction equilibrium is shifted significantly in favour of the Schiff base. The Schiff bases formed from sugars are stabilised by a reversible cyclisation to *N*-substituted glycosylamines (Figure 4.76).

In solutions, *N*-glycosylamines (as well as the parent sugars) occur mainly in the form of pyranoses or furanoses. They mutarotate as a result of the formation of an immonium intermediate (Schiff base cation) and are easily hydrolysed to the original sugar and amine (Figure 4.77). Glycosylamines derived from aromatic or heterocyclic amines are relatively stable, while glycosylamines derived from aliphatic amines and especially glycosylamines derived from amino acids (that is, glycosylamino acids) are subjected to further reactions to give more stable products.

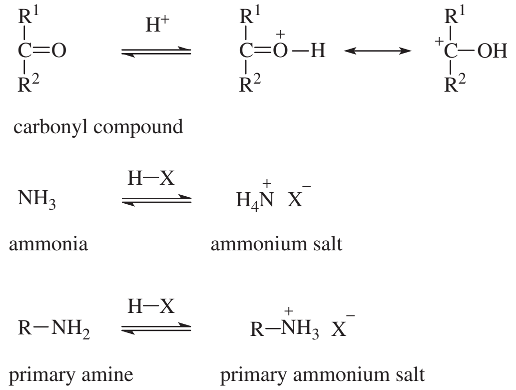

Figure 4.74 Formation of cations of carbonyl compounds and amino compounds.

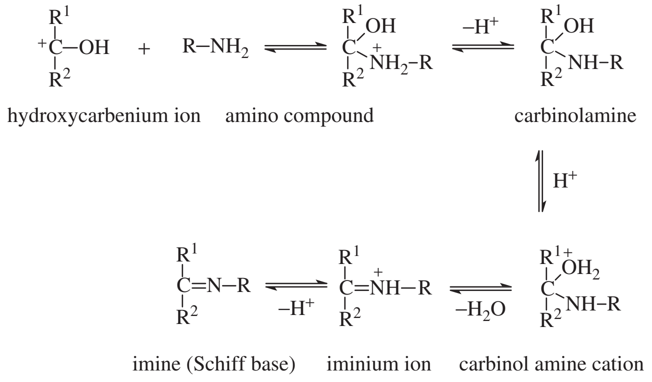

Figure 4.75 General scheme of reactions of carbonyl compounds with amino compounds.

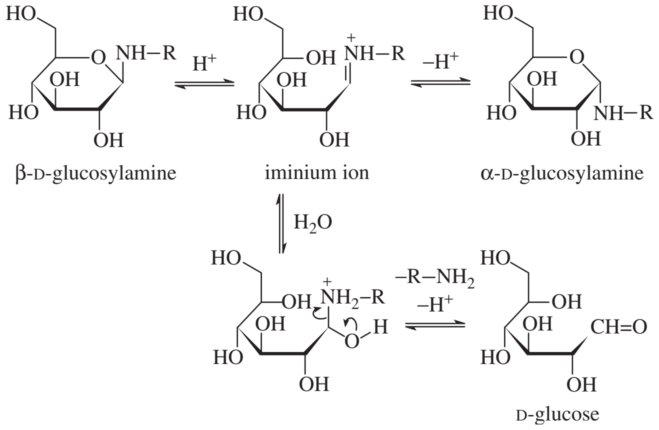

Figure 4.77 Mutarotation and hydrolysis of glycosylamines.

The fate of *N*-glycosylamines depends on water activity, pH and temperature. In media with moderate to high water content and a pH range of 5–7, the Schiff bases are usually rearranged to substantially more stable compounds. Aldosylamines are transformed into **ketosamines**, also known as **1-amino-1-deoxyketoses** or **Amadori compounds**, by the **Amadori rearrangement**. Ketosylamines are similarly transformed into **aldosamines** (**2-amino-2-deoxyaldoses**, also called **Heyns compounds**) by the **Heyns rearrangement**. The reaction is equivalent to the aldose–ketose isomerisation. The Amadori and Heyns rearrangements are generally acid–base catalysed reactions (Figure 4.78).

The Amadori rearrangement begins by protonisation of aldosylamine, leading to ring opening to form a semiacetal immonium ion. This reaction is followed by proton cleavage on carbon C-2 and the enaminol produced stabilises to the keto form by isomerisation and by cyclisation to form the hemiacetal. The reaction rate is significantly influenced by the form in which the glycosylamines occur. Aldosylamines present as furanoses rearrange about ten times more quickly than pyranoses. The reacting amino compound acts simultaneously as a catalyst, because the amino acid carboxyl group provides the necessary proton. The reaction rate increases in the presence of carboxylic acids and phosphates. The catalytic effect of carboxylic acids is explained by reaction of the immonium ion with the carboxyl anion to form an intermediate, which decays to enaminol and carboxylic acid (Figure 4.79).

The active ion of phosphates (the catalytic effect is optimal at pH 5–7) is the dihydrogenphosphate anion. This anion is a base that withdraws a proton from the carbon C-2 of glycosylamine during the Amadori rearrangement. The Amadori and Heyns rearrangements are favoured under acidic conditions, but these reactions may also take place in a strongly alkaline medium, as they are generally acid–base catalysed (Figure 4.80). The Amadori rearrangement has long been considered to be an irreversible reaction. Some studies in recent years, however, have admitted the

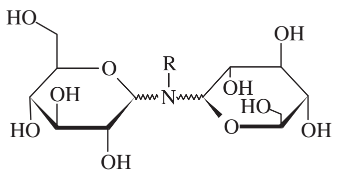
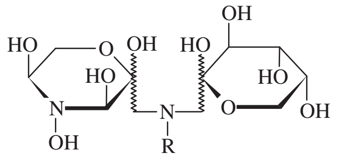
possibility of a reversible reactions to form the parent sugar or its epimer.

Ketosamines have been demonstrated in a number of stored and heat-processed foods, such as dried fruits, dried vegetables, dried milk, soy sauces and other products. They arise similarly in infusions containing glucose and amino acids and even in the human organism (particularly in diabetics) as intermediates of the Maillard reactions that are on-going *in vivo*. Some aminodeoxysugars occurring in foods, however, arise by biochemical (enzymatic) reactions, for example D-glucosamine and D-galactosamine that are the building units of chitin.



4-211, di-D-glucosylamine



4-212, di-D-fructosamine

4.7.5.2 Other reactions of glycosylamines

The Amadori and Heyns rearrangements are the main but not the only possible conversions of *N*-glycosylamines. Aldosylamines derived from primary amines (and also from amino acids) can react with another aldose molecule to form a dialdosylamine before the Amador rearrangement. For example, D-glucose reaction with D-glucosylamine gives di-D-glucosylamine (**4-211**). Analogously to aldosylamines, dialdosylamines are rearranged to diketosamines and di-D-fructosamine (**4-212**) is produced from di-D-glucosylamine.

In foods or parts of foods with low water activity, other transformation pathways can also occur. In alkaline solutions and at low temperatures and even during pyrolysis, transamination can yield the corresponding oxoacid and 1-amino-1-deoxyalditol. In weakly acidic or neutral solutions and at elevated temperatures, Schiff bases can form cyclic products. Schiff bases derived from amino acids can yield oxazolidinone derivatives; Schiff bases derived from peptides generate imidazolidinone derivatives. These cyclic products decarboxylate easily to form isomeric imines (Figure 4.81). The Strecker degradation of bound amino acids in Schiff bases derived from sugars and amino acids yields the corresponding aldehyde, carbon dioxide and 2-deoxyaldose through oxidation.

Schiff bases derived from α-hydroxycarbonyl fragmentation products of sugars (such as glycolaldehyde), where the free hydroxyl group in the original glycolaldehyde is in the β-position to the nitrogen atom (in *N*-glycosylamines it is usually part of a pyranose or a furanose ring, therefore their decomposition via an Amadori product prevails) may yield imine by rearrangement of an azomethine ylid. This imine is a decarboxylated analogue of an

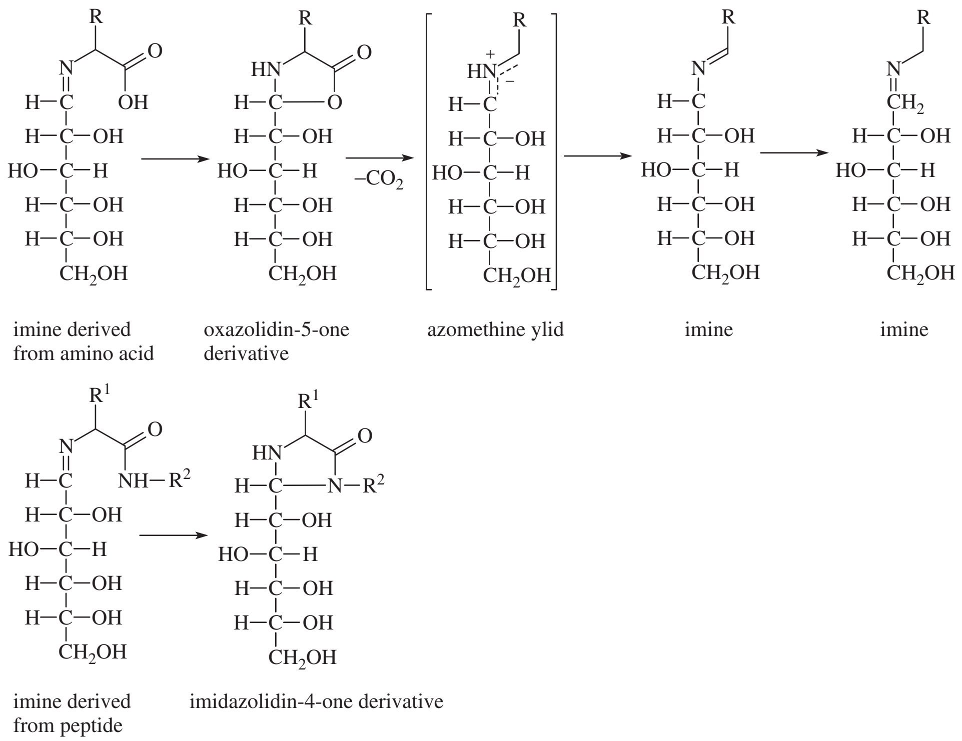


Figure 4.81 Formation of imines, imidazolidinones, oxazolidinones from imines derived from amino acids and peptides.

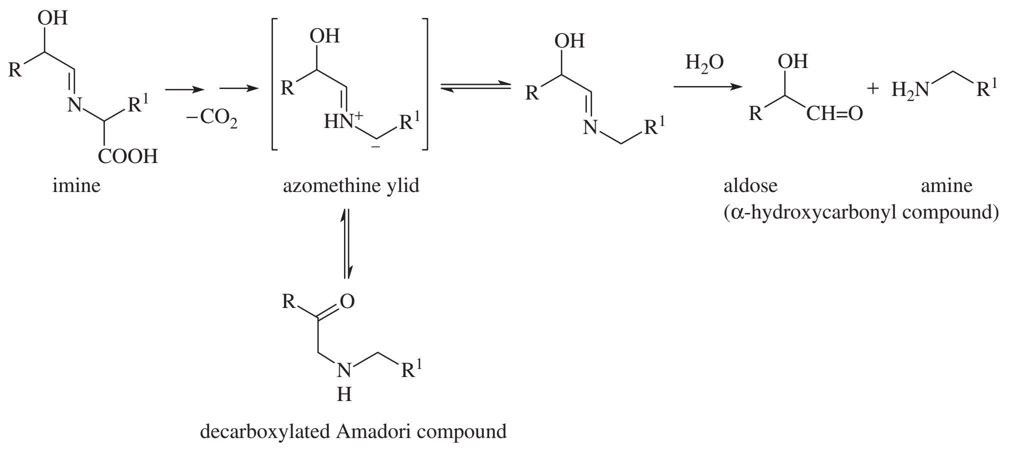

Figure 4.82 Imine degradation and formation of decarboxylated Amadori product (R = aldose or α-hydroxy compound residue, R^1 = amino acid residue).

Amadori compound (Figure 4.82), which provides the original α-hydroxycarbonyl compound after isomerisation, elimination of water and amine hydrolysis. If the decarboxylated Amadori compound is in the form of an amine, the C–N bond can be directly cleaved to form a 1-amino-2-oxo compound (1-amino-1-deoxyketose) and the original amino acid derivative with a vinyl group, as in, for example, the formation of acrylamide from asparagine. Another possibility of acrylamide formation is oxidation of glycosylated asparagine to oxoimine and its decarboxylation, which is then followed by hydrolysis to the immediate precursor of acrylamide, 3-aminopropionamide (see Section 12.2.2).

Another important reaction of *N*-glycosylamines is retroaldolisation, which generates the highly reactive C_2 intermediates glycolaldehyde *N*-alkylimines (*N*-substituted aminoacetaldehyde derivatives) and D-erythrose (Figure 4.83). Glycolaldehyde alkylimines dimerise almost immediately to *N*,*N*′-dialkyldihydropyrazines that are transformed into pyrazinium salts by two electron oxidation (Figure 4.84). Imine hydrolysis yields glycolaldehyde, while glyoxal is formed by their oxidation (Figure 4.85). Glyoxal is likewise formed by retroaldolisation of hexos-2-uloses. Reactive hydroxycarbonyl and dicarbonyl compounds (glycolaldehyde and glyoxal) can be thus formed evne in the early stage of the Maillard reaction, while the classical Hodge scheme expects the formation of these compounds in the advanced stages of the Maillard reaction by decomposition of aminodeoxysugars via 2,3-enolisation. Glyoxal, however, is also a product of lipid oxidation.

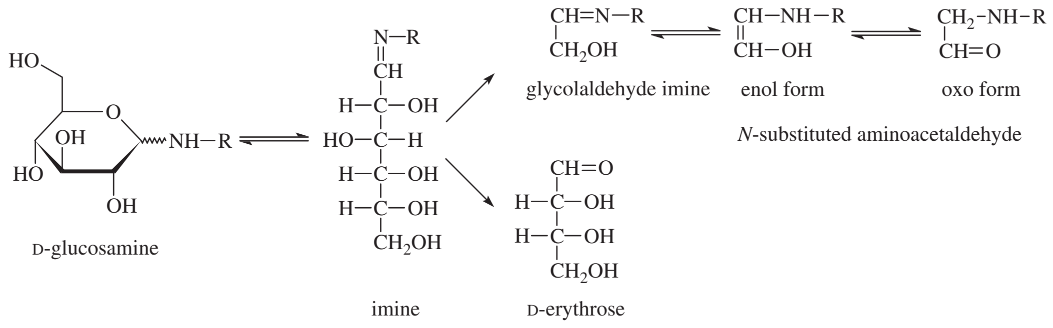

Figure 4.83 Retroaldolisation of glycosylamines.

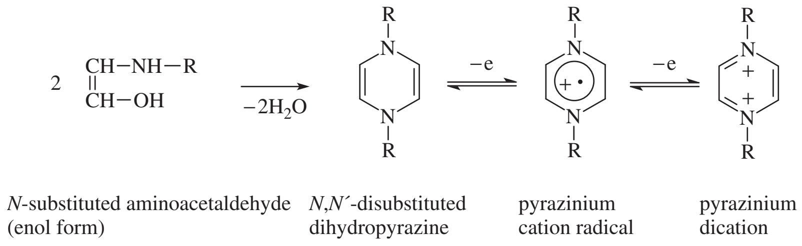

Figure 4.84 Formation of pyrazine derivatives.

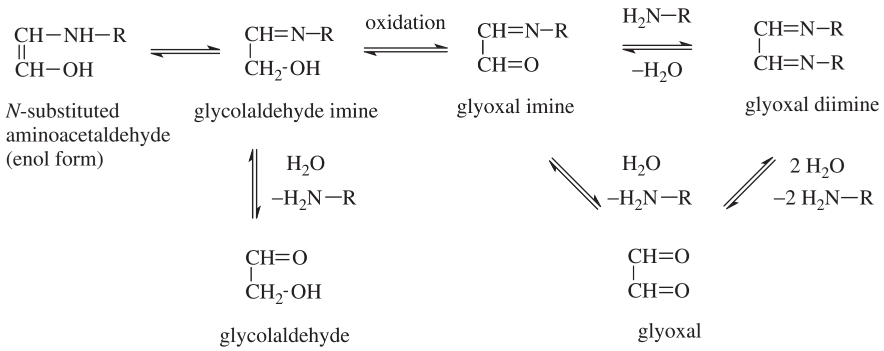

Figure 4.85 Formation of glycolaldehyde and glyoxal.

Reactions of sugars with amino acids, which have more reactive functional groups (such as sulfur, hydroxy, aromatic and heterocyclic amino acids), also bypass the Amadori rearrangement and the reaction gives rise to various heterocyclic compounds. For example, glucose yields a thiazolidine derivative, 2-(D-gluco-1,2,3,4,5-pentahydroxypentyl)thiazolidine-4-carboxylic acid (**4-213**), with cysteine and a β-carboline derivative, 1,2,3,4-tetra hydro-1-(D-*gluco*-1,2,3,4,5-pentahydroxypentyl)-β-carboline (**4-214**), arises from tryptophan or tryptamine.

4-214, 1,2,3,4-tetrahydro-1-(D-*gluco*-1,2,3,4,5 -pentahydroxypentyl)-β-carboline

4.7.5.3 Decomposition of aminodeoxysugars

All aminodeoxysugars are strong reducing agents, less reactive than reductones, but more reactive than the original sugars. Their mutarotation in aqueous solutions leads to an equilibrium mixture of different forms of aminodeoxysugars.

Diketosamines are unstable compounds that decompose to ketosamines and many other compounds, even in aqueous solutions at room temperature. Ketosamines (Amadori compounds) are relatively stable in the solid state and in neutral aqueous solutions, but their stability is significantly lower than the stability of the original sugar. In acidic and alkaline solutions, ketosamines decompose. Their degradation in alkaline solutions is faster than in acidic solutions. In addition to pH, the rate of ketosamine degradation is influenced considerably by the different stabilities of the individual cyclic forms. Their decomposition is particularly fast when ketosamines are present in the less stable furanose or acyclic form. For example, ketosamines formed in the reaction of glucose with amino acids (derivatives of 1-amino-1-deoxyfructose) at 20 °C are present in the form of β-pyranose (approximately 64%), α-furanose (15%), β-furanose (15%) and α-pyranose (6%). The equilibrium mixture contains the acyclic form in quantities up to 2%. The composition of the equilibrium mixture varies only slightly with pH. Decomposition of aldosamines proceeds in a similar way to the decomposition of ketosamines, with the difference that some original ketose also arises.

Decomposition of ketosamines starts, like most other reactions of monosaccharides, by 1,2-enolisation that yields an amino analogue of 1-ene-1,2-diol, which is 1-ene-1-amino-2-ol (Figure 4.86). The reaction proceeds by elimination of the C-3 hydroxyl group and hydrolysis of the bound amino compound provides 3-deoxy-D-*erythro*-hexos-2-ulose and, further, 3,4-dideoxy-D-*glycero*-hex-3-enos-2-ulose, 5-hydroxymethylfuran-2-carbaldehyde in addition to other products that are formed by degradation of glucose by 1,2-enolisation.

2,3-Enolisation of ketosamines (Figure 4.86) gives 2-ene-2,3-diol as a primary intermediate and decomposition of the bound amino compound yields 1-deoxy-D-*erythro*-hexo-2,3-diulose as the main intermediate. The same compound is formed to a small extent from fructose in the absence of amino compounds. A minor reaction product is 4-deoxy-D-*glycero*-hexo-2,3-diulose. Both uloses are transformed into a variety of products by subsequent reactions, similar to in the absence of amino compounds, but in higher yields.

It is obvious that the decomposition of aminodeoxysugars by 1,2-enolisation and 2,3-enolisation gives rise to the same key intermediates that also arise during the degradation of sugars in the absence of amino compounds (3-deoxy-D-*erythro*-hexos-2-ulose, 1-deoxy-D-*erythro*-hexo-2,3-diulose and 4-deoxy-D-*glycero*-hexo-2,3-diulose). The fundamental difference is that these and many other products are produced from carbohydrates in the absence of

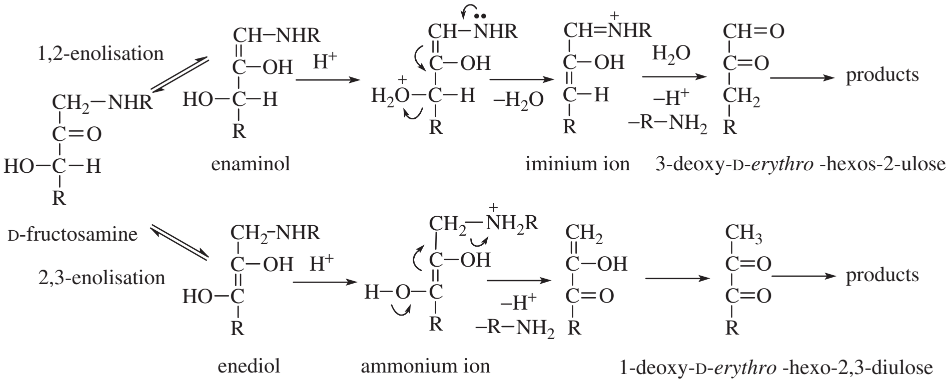

Figure 4.86 1,2-Enolisation and 2,3-enolisation of ketosamines.

amine only in strongly acidic or strongly alkaline media (pH lower than 3 or higher than 8) or at higher temperatures (e.g. during caramelisation). Amino compounds catalyse the degradation of saccharides, therefore the reaction rate is higher and degradation of aminodeoxysugars proceeds under normal temperatures and in virtually a neutral media, which are typical for most foods (pH 4–7). Reactions differ too in terms of the quantitative representation of individual products. In the absence of amino compounds, mainly 3- and 4-deoxyuloses are formed, while in the presence of amino compounds the characteristic products are 1-deoxyuloses. A number of degradation products of sugars, including deoxy sugars, furans, pyrans and fragments containing reactive carbonyl groups, also react with amino compounds with the formation of compounds containing nitrogen or sulfur in the molecule in the case where sulfur amino acids and other sulfur compounds are involved these reactions. The characteristic products of the Maillard reaction are, therefore, nitrogen and sulfur-containing heterocyclic compounds.

Factors that determine whether aminodeoxysugars undergo 1,2-enolisation or 2,3-enolisation have been studied for decades, but the reaction mechanisms are still not fully understood. It is generally considered that 1,2-enolisation takes place in acidic media where the nitrogen atom of the aminodeoxysugars is protonated. The level of 1,2-enolisation products, such as derivatives of furan-2-carbaldehyde, also increases with increasing amino compound basicity. Aminodeoxysugar must be present as the free base in order to allow the 2,3-enolisation. For this reason, 2,3-enolisation occurs especially in alkaline or non-aqueous media, for example during caramelisation.

According to recent surveys, ketosamines degrade preferentially via 1,2-enolisation and via 2,3-enolisation under milder reaction

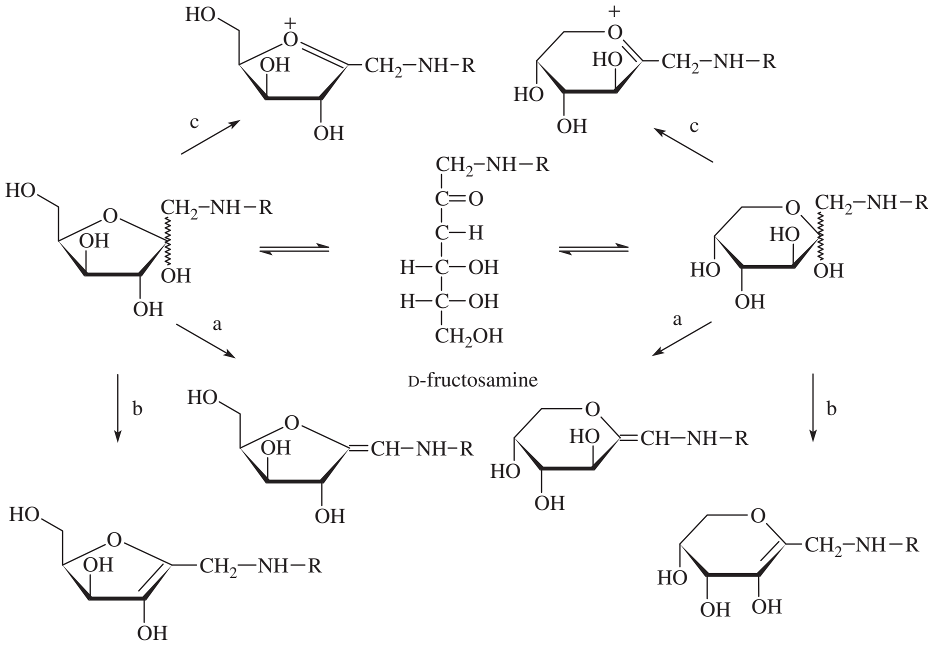

Figure 4.87 Ketosamine degradation by 1,2-dehydration (a), 2,3-dehydration (b) and 2-dehydroxylation (c).

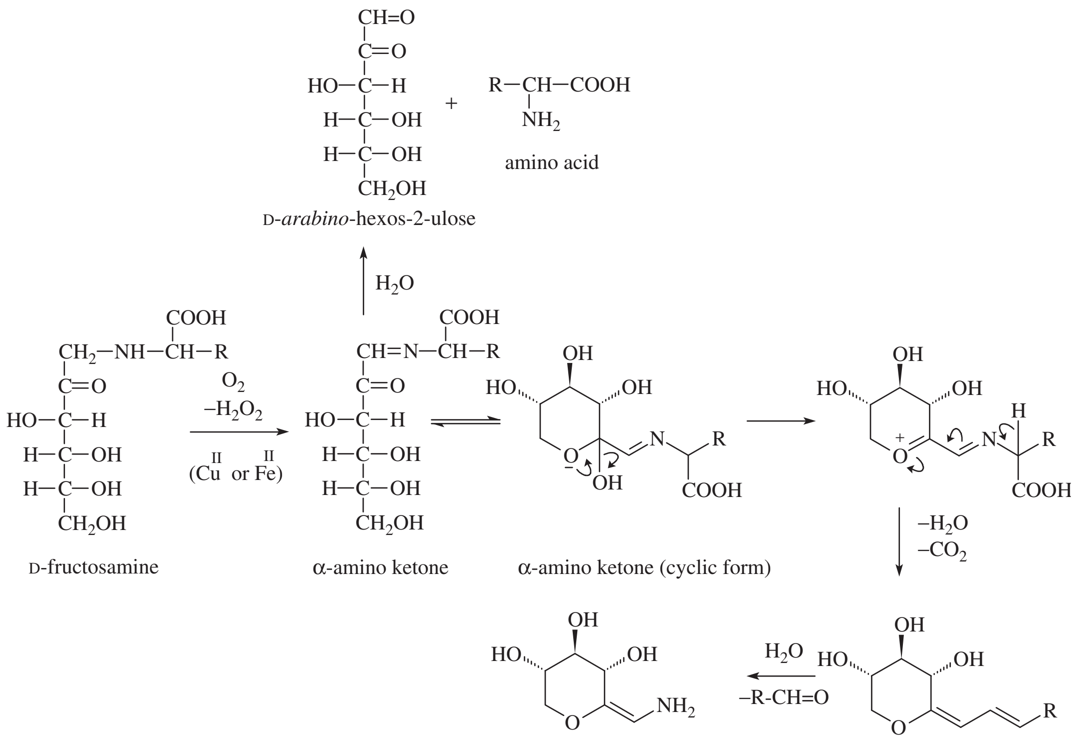

Figure 4.88 Oxidation of ketosamines to D-*arabino*-hexos-2-ulose and Strecker aldehydes.

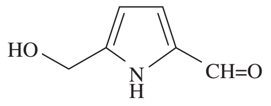
conditions (in solutions at relatively low temperatures) as mentioned previoulsy. At higher temperatures, however, ketosamine decomposition prevails by 1,2-dehydration, 2,3-dehydration and the so called *O*,2-dehydroxylation, which is an elimination of the hemiacetal hydroxyl group (Figure 4.87). It is assumed that the 1,2-dehydration occurs primarily in furanoses, while the 2,3-dehydration mechanisms predominates in pyranoses. The 2,3-dehydration products of pyranoses are stabilised by hydrogen bonds between nitrogen atoms and C-3 hydroxyl groups.

Another important reaction is decomposition of amino acid derived ketosamines in the presence of oxygen, which is catalysed by transition metal ions. Products of this decomposition are glycos-2-uloses. For example, D-fructosamine yields D-*arabino*-hexos-2-ulose and in addition to other products, this reaction produces the corresponding Strecker aldehyde (Figure 4.88).

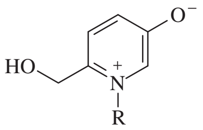
4.7.5.3.1 Decomposition of 3-deoxyglycosuloses

The main products of 3-deoxy-D-*erythro*-2-hexos-2-ulose degradation are (*Z*)-3,4-dideoxy-D-*glycero*-hex-3-enos-2-ulose (2-hydroxy-6-hydroxymethylpyran-3-one), the corresponding (*E*)-isomer and 5-hydroxymethylfuran-2-carbaldehyde.

Except for furan derivatives in the case of 3-deoxyglycos-2-ulose decomposition, considerable amounts of pyrrole derivatives, *N*-substituted 5-hydroxymethylpyrrole-2-carbaldehydes (**4-215**) and their isomeric pyridines (pyridinium betaines, **4-216**) are formed in the presence of excess amine. These compounds are formed in only trace amounts in the reaction of 5-hydroxymethylfuran-2-carbaldehyde with amino compounds, which suggests that incorporation of an amino compound occurs preferentially in a reaction with its precursors. If the reacting amino compound is ammonia, nitrogen atoms of the resulting pyrrole and pyridine derivatives are unsubstituted. In the presence of amino acids, the reaction products are carboxymethyl substituted 1-pyrrole-2-carbaldehydes (**4-215**). Their cyclisation yields the corresponding lactones (**4-217**). Lactams (dihydropyrrolopyrazinones, **4-218**) are formed in the presence of peptides.



4-215, 5-hydroxymethylpyrrol-2-carboxaldehyde



4-216, pyridinium betaines

The C-1/C-2 bond cleavage of 3-deoxy-D-*erythro*-hexos-2-ulose yields formic acid and 2-deoxy-D-*erythro*-pentose, which is transformed into 2-furfuryl alcohol and, in the presence of

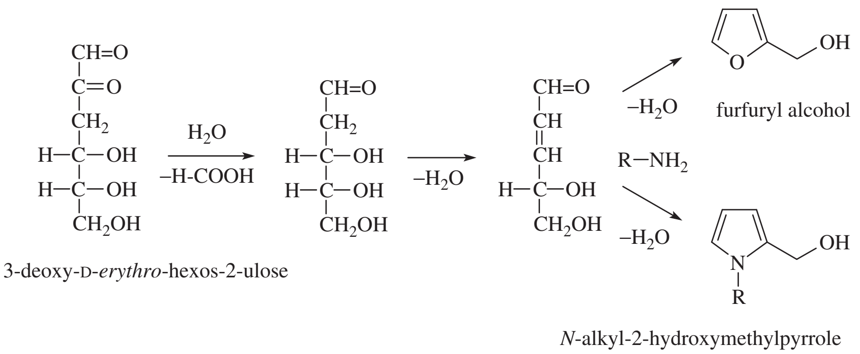


Figure 4.89 Degradation of 3-deoxy-D-*erythro*-hexos-2-ulose.

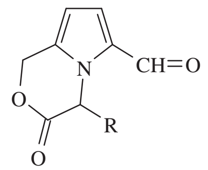
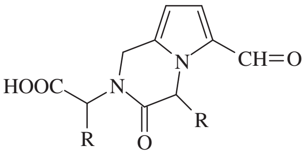


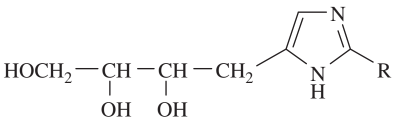
4-217, lactones of *N*-carboxymethyl-5-hydroxymethylpyrrole-2-carboxaldehydes



4-218, dihydropyrrolopyrazinones

amino compounds, into *N*-substituted 2-hydroxymethylpyrroles (Figure 4.89). These substances tend to form polymers. Pyrrole and pyridine derivatives also form in reactions of amino compounds with 3-deoxyglycos-2-uloses derived from disaccharides. Another mechanism for the formation of 2-furfuryl alcohol from glucose in aqueous systems involves the oxidation of glucose to gluconic acid, which is decarboxylated to a pentitol and then followed by dehydration and cyclisation. In wort, *Saccharomyces cerevisiae* yeast can reduce furan-2-carbaldehyde to 2-furfuryl alcohol, but the main pathway during boiling of the wort seems to be the decomposition of the Amadori product derived from maltose via 3-deoxy-D-ribulose, which dehydrates to 2-furfuryl alcohol.

Reactions of 3-deoxyhexos-2-uloses with ketosamines derived from ammonia yield polyhydroxyalkyl substituted pyrroles and reactions of ketosamines derived from amines produce *N*-substituted polyhydroxyalkyl pyrroles. When the aforementioned uloses react with ketosamines in the presence of ammonia, 2,5-polyhydroxyalkyl substituted pyrazines are formed (Figure 4.90). These compounds also arise by dimerisation of ketosamines. 2,6-Disubstituted analogues of these compounds are formed by condensation of aldosamines with ketosamines. Polyhydroxyalkyl substituted imidazoles (**4-219**) are formed as additional products in reactions of 3-deoxyglycos-2-uloses with ammonia. It is assumed that all polyhydroxyalkyl substituted heterocyclic compounds can be transformed into normal alkyl substituted analogues (such as dimethyl derivatives) during thermal operations.



4-219, 1,4-polyhydroxyalkyl substituted imidazoles

3-Deoxyglycos-2-uloses react differently with secondary amines than with primary amines. Usually significant amounts of cyclic compounds form, but 5-hydroxymethylfuran-2-carbaldehyde does not arise at all (or only in small amounts). For example, the reaction of proline with 3-deoxy-D-*erythro*-hexos-2-ulose yields the so-called maltoxazine, a flavour-active compound occurring in beer and malt (Figure 4.91).

Condensation of *N*-substituted pyrrole-2-carbaldehyde derivatives mainly leads to coloured products, examples of which are compounds **4-220** and **4-221**. Derivatives of furan-2-carbaldehyde and many other furans are also significantly involved in non-enzymatic browning reactions. Reactions of furan-2-carbaldehyde with amino acids produce common Maillard reaction products, such as imines. Subsequent reactions of imines produce more complicated structures, mostly coloured compounds (Figure 4.92). The product illustrated in **4-222** forms

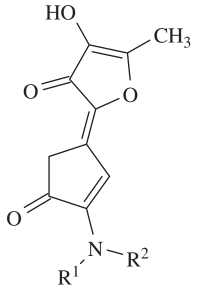
in the presence of primary amines. The reaction of 4-hydroxy-5-methyl-2*H*-furan-3-one with secondary amines yields the major coloured product shown in **4-223**.



4-223, reaction product of secondary amines with 4-hydroxy-5-methyl-2*H*-furan-3-one

4.7.5.3.2 Decomposition of 1-deoxyglycodiuloses

1-Deoxyglyco-2,3-diuloses are highly reactive compounds that scientists have so far failed to isolate from either foods or model reaction systems. Their presence has been indirectly confirmed by analysis of suitable derivatives. Important degradation products of 1-deoxyhexo-2,3-diuloses are furanones.

In the presence of sulfur compounds (e.g. cysteine) pentoses and methylpentoses produce, in addition to 4-hydroxy-5-methyl-2*H*-furan-3-one and 4-hydroxy-2,5-dimethyl-2*H*-furan-3-one, respectively, related compounds containing sulfur in the molecule. Many of these compounds resemble the aroma of cooked or roasted meat. In the presence of primary amines, 1-deoxyhexo-2,3-diuloses derived from disaccharides yield pyridinium betaines and, further, pyrid-4-ones and isomeric 2-acetylpyrroles. The reaction with secondary amines leads to *N*-substituted furan derivatives (Figure 4.93). 1-Deoxyhexo-2,3-diuloses also condense with carbonyl compounds and form coloured products (**4-224**). The reaction with proline or hydroxyproline results in cyclopenta[*b*]azepin-8(1*H*)-ones (**4-225**) and bispyrrolidinohexose reductones (**4-226**).

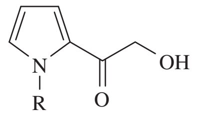
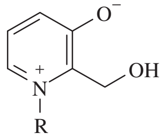
4.7.5.3.3 Decomposition of 4-deoxyglycosuloses and 1-amino-1,4-dideoxyglycosuloses

In the presence of amino compounds, the decomposition of 4-deoxyglycosuloses, such as 4-deoxy-D-*glycero*-hexo-2,3-diuloses (whose existence is expected during the transformation of lactulose and fructose into 2-hydroxyacetylfuran) yields the corresponding pyrroles (**4-227**) and isomeric pyridinium betaines (**4-228**). These pyridinium betaines, however, differ from pyridinium betaines (**4-216**) formed by decomposition of 3-deoxyglycos-2-uloses.



4-227, 2-hydroxyacetylpyrroles

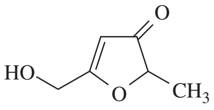


4-228, pyridinium betaines

In the Maillard reaction of oligosaccharides with a 1,4-glycosidic bond (such as maltose, lactose and lactulose) in media of low water activity, the 1-deoxyhexo-2,3-diuloses, 3-deoxyhexos-2-uloses and short-chain α-dicarbonyl compounds that are formed represent only a minor portion of the dicarbonyl intermediates. An important intermediate is the amino analogue of 4-deoxy-D-*glycero*-hexo-2,3-diulose, that is, 1-amino-1,4-dideoxy-D-*glycero*-hexo-2,3-diulose. Probably the most common product of decomposition of this diulose is 2-aminoacetylfuran, which arises (analogously to 2-hydroxyacetylfuran) by cyclisation and dehydration. Aminoacetylfuran is stable in acidic media, but at pH higher than 5 readily oxidises and condenses to form more complex structures (Figure 4.94). In cases where the amino compound bound in aminoacetylfuran is protein (bound by the ε-amino group of lysine), the resulting aminopyrrole forms cross-links, which connect the peptide chains of the proteins. Aminoacetylfurans react with ammonia with the formation of imidazole derivatives.

The main dicarbonyl product of the Maillard reaction with oligosaccharides that have 1,4-glycosidic bonds are 1,4-dideoxyhexo-2,3-diuloses (Figure 4.95). 2,3-Enolisation of the Amadori compound is followed by splitting of the oligosaccharide residue by β-elimination to form 1-amino-1,4-dideoxy-D-*glycero*-hexo-2,3-diulose. Reduction and hydrolysis of the bound amino acid yields 1,4-dideoxy-D-*glycero*-hexo-2,3-diulose. The residue of the reducing oligosaccharide with a 1,4-glycosidic linkage in the reducing end can be transformed in this way repeatedly. 1,4-Dideoxyhexo-2,3-diuloses may also result from 1-deoxyhexo-2,3-diuloses, which are reduced during the Strecker degradation of amino acids.

1,4-Dideoxyhexo-2,3-diuloses are unstable compounds and their cyclisation and dehydration leads, for example, to 5-hydroxymethyl-2-methylfuran-3-one (**4-229**). Cyclisation and dehydration of 1-amino-1,4-dideoxyhexosulose produce aminoacetylfurans. The most famous of these products is furosin. In non-acid media, maltooligosaccharides and other (1→4)-oligosaccharides give rise, via 1-amino-1,4-dideoxyhexosuloses, to α-dicarbonyl compounds with five carbon atoms, namely 3-deoxy-D-*glycero*-pentulose, 3-deoxy-D-*glycero*-pentos-2-ulose and 3,4-dideoxypentosulose (Figure 4.32).



4-229, 2-methyl-5-hydroxymethyl-2*H*-furan-3-one

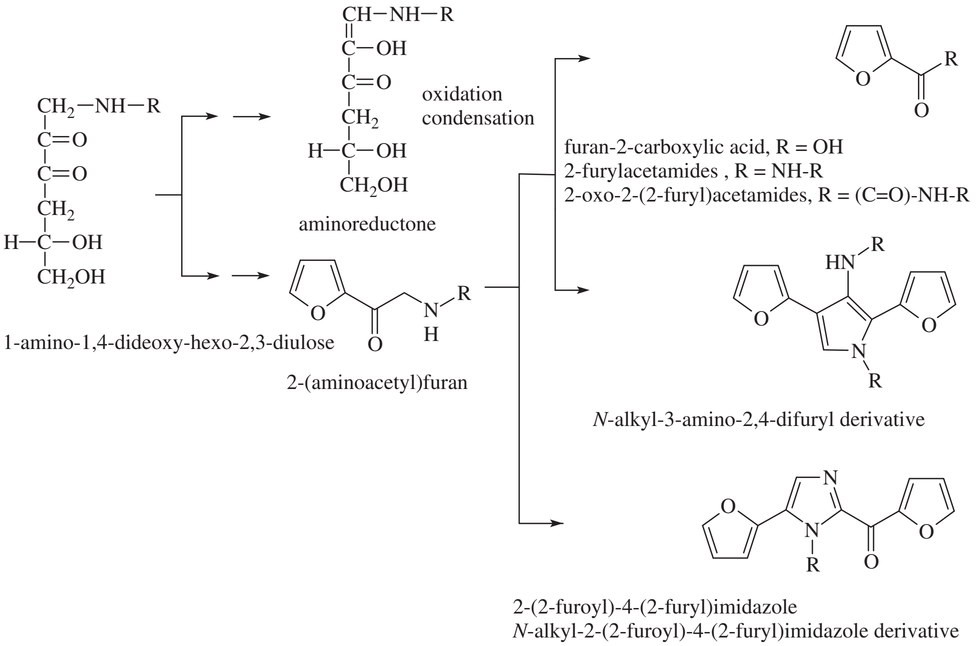


Figure 4.94 Important reactions of 1-amino-1,4-dideoxyhexo-2,3-diuloses.

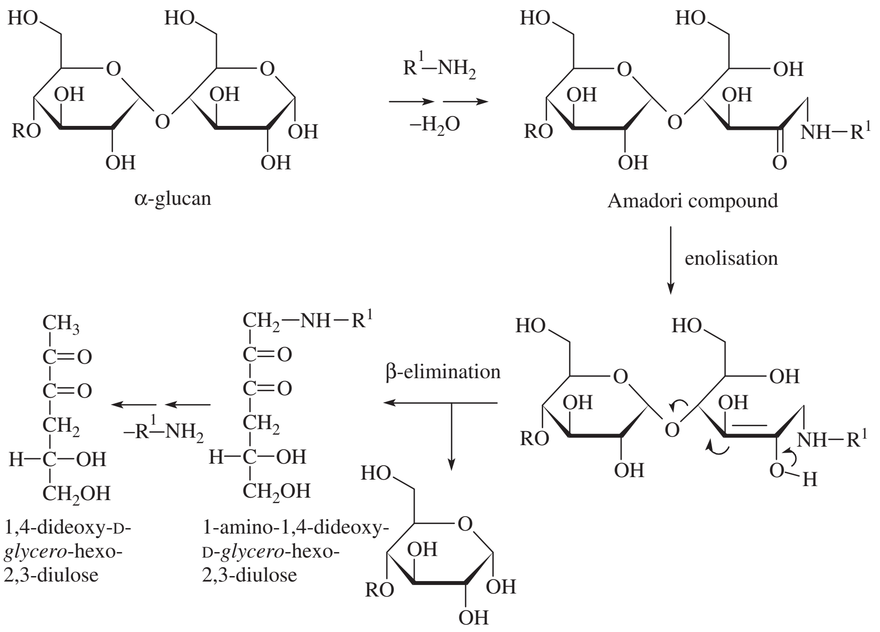

Figure 4.95 Formation of diuloses from maltooligosaccharides.

The key intermediates in the formation of furan and pyrrole derivatives from 3-deoxyglycos-2-uloses via β-dicarbonyl compounds are 3-deoxy-2,4-diuloses and 1-amino-1,3-dideoxy-2,4-diuloses. Cyclisation, dehydration and keto-enol tautomerisation of diuloses yield 2-acetylpyrrole derivatives as the main products (Figure 4.96).

4.7.5.4 Formation of aminoreductones

1-Deoxyhexo-2,3-diuloses can be easily converted into aliphatic aminoreductones of the general structure given by formula **4-230**. Aliphatic aminoreductone derived from propylamine was the first linear six carbon chain aminoreductone, whose formation in the Maillard reaction was assumed and then was later identified (Figure 4.94). A very reactive compound, formed by degradation of 1-deoxyhexodiuloses, is diacetylformoin (Figure 4.40, R = H). This compound, existing in several tautomeric forms, reacts with primary amines to form pyrrolid-3-one derivatives that are transformed into methylene reductic acid (R = H) (Figure 4.97). Reductic acid forms analogously from pentoses and from ascorbic acid. Diacetylformoin reacts with secondary amines to form 5-dialkylamino substituted 2*H*-dihydrofuran-3-one derivatives. The reaction of diacetylformoin with the ε-amino group of lysine bound in proteins causes protein cross-linking. Aminohexose reductones and derivatives of pyrrolidone derived from disaccharides (R = glycosyl, Figure 4.97) are formed by similar reactions.

X = OH, NR_2 or NHR
Y = OH, NR_2 or NHR

4.7.5.5 Strecker degradation of amino acids

The mechanism of this very important reaction is given elsewhere (Figure 2.43). In addition to numerous other substances, the active compounds are also aldoses, ketoses, derivatives of furan-2-carbaldehyde, α-dicarbonyl compounds derived from sugars, such as glycos-2-uloses or glyco-2,3-diuloses, and in particular the simple decomposition products of sugars, such as glyoxal and methylglyoxal.

The importance of Strecker degradation is mainly in the formation of reactive and often sensory active aldehydes and ammonia (free or bound in reactive α-amino carbonyl compounds). Strecker aldehydes, together with α-amino carbonyl compounds, contribute significantly to the formation of many heterocyclic compounds (which are important flavour-active components of processed foods) and the brown pigments melanoidins. Aldoses simultaneously produce the corresponding 2-deoxyaldoses or 1-amino-1-deoxyalditols and 2-oxoacids.

4.7.5.6 Melanoproteins

During processing and storage of foods, numerous reactions lead to protein structure modification. As well as denaturation and addition reactions, which lead to the formation of disulfide bridges and reversible oxidation of side chains of bound amino acids, isopeptide

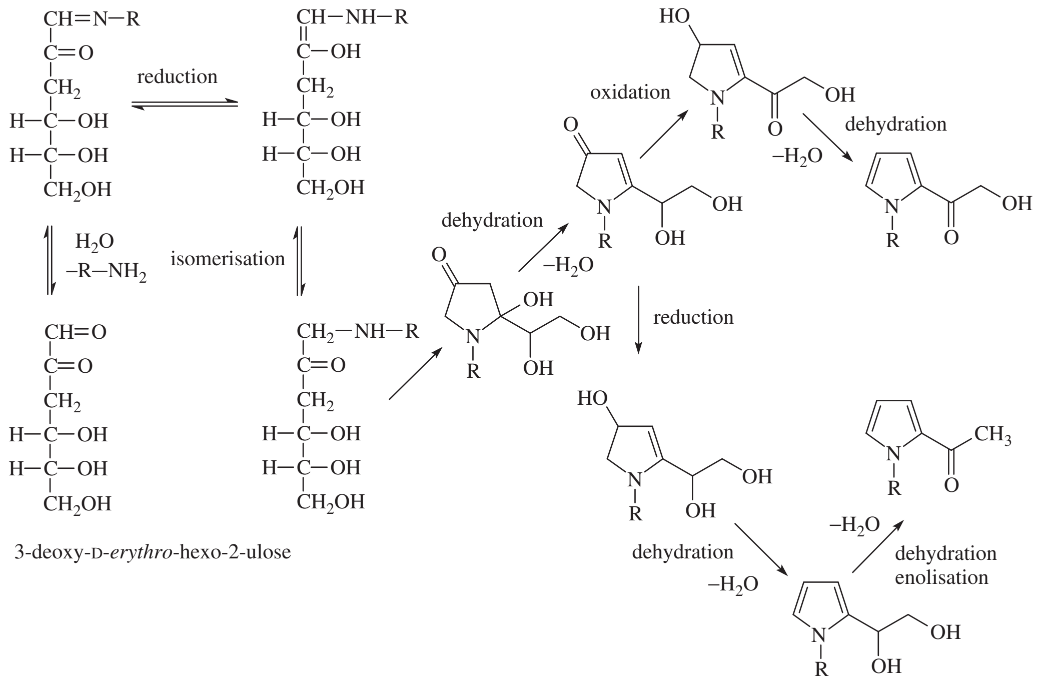

Figure 4.96 Transformation of 3-deoxy-D-*erythro*-hexos-2-ulose in the presence of amino compounds.

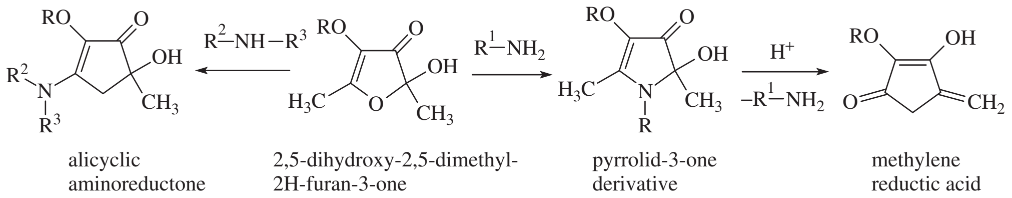

Figure 4.97 Reaction of diacetylformoin with amines.

bonds (Figure 2.50) or to the formation of amino acids derived from dehydroalanine (Figure 2.53), modifications of protein molecules are also caused by reactive dicarbonyl compounds formed during transformations of reducing sugars or products formed during oxidation of lipids. These bifunctional carbonyl compounds form adducts with one or two reactive amino acid residues in the peptide chains, which leads to inter- and intramolecular cross-linking of proteins. These reactions are of especially great importance for functional properties of proteins and likewise adversely affect their nutritional value. Proteins modified by reactions with carbonyl intermediates of the Maillard reaction or with secondary lipid oxidation products are often referred to as **melanoproteins**.

Significant in terms of health risks are spontaneous non-enzymatic reactions in living organisms that lead to the same or similar modifications of native protein as during food processing. This so-called protein **glycation** (or glycosylation) plays an important role both in physiological and pathological processes in the organisms. The modified protein, or strictly the modified amino acids released from the protein, are known by the acronym AGE (advanced glycation end products). Analogous structures abbreviated ALE (advanced lipoxidation end products) are produced by reactions of proteins with certain products of lipid oxidation (see Section 3.8.1.12.1). Excessive reactions are an indicator of tissue aging and pathological manifestations of certain diseases, such as increased oxidative stress due to hyperglycaemia in patients with type 2 diabetes. AGEs accumulate at sites of microvascular injury in diabetes, including the kidney, the retina and within the vasculature. One of the causes of oxidative stress in aging, diabetes and other diseases is considered to be the formation of oxygen radicals from glycated proteins. For example, even the Amadori compounds (products of early glycation of proteins) can apparently generate the superoxide radical anion, which arises from hydrogen peroxide in the presence of oxygen. It can react with traces of metal ions to form hydroxyl radicals. The potential adverse effects on health of diet-derived AGEs is of current interest, due to their proposed involvement in the disease progression of diabetic and uraemic conditions.

The enhanced formation of AGEs also exists in various other diseases, such as atherosclerosis, Alzheimer's disease, end-stage renal disease (ESRD), rheumatoid arthritis and liver cirrhosis. Whether AGEs are also risk factors for these diseases is still unclear. Most modifications *in vivo* are found in proteins with long life, such as collagens, myelin or α-crystalline. For example, a gradual change in the structure of collagen during aging causes a decrease

in the tissue elasticity. Ultimately, these changes lead to restrictions of joint mobility, decreased muscle performance, changes in the cardiovascular system or changes in the ocular lens. Modification of proteins may similarly have a negative impact in cases where AGEs are located in areas of interaction with other protein chains, the substrate in interaction in the enzyme–substrate or DNA during transcription.

AGEs can arise not only from glucose, but also from the reactive products of glucose metabolism and non-enzymatic degradation. The most important Maillard reaction products reacting with proteins are methylglyoxal, glyoxal and 3-deoxyhexosuloses, but also identified are other precursors of AGEs, namely α-hydroxycarbonyl products of sugar fragmentation, transformation products of ascorbic acid or some secondary decomposition products of lipid hydroperoxides. Some common intermediates of sugar metabolism also contribute to the formation of AGEs *in vivo*. For example, triose phosphates or fructose phosphates are effective modifiers of proteins.

The most frequently modified part of the protein is the ε-amino group of protein-bound lysine and the guanidyl group of protein-bound arginine, which are involved in the cross-linked AGEs formation. They react with bifunctional reagents (such as dicarbonyl compounds) and the product then reacts through the other functional group with another lysine or arginine residue of the same or another protein molecule. Tryptophan and histidine bound in proteins react with only one functional group of bifunctional reagents yielding non-cross-linked AGEs. Little is known about the reactions of bound cysteine, whose thiol group is a better nucleophile than the amino groups of lysine or arginine. Cysteine conjugates can significantly influence the technological and physiological properties of glycated proteins and also serve as a carrier and reservoir of reactive dicarbonyl compounds.

AGEs are released by controlled physiological or enzymatic hydrolysis of modified proteins as modified low molecular weight peptides or modified amino acids. The number of AGEs identified up-to-now may be just the tip of the iceberg, because different types of modifications are formed in tissue proteins and the products that usually occur only in trace quantities are difficult to identify. Adducts identified after hydrolysis are called by trivial names and acronyms. They can be classified according to the structure, the participating amino acids or carbonyl compounds, the origin of the precursors (carbohydrates, their degradation products, oxidation products of lipids or both groups of these nutrients) or by whether or not the AGEs are cross-linked or not. Many cross-linked products are fluorescent, while some of them are coloured or have reducing properties.

The non-cross-linked AGE N^{ε}-(carboxymethyl)lysine (CML) was the first stable AGE to be discovered. CML is present in a range of heat treated foods and a major AGEs structure is formed *in vivo* by oxidative cleavage of Amadori products between C-2 and C-3 of the carbohydrate chain (glyoxal) or by a gradual degradation of lactulosyllysine in dairy products (see Figure 4.102 later). It is a marker of oxidative stress and long-term damage to protein in clinical studies (aging, atherosclerosis and diabetes). Protein modification has been demonstrated in collagen, eye lenses, serum proteins or erythrocytes, among others. Together with some other AGEs, CML has also been demonstrated in lipofuscin granules, the intracellular proteolipid pigment that causes of age related spots. CML is also a marker of the Maillard reaction in foods. For example, cereal (26 mg/kg food) and fruit and vegetable (1.3 mg/kg food) categories have the highest and lowest level of CML.

The CML homologue N^{ε}-(carboxyethyl)lysine (CEL, **4-231**) forms in analogous intracellular reactions with methylglyoxal and is an important marker for age-dependent disease, such as cardiovascular disease in diabetic patients. The reaction of 3-deoxyhexosuloses with the ε-amino group of bound lysine yields pyrraline, bound 6-(2-formyl-5-hydroxymethylpyrrol-1-yl)-L-norleucine (**4-232**), identified in hydrolysates of milk proteins and found in higher levels in serum of patients with diabetes, arteriosclerosis and Alzheimer's disease (Figure 4.98).

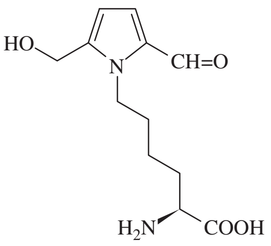
CEL, R = CH_3



4-232, pyrraline

The reaction of two lysyl residues with two molecules of glucose creates the so-called crossline (cross-linked AGE) (**4-233**), which is found in the serum and kidneys of diabetic patients. An analogous structure, called fluorolink (**4-234**), actually arises by dehydration and oxidation of crossline. Another cross-linked AGE is imidazolium salt of glyoxal-lysine dimer, trivially called GOLD (**4-235**), which is 2-ammonio-6-[1-(5-ammonio-6-oxido-6-oxohexyl) imidazolium-3-yl]hexanoate. The compound known as MOLD, (2-ammonio-6-[1-(5-ammonio-6-oxido-6-oxohexyl)-4-methylimidazolium-3-yl] hexanoate (**4-236**), results from the analogous reaction with methylglyoxal. These examples, however,

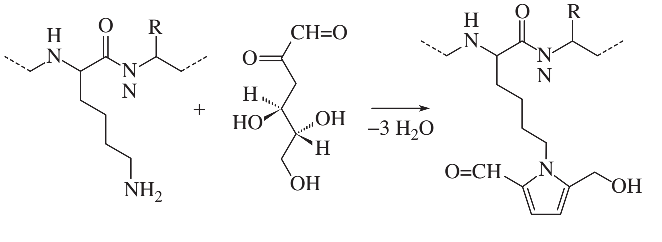


Figure 4.98 Reaction of 3-deoxyhexos-2-uloses with bound lysine to form pyrralines.

do not cover all known AGEs that are involved in cross-linking of two lysyl residues. The non-cross-linked AGE referred to as argpyrimidine, N^{δ}-(5-hydroxy-4,6-dimethylpyrimidin-2-yl)-L-ornithine (**4-237**), is derived from the reaction of methylglyoxal with the arginine protein residue. Reactions of methylglyoxal (MG) (**4-238**) or 3-deoxyglycosuloses (DG) (**4-239**) with an arginine residue yield the corresponding imidazolones, MG-imidazolone and 3DG-imidazolone. Analogous imidazolones are formed in reactions of methylglyoxal and 3-deoxyglycosuloses with protein-bound lysine. 3,4-Dideoxypentosulose formed exclusively from oligosaccharides with a (1→4) glycosidic bond is another dicarbonyl precursor in the modification of arginine residues and formation of (N^{δ}-[5-(3′-hydroxypropyl)-4-oxoimidazolon-2-yl]-L-ornithine, known as PIO (**4-240**), in foods containing reducing (1→4)-disaccharides, such as lactose, maltose or lactulose.

The result of cross-linking between the side chains of lysine and arginine are usually derivatives of imidazole. Pentosidine (**4-241**), 2-ammonio-6-{2-(4-ammonio-5-oxido-5-oxopentyl)-amino-3*H*-imidazo[4,5-b]pyridin-4-ium-4-yl}hexanoate, is a fluorescent compound that is formed on reaction of pentoses (and possibly of ascorbic acid) with lysyl and arginyl residues in proteins. It was detected in plasma β_2 microglobulin from patients with haemodialysis-related amyloidosis (a disease that results from the abnormal deposition of the protein amyloid). Pentosidine is normally present in acid hydrolysates of tissue rich in collagen. Other cross-linkages, which include side chains of lysine and arginine, are structures that are formed by reactions with glyoxal. An example of these compounds is 2-amonio-6-({2-[(4-amonio-5-oxido-5-oxopentyl)amino]-4,5-dihydro-1*H*-imidazol-5-ylidene}amino)hexanoate, or for short GODIC (**4-242**). By analogy, the reaction of methylglyoxal yields 2-amonio-6-({2-[(4-amonio-5-oxido-5-oxopentyl)amino]-4-methyl-4,5-dihydro-1*H*-imidazol-5-ylidene}amino)hexanoate, known as MODIC (**4-243**), 3-deoxyglycosuloses give rise to 2-amonio-6-({2-[(4-amonio-5-oxido-5-oxopentyl)amino]-4-(2,3,4-trihydroxybutyl)-4,5-dihydro-1*H*-imidazol-5-ylidene}amino)hexanoate, or DODIC (**4-244**), and the product of hexoses is 2-amonio-6-({2-[(4-amonio-5-oxido-5-oxopentyl)amino]-6,7-dihydroxy-4,5,6,7,8,8a-hexahydroimidazo[4,5-b]azepin-4-yl}hexanoate, known as glucosepane (**4-245**), the major protein cross-link of the senescent human serum albumin and lens protein. The levels of these adducts in hydrolysed foods (biscuits, cereal bars, boiled egg white) are up to tens of milligrams per kilogram.

An organism usually has a number of protective mechanisms that may limit and minimise the adverse consequences associated with AGEs formation. There are both chemical and biochemical processes, including enzymatic and immune responses. Suppression of glycation reactions and repair of glycated proteins in physiological systems are facilitated by a group of enzymes including glyoxalases, aldehyde reductases, aldehyde dehydrogenases, amadoriases and fructosamine 3-phosphokinases. The enzyme system of glyoxalase I and glyoxalase II, which plays a significant role in delaying the aging of tissues, metabolises the major AGEs precursors, such as glyoxal and methylglyoxal, and thus prevents glycation of cellular and extracellular proteins.

The risk of physiological AGEs is also reduced by a number of substances occurring in foods. Antioxidants (flavanones and other phenolic compounds, vitamin E, ascorbic acid and carotenoids) may inhibit oxidative stress in tissues and thus interfere with the formation of AGEs. Similar protective antiglycation effects are found with the elements Se, Zn, Cu and Mn, which are part of the redox enzyme systems. In addition to agents such as aminoguanidine, the α-reactive dicarbonyl precursors may also decompose thiamine and its derivatives. Foods high in fat (roasted almonds and walnuts, butter and mayonnaise) and protein (heat processed meats and cheeses) have 30 times and 12 times higher levels, respectively, the AGEs (expressed in CML content) of foods that are rich in carbohydrates (bread and other cereal products, fruits and vegetables). The important factor influencing the formation of AGEs is high temperature in processes such as grilling, frying or roasting. The dietary intake of AGEs substantially exceeds their amount generated physiologically. Usually less than 10% AGEs is absorbed from the dietary intake. Modified proteins are more resistant to proteolysis, and some AGEs even inhibit intestinal proteases. AGEs that are absorbed, are mainly glycated amino acids (adducts released by protein hydrolysis), which are rapidly excreted in urine in healthy people. Peptides that contain AGEs are eliminated from the body in the same way as xenobiotics. The relationships with the increase in the physiological levels and other negative influences have not yet been demonstrated for dietary AGEs and their interactions and reactions in the colon have not yet been adequately documented.

A considerable, but so far little explored technological potential of glycation reactions involves changes in the functional properties of proteins (formation of emulsions, foams, gels, changes in solubility, stability or improvement of taste). The disadvantage of these reactions is the certain, but usually negligible reduction of the nutritive value of proteins. Unlike acetylation, succinylation or other chemical methods used to improve the functional properties of proteins, the Maillard reaction occurs spontaneously during thermal processes without the addition of foreign substances. For example, increased solubility and emulsifying properties of proteins depend on the introduction of a limited number of hydrophilic sugar structures that are in contact with the aqueous phase, while the hydrophobic protein areas are oriented to the lipid phase. Increased stability of proteins may be partly related to the blocking of lysine and arginine residues that are attacked by proteolytic enzymes.

4.7.5.7 Melanoidins

The compounds produced in the first two phases of the Maillard reaction are usually colourless compounds, which are often collectively called **premelanoidins**. Different coloured compounds are formed mainly in the final stage of this reaction. Some of these are low molecular weight substances (usually with a relative molecular weight below 1000 Da), and other coloured substances known as **melanoidins** have relative molecular weights higher than 1000 Da. They have characteristic physico-chemical properties, such as solubility and antioxidant activity.

Coloured pigments that do not contain nitrogen are formed from various decomposition products of sugars. They can be formed, for example, by dehydration of the individual oligomers produced from 3-deoxy-D-*erythro*-hexos-2-uloses (the corresponding acids formed by their oxidation; **4-246**) or oligomers of 1-deoxy-D-*erythro*-hexo-2,3-diulose (**4-247**). In mixtures of pentoses and hexoses with amino acids, low molecular weight chromophores have been characterised, formed from the transformation products of 3-deoxyglycos-2-uloses (e.g. furan-2-carbaldehyde) and from reactive sugars fragments (**4-248** and **4-249**). The significant degradation product of 1-deoxyhexo-2,3-diuloses diacetylformoin (Figure 4.39) is another precursor of nitrogen free chromophores, but only if primary amino acids are not present. Otherwise its reaction with amino acids gives rise to pyrrolinone reductones that react via a methyl group with carbonyl compounds (such as furan-2-carbaldehyde) to form coloured compounds (Figure 4.99). Some other coloured reaction products are described in Section 4.7.1.1.4.

4-249, coloured 6*H*-pyran-3-one derivative

While low molecular weight chromophores arise mainly in systems with free amino acids, the coloured Maillard reaction products with proteins are almost exclusively macromolecular substances,

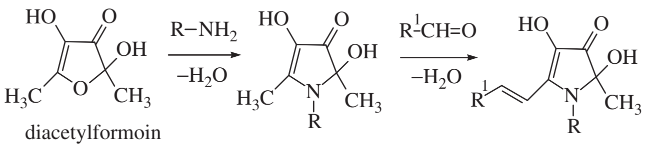

Figure 4.99 Formation of chromophores from diacetylformoin, aldehydes and amino acids.

unless there is subsequent proteolysis. Current hypotheses include two main types of high molecular weight pigments. The first type of formation assumes the condensation of low molecular weight Maillard reaction intermediates to form the coloured substances. The structure of melanoidins resulting from the condensation of monomeric units (especially heterocyclic Maillard reaction intermediates) has not been described satisfactorily. For example, melanoidins may also arise in reactions of hydroxylated 1,4-dihydropyrazines formed by oxidation and hydration of pyrazinium radicals (Figure 4.84) or by their condensation with aldehydes (especially with furan-2-carbaldehyde). Other degradation products of pentoses and hexoses, such as *N*-substituted pyrroles or *N*-substituted pyrrole-2-carbaldehydes, similarly form easily coloured products. Coloured oligomers formed from 2-hydroxymethyl-1-methylpyrrole (**4-250**) by condensation of 1-methylpyrrole with 1-methylpyrrole-2-carbaldehyde (**4-251**) or furan-2-carbaldehyde (**4-252**) have been identified. The other two types of polymers are formed by nucleophilic addition of amino groups of Amadori compounds to carbonyl compounds and by subsequent dehydration. The resulting polymer is oxidised with the formation of a system of conjugated double bonds. Decarboxylation and elimination reactions transform these polymers into other conjugated systems (Figure 4.100).

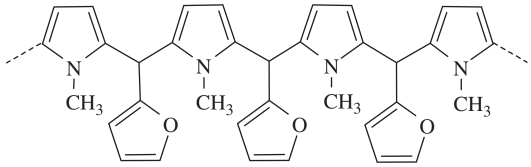
4-251, 1-methylpyrrole and pyrrole-2-carbaldehyde polymer



4-252, 1-methylpyrrole and furan-2-carbaldehyde polymer

The second method of melanoidin formation, which also leads to protein oligomers, is more typical for foods. This reaction assumes covalent bond formation of transformation products of sugars on the side chains of proteins, especially of bound lysine, arginine or cysteine, to form chromophore structures. Some of the previously mentioned AGE structures, such as pentosidine (**4-241**) are coloured. Other chromophores include substances that are formed in systems containing furan-2-carbaldehyde. The lysyl residue in a peptide chain reacts in a neutral solution with furan-2-carbaldehyde, forming chromophore (**4-253**). Also described are

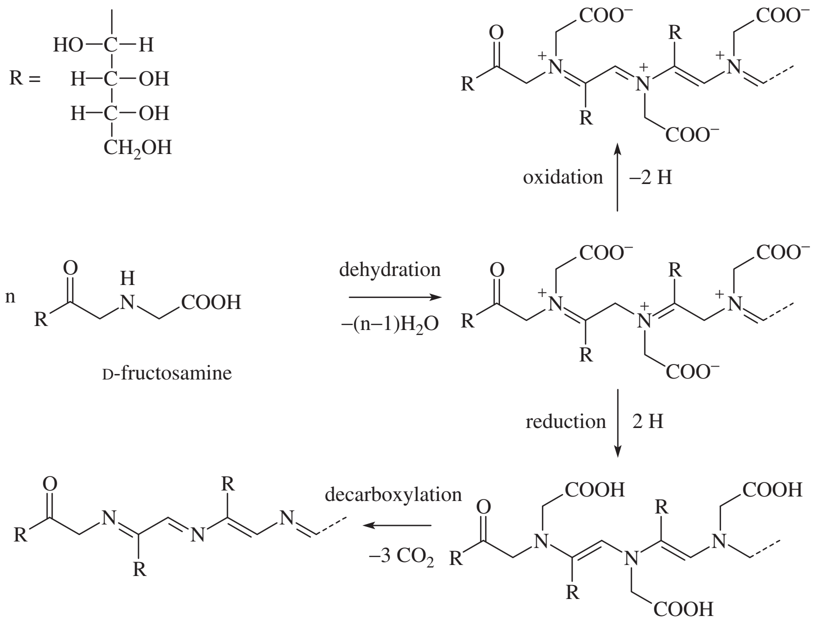


Figure 4.100 Expected structure of glucose–glycine pigments.

chromophores formed between two lysyl residues (**4-254**). Reaction of the guanidyl group of an arginine residue with glyoxal and furan-2-carbaldehyde yields the chromophore (**4-255**). Among the structures that cause protein cross-linking is the radical 1,4-bis(5-amino-5-carboxy-1-pentyl)pyrazinum cation abbreviated crosspy (**4-256**) bound to two lysyl residues of the peptide chains. Its formation is given in Figure 4.85. This structure is also considered one of the key precursors of melanoidins in bread crust and in roasted coffee. It is also possible that the chromophores of low molecular weights are only captured by the polymer via physical bonds instead of covalent bonds. The colour is sometimes attributed to the presence of free radicals stabilised in the structure of Maillard polymers. Other coloured structures may represent complexes with metal ions that create chromophores via chelation from colourless organic compounds, such as reductones.

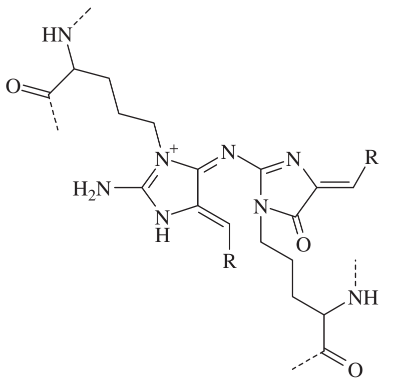
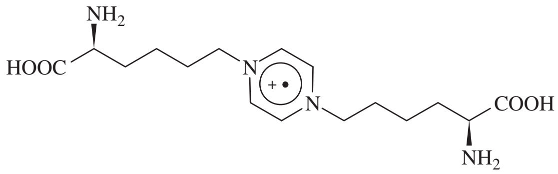
4.7.5.8 Antioxidant properties of reaction products

The important property of some melanoidins is their antioxidant activity. Antioxidant activity is highly dependent on the



4-255, coloured products of glyoxal and furan-2-carbaldehyde (R = furyl) with two arginine residues



4-256, 1,4-bis(5-amino-5-carboxy-1-pent-1-yl)pyrazinium radical cation

nature of the reactants from which melanoidins are formed. Some melanoidins also exhibit prooxidant properties.

The antioxidant properties of some reaction products of reducing sugars with amino acids and with other amino compounds (ammonia, amines) have been known for several decades, and have been used in industrial processes. Amino acids are less active antioxidants, but sugars and their transformation products do not show these properties. For example, the addition of glucose and certain amino acids (particularly glycine, valine and lysine) to the dough in the production of biscuits increased the stability of the fat towards autoxidation. The same effect is seen for the addition of reaction products of glucose with histidine in sausages stored at refrigerated temperatures. Heating milk with a mixture of glucose and histidine increases the oxidative stability of the milk after drying, but reduces the available lysine content and can bring about discolouration during storage. Products of the Maillard reaction exhibit synergistic effects in the presence of some antioxidants. For example, products arising from D-xylose and ammonia can increase the antioxidant effects of tocopherols.

The chemical principle behind the antioxidant properties of Maillard reaction products is currently not well understood. It is assumed that these properties show both low molecular weight products and high molecular weight melanoidins. As the structure of melanoidins has not been clarified satisfactorily, it is difficult to explain the chemical nature of their antioxidant activity. The active structures are probably reductones and aminoreductones, bound in melanoidin molecules that reduce the products of autoxidation. One of a few identified reductone structures in real food melanoidins is 2,4-dihydroxy-2,5-dimethyl-1-(5-acetamino-5-methoxycarbonylpentyl)-3-oxo-2*H*-pyrrole bound by a peptide bond. This so-called pronyl-L-lysine (pyrrolinone

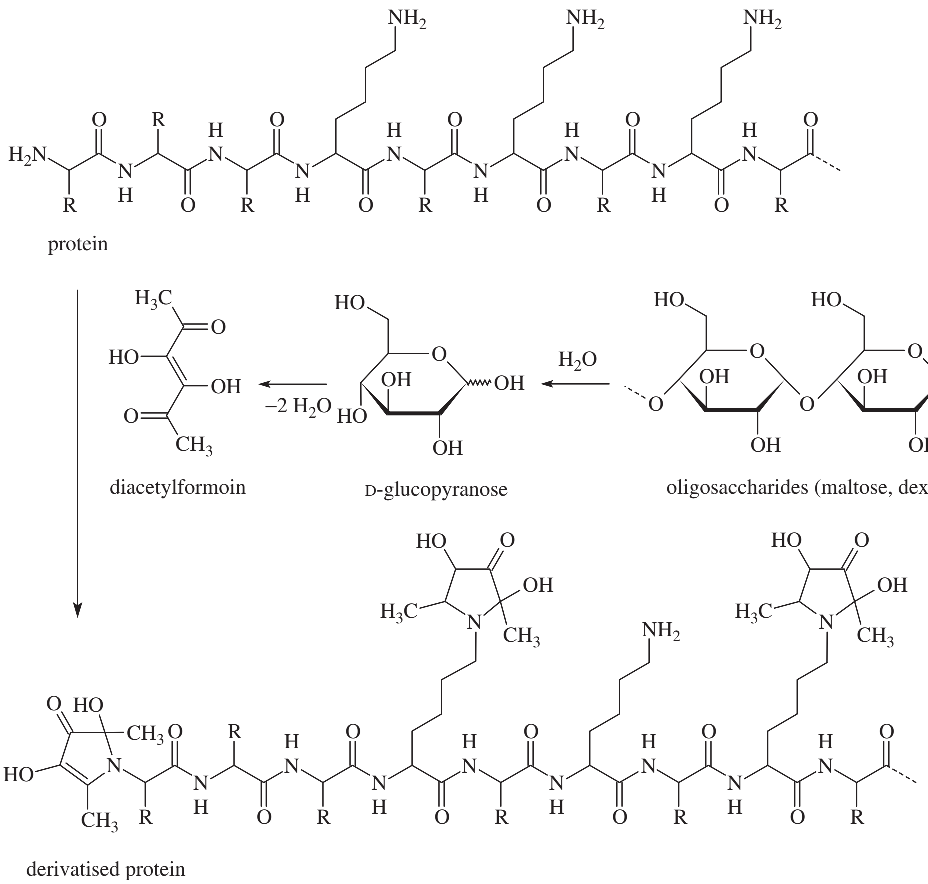


Figure 4.101 Formation of bound pronyl-L-lysine in bread crust.

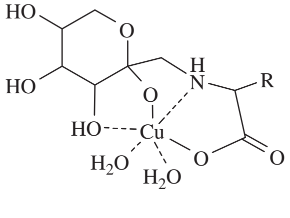
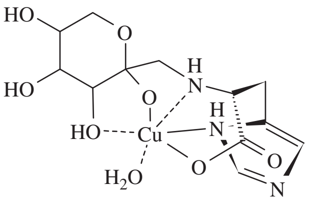
reductonyl lysine) contributes significantly to the antioxidant properties of bread crust, where it is found in concentrations of about 60 mg/kg. Its amount depends on the type of bread dough, the pH during dough fermentation and conditions during baking. Pronyl-lysine forms in the reaction of diacetylformoin (dehydration product of D-glucose via 1-deoxy-D-*erythro*-hexo-2,4-diulose) with ε-amino groups of lysyl residues and also, by analogy, with the *N*-terminal lysyl residues of the peptide chain (Figure 4.101).

In addition to reductones, structures capable of binding metal ions that act as oxidation catalysts also have significant antioxidant activities. Although amino acids can bind metals to coordination compounds (see Section 6.2.2.1), metal chelates (M^{2+}) with Amadori compounds (**4-257**) have considerably higher stability and therefore higher antioxidant activity. The increased stability is due to additional metal ion binding by C-2 and C-3 hydroxyl groups. Significant amounts of N^{α}-(1-deoxy-D-fructos-1-yl)-L-histidine were found in dried tomatoes and some other dried products (**4-258**).



4-257, general structure of Amadori compound/metal complex



4-258, N^{α}-(1-deoxy-D-fructos-1-yl)-L-histidine/Cu^{2+} complex

The highest antioxidant activity is seen in reaction products formed from sugar degradation products (such as methylglyoxal and 1,3-dihydroxyacetone) and from dehydroascorbic acid. Less active as antioxidants are the reaction products of pentoses, and even less active reaction products are formed from hexoses. The products of sugars with a basic amino acid (arginine, lysine and histidine) show higher antioxidant activity than products of other amino acids. Products of arginine and histidine with xylose are effective as antioxidants. Glutamic acid reaction products with glucose or fructose do not exhibit antioxidant properties. Reaction conditions play an important part. Antioxidant activity of the

reaction products generally increases with increasing pH, and with increasing weight ratio of the amino compound to sugar.

4.7.5.9 Nutritional and toxicological aspects

The consequences of the Maillard reaction are desirable changes to the organoleptic properties of foods, such as the formation of the typical aroma, taste and colour. However, some adverse changes can also appear, the most serious of which is the emergence of unusual taste and odour, undesirable colour (e.g. in dried foods) and reduced nutritional value. The decrease in nutritional value is caused by the actual loss of essential amino acids by irreversible reactions (e.g. in Strecker degradation), by binding of amino acids to unusable complexes and covalent compounds and by decreased protein digestibility due to resistant cross-links. The non-enzymatic browning reactions mainly affect the ε-amino group of lysine and sulfur containing amino acids.

The initial phase of the Maillard reaction, in which Schiff base stabilising by cyclisation is effective, does not negatively affect the nutritional value of foods, because both of these reaction intermediates are easily hydrolysed to the original components. The next stage of the Maillard reaction, which is the rearrangement of *N*-glycosylamine to aminodeoxysugar, results in a reduction of the food's nutritional value. For example, aldoses yield the so-called Amadori compounds (1-amino-1-deoxyketoses), which are the main bound and unusable forms of lysine in foods. The reduction of the nutritional value during the Maillard reaction occurs primarily in heat-stressed foodstuffs with low water content (drying, baking, frying and roasting). Bread baking, for example, results in a 10–15% loss of total lysine, and of up to 70% of lysine from the bread crust. Higher losses of lysine also occur during the drying of milk, where the loss can reach up to 30%, depending on the drying technology.

Melanoidins in foods high in saccharides, such as bread crust or coffee, can have particular biological functions of fibre, including the growth of desirable intestinal microflora (prebiotic effect). Melanoidins derived mainly from proteins do not show these properties.

As products of the Maillard reaction, numerous toxic substances can also be formed that exhibit clastogenic, mutagenic and carcinogenic effects. In this respect, various pyridoimidazoles, pyridoindoles and tetraazafluoranthenes occupy significant positions (see Section 12.2.1). Some products of the Maillard reaction are secondary amines. Reaction with nitrous acid or with nitrogen oxides may transform these compounds into mutagenic and carcinogenic *N*-nitroso compounds. In addition to these compounds, some Maillard reaction products show mutagenic activity, such as glyoxal, methylglyoxal and 5-hydroxymethylfuran-2-carbaldehyde.

4.7.5.10 Factors influencing reactions

The practical application of the Maillard reaction during food processing requires it to be under control in order to suppress side reactions and highlight the desirable or beneficial reactions. The main factors influencing the course of the Maillard reaction, which can be used for its control during food processing, are:

- temperature
- reaction time
- pH
- water activity
- type of reactants
- availability of reactants.

Owing to the complexity of the Maillard reaction, its optimisation is not an easy task. Optimisation is also impeded by the fact that the individual factors, such as temperature, water activity and pH, do not act in isolation, but can influence each other. The study of the influence of individual factors on the reaction is considerably more difficult, and the interdependence of the various factors is often the cause of conflicting and contradictory results obtained in different situations.

The effect of temperature on chemical reactions is expressed as the activation energy of reaction (higher activation energy means that the reaction rate depends more on temperature). The values of activation energy of the Maillard reactions vary over a wide range from 10 to 160 kJ/mol. The activation energy is also highly dependent on water activity. For example, at low water activities the activation energy of Amadori compound formation increases rapidly, while at medium and higher values of water activity, the activation energy is virtually independent of water activity. The activation energy (especially the activation energy of brown pigment formation) is also dependent on pH. For example, the activation energy of the formation of pigments in a lysine–glucose system increases with decreasing pH. Temperature affects not only the Maillard reaction rate, but also often the reaction mechanisms leading to the final products. A typical example is the formation of aromatic compounds, as the same reaction mixtures heated to different temperatures can produce very different flavour-active compounds. Higher temperatures generally lead to extensive fragmentation of reactants and a more diverse mixture of reaction products.

Water activity also significantly influences the formation of the brown colour. At high values of water activity, due to dilution of reactants, the reaction rate is very low. With decreasing water activity, the reaction rate increases, especially at medium water activity values (0.3–0.7), and reaches a maximum. Further reduction in water activity leads to a further decrease of reaction rates (see Section 7.9.2). Very low values of water activity can lead to the reaction stopping due to lack of mobility of the reactants. The value of water activity at which the Maillard reaction rate reaches a maximum can be influenced by the addition of glycerol or ethylene glycol. While the addition of these agents in systems with higher water activity reduces the reaction rate (dilution of reactants), their addition to systems with low water activity increases the reaction rate (higher mobility of reactants).

The Maillard reaction is highly dependent on pH (the reaction is usually accompanied by a decrease in pH as a result of formation of various carboxylic acids). The Maillard reaction rate generally increases with an increase in pH value. Brown colour formation in reactions of sugars with various amino acids increases with pH and reaches a maximum in the pH range 9–10 (the system glucose–lysine produces about 500 times higher amounts of pyrazines in pH 9 in comparison with pH 5). As with temperature, pH affects not only the Maillard reaction rate (and, therefore, the quantitative composition of the reaction mixture), but also its qualitative composition. A typical example is the decomposition of ketosamines, where pH is a very important factor in determining whether the decomposition takes place by 1,2- or 2,3-enolisation. While the 1,2-enolisation is favoured in sufficiently acidic media that allow protonisation of the Amadori compound nitrogen, during 2,3-enolisation the Amadori compound must be partially deprotonised. Therefore, 2,3-enolisation dominates in alkaline solutions and under non-aqueous conditions.

The effect of reaction partners on the rate of the Maillard reaction in the early stages has been already discussed (see Section 4.7.5.1). The rate of addition is mainly related to the pK_a value of amino compound, which determines the concentration of reactive species at a certain pH of the reaction mixture. The fastest reacting free amino acid in a wide range of pH values is lysine; the least reactive are aliphatic hydrophobic amino acids valine, leucine and isoleucine. Under normal conditions (pH 3–8) oligopeptides (mainly dipeptides) are more reactive than the corresponding amino acids, because their pK_a values are substantially lower. Reactivity of peptides is highly dependent on their primary structure. For example, dipeptides with *C*-terminal glutamic acid are more reactive. Another parameter of comparative reactivity of compounds is their disposition to the formation of aromatic or coloured products. For example, lysine, glycine or tryptophan produce a very intense colour with sugars, but the acidic, sulfur and hydroxyamino acids contribute little to the browning reaction. Furan-2-carbaldehyde and glycolaldehyde belong to the most effective colour precursors in the presence of amino acids and common carbonyl intermediates such as pyrrole-2-carbaldehyde, methylglyoxal or glyoxal similarly have considerable potential. Amadori products provide fewer colours than the starting hexoses and pentoses. 5-Hydroxymethylfuran-2-carbaldehyde or acetoin are insignificant reaction products as pigment precursors.

Some importance is attributed to the Maillard reaction during the germination of plant seeds due to the increased availability of free amino acids and sugars. Several intermediates of the Maillard reaction are apparently applied as stimulants of germination.

4.7.5.11 Reaction inhibition

Taking into account that the Maillard reaction is not always desirable during the processing and storage of foods, a range of possibilities of its inhibition have been studied. Inhibition of the Maillard reaction consists mainly of creating conditions unfavourable to its progress. Knowing the factors that influence the course of the Maillard reaction, it is clear that a reduction of its rate or inhibition of this reaction can be achieved in many ways, but not all of them are applicable in practice. The choice of inhibition method therefore greatly depends on the specific food and its processing technology. Most often the following inhibition methods are employed:

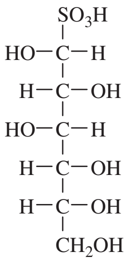
- elimination of one of the reaction partners
- water content adjustment
- decreased temperature
- shorter heating period
- pH adjustment
- addition of substances inhibiting or slowing down the reaction.

Removal of glucose has been used successfully in the production of powdered (dried) whole eggs and egg whites. Glucose is oxidised to inactive gluconic acid by the addition of a yeast preparation with glucose oxidase activity, or by the addition of glucose oxidase enzyme. Simultaneous removal of oxygen slows down the autoxidation reaction.

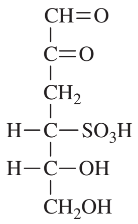
Limiting the extent of the Maillard reaction in the production of dried foods is often achieved by reducing the temperature currently used and drying time to a minimum. This can be done by frequently turning the food, or drying it in the thinnest layer possible. It is important to reduce the temperature at which the Maillard reaction takes place quickly, especially when the food has a critical water content (water activity). It is also necessary to ensure that the finished dried product is not heated unnecessarily. For example, during spray drying of milk it is necessary to avoid heating the dried powder above 60 °C. Reducing the heating time is employed, for example, in the production of jams. The use of small production batches can shorten the time of heating by up to one third, which has a significant positive effect on the sensory quality of the product. While products produced in large batches tend to have a reddish brown colour and a caramel-like flavour, the product prepared by the same formula, but in smaller batches, has a deep red colour and typically a strawberry flavour. Reducing the heating time also indirectly influences the course of the Maillard reaction by lowering the amount of glucose produced by saccharose inversion.

Inhibition of the Maillard reaction in certain foods can also be achieved by the addition of sulfur dioxide or hydrogen sulfites (bisulfites). It is assumed that the inhibition occurs due to hydrogen sulfite addition to the carbonyl group of sugar, which is then blocked and cannot react with amino compounds. In a weakly acidic medium and at normal temperatures, glucose yields the corresponding 2-hydroxysulfonic acid, the systematic name of which is D-*glycero*-D-*ido*-1,2,3,4,5,6-hexahydroxyhexanesulfonic acid (**4-259**). In a neutral solution 4-sulfohexos-2-ulose (3,4-dideoxy-4-sulfo-D-*glycero*-hexos-2-ulose) is produced, shown in **4-260**. 4-Sulfohexos-2-ulose can be further transformed into isomeric acids by oxidation or benzilic acid rearrangement. Inhibition of reactions with sulfur dioxide or hydrogen sulfides in the presence

of ascorbic acid or pentose yields, analogously, 3,4-dideoxy-4-sulfopentos-2-uloses.



4-259, D-*glycero*-D-*ido*-1,2,3,4,5,6-hexahydroxyhexane sulfonic acid



4-260, 3,4-dideoxy-4-sulfo-D-*glycero*-hexos-2-ulose

The effectiveness of inhibition by hydrogen sulfites is undoubtedly related to their ability to react with a wide range of products produced at all stages of the Maillard reaction. Enzymatic browning reactions are also inhibited. Carbon dioxide also has a preservative function, or may act as an antioxidant. Inhibition of the Maillard reaction can also be achieved by adding sulfur-containing amino acids such as cysteine; however, due to the possibility of degradation of sulfur amino acids and formation of unpleasant sulfur-containing flavour-active degradation products, the practical application of this inhibition is only possible in exceptional cases.

4.7.5.12 Significance for food technologies

Most food technologies have a long tradition, and control of the Maillard reaction is based on extensive empirical experience rather than on scientific knowledge gained by systematic research. When new technologies have to be introduced, food processing technologists are faced with the task of optimising these technologies in order to achieve the required product quality.

When the pre-existing technology stands to benefit from improvements that enhance and complement its performance-in-use, the required product quality has to be at least comparable to the product quality obtained by the traditional technology (such as microwave cooking versus traditional cooking). Optimisation of the Maillard reaction in new technological processes is made more difficult by the fact that besides the lack of empirical experience, technologists must often establish new parameters, which previously influenced the course of the Maillard reaction only marginally. For this reason, they are forced to use their scientific knowledge for control of the Maillard reaction to a greater extent than in the conventional technology. The relatively new technologies, where the influence of the Maillard reaction is not fully optimised, are:

- extrusion
- microwave cooking
- infrared heating.

4.7.5.12.1 Roasting

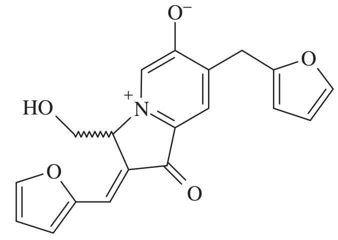
One of the traditional processes, in which the Maillard reaction is very intense, is roasting (manufacture of cocoa and coffee and nut roasting). Roasting affects not only colour, but also mainly the odour and taste of the processed raw materials.

During the roasting of cocoa beans, hundreds of volatile compounds are created, of which more than 400 have already been identified. The mechanisms of formation of many of these substances have been satisfactorily explained. It was also found that the formation of volatiles is not only affected by the conditions of roasting, but to a large extent also by fermentation prior to roasting, which leads to the release of amino acids and reducing monosaccharides. Not all volatile products generated during roasting of cocoa beans, however, are important components of cocoa aroma.

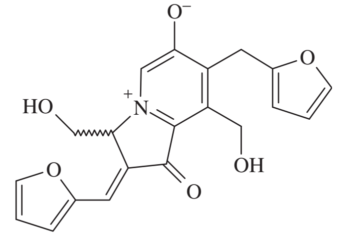
Roasting of green coffee beans also creates hundreds of volatile substances. Even more compounds have been identified in roasted coffee than in roasted cocoa. Depending on the roasting conditions (particularly temperature and roasting time), roasted coffee with different sensory properties can be obtained. During the roasting process, reducing monosaccharides are decomposed in the first instance. In later stages of roasting, non-reducing oligosaccharides and polysaccharides, after cleavage to reducing sugars, are also involved in the Maillard reaction. At lower roasting temperatures, the rate of release of reducing sugars from polysaccharides and oligosaccharides is higher than their decomposition. Coffee roasted in this way has a lighter colour and contains up to 1% of glucose and fructose. At high temperatures, rapid decomposition of reducing sugars occurs and higher amounts of polymeric brown pigments are formed. Reducing sugars are also partially decomposed to acids under these conditions and the acids contents grow. Thus, roasted coffee normally contains only traces of reducing sugars, has a dark colour and a slightly sour taste. In recent years the so-called fast roasting process has also been introduced (at temperatures higher than 230 °C), in which the saccharose content in coffee beans sharply decreases, but the loss of polysaccharides is substantially lower than during the conventional roasting, which is reflected in reduced acidity.

The most famous coffee substitute (surrogate) is undoubtedly chicory root, which contains a considerable amount of inulin. Inulin is accompanied by free reducing sugars (glucose and fructose). Roasting chicory root gradually reduces the amount of inulin, and reducing sugars and fructose produced from inulin are subsequently degraded to dark caramelisation products (see Table 4.10).

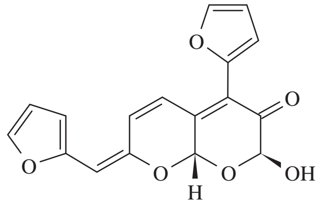
The roasting processes produce a number of taste-active substances, bitter compounds in particular. Unlike the odour-active substances created by the Maillard reaction, knowledge of the bitter compounds is rather limited. Most of the identified substances were found in model reaction mixtures. It is known that pentoses and α-amino acids (such as xylose and alanine) produce intensely bitter substances identified as (*E*)-7-(2-furylmethyl)-2-(2-furylmethylidene)-3-(hydroxymethyl)-1-oxo-2,3-dihydro-1*H*-indolizinium-6-olate (quinizolate, **4-261**) and (*E*)-7-(2-furylmethyl)-2-(2-furylmethylidene)-3,8-bis(hydroxymethyl)-1-oxo-2,3-dihydro-1*H*-indolizinium-6-olate (also known as homoquinizolate, **4-262**). Diastereoisomers of 2*H*,7*H*,8a*H*-pyrano[2,3-*b*]pyran-3-one (**4-263**) have a taste reminiscent of capsaicin. Bitter tasting compounds in reaction mixtures of hexoses with proline are a spirodiolone derivative **4-264**, bispyrrolidinohexose reductones (**4-225**) and also cyclopenta[*b*]azepin-8(1*H*)-ones (**4-226**). Other products, such as 2,5-dimethyl-4-(1-pyrrolidinyl)-2*H*-furan-3-one (**4-266**) or 5-methyl-2-(1-pyrrolidinyl)-2-cyclopenten-2-one (**4-265**), cause afterimage cooling and a refreshing taste in the mouth. These substances have similarly been found in roasted malts. Mixtures of hexoses with alanine yield an inner salt of 1-(1-carboxyethyl)-5-hydroxy-2-(hydroxymethyl)pyridinium (**4-267**), which increases the intensity of the sweet taste perception. For example, similar pyridinium betaines were found in beef broth.



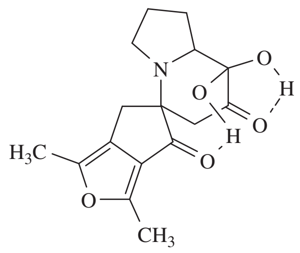
4-261, quinizolate



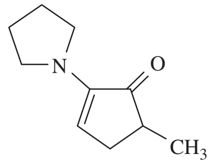
4-262, homoquinizolate



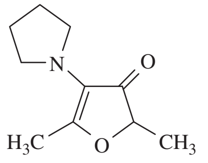
4-263, 2*H*,7*H*,8a*H*-pyrano[2,3-*b*]pyran-3-one



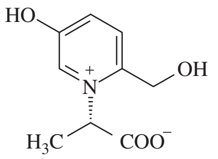
4-264, spirodiolone derivative



4-265, 5-methyl-2-(1-pyrrolidinyl)-2-cyclopenten-2-one



4-266, 2,5-dimethyl-4-(1-pyrrolidinyl)-2*H*-furan-3-one



4-267, 1-(1-carboxyethyl)-5-hydroxy-2-(hydroxymethyl)pyridinium

4.7.5.12.2 Boiling, baking and frying

Besides roasting, many other processes exist where the Maillard reaction is desirable (e.g. cooking, baking and frying). The Maillard reaction can also have negative consequences, such as a certain reduction of the nutritional value of food, production or mutagens, but the positive aspects of the Maillard reaction (especially the typical colour, smell and taste) significantly predominate. Examples include the formation of bread crust flavour and the flavour of cooked and roasted meat. Formation of aromatic compounds in the traditional processes of food production have always received, and continue to receive, considerable attention. Research is currently focused mainly on identifying compounds responsible for the characteristic odour and taste.

4.7.5.12.3 Drying

A typical example of a traditional technology in which the Maillard reaction manifests itself in a profoundly negative manner is the drying of milk, fruits and vegetables.

In milk and dairy products the intensity of the Maillard reaction is very high under certain conditions, due to the relatively

high concentration of lactose and the presence of thermolabile proteins (especially whey proteins). During drying, heat treatment of milk, and also during improper storage of milk powder, the non-enzymatic browning reactions destroy lysine almost exclusively. This amino acid becomes a limiting amino acid, although it was present in the original raw material in sufficient amounts. Losses of lysine greatly depend on the technology of the milk processing, as well as on appropriate practice of these procedures. The total amount of lysine bound to lactose in raw milk is very small, but the bound lysine is non-utilisable. During the traditional drying process using steam-heated drying cylinders, the lysine losses reached 10–30%, while spray drying losses only reach up to 3%. In the freeze-dried milk, practically no loss of lysine occurs.

The Maillard reaction in dried milk affects the originally free ε-amino group of L-lysine bound in proteins that reacts with lactose yielding the corresponding glycosylamine, which is fully utilisable as a source of lysine. Its rearrangement produces the non-utilisable protein bound Amadori compound (ε-*N*-deoxylactulosyllysine also known as 1-lysino-1-deoxylactulose). Hydrolysis of these modified proteins initially gives the free Amadori compound, which is subsequently degraded to furosine, pyridosine and lysine via the intermediate 1-lysine-1,4-dideoxy-D-*glycero*-hexo-2,3-diulose (Figure 4.102). Determination of pyridosine and furosine is used in practice for the tentative determination of the degree of damage in dried milk. The degree of damage to the milk powder, that is the amount of non-utilisable lysine, is very important information, especially for manufacturers of infant formulae.

The Maillard reaction is responsible for only about 20% of the losses of lactose in milk as the main cause of the losses (about 80%) is lactose isomerisation. Lactose isomerises even in the neutral medium of milk to produce lactulose (aldose–ketose isomerisation), which is accompanied by a small amount of epilactose (aldose–aldose isomerisation, known as epimerisation; Table 4.15). Lactulose in milk is a mixture of three isomers differing in the structure of bound fructose (β-furanose, α-furanose, β-pyranose in the ratio of about 75 : 10 : 15). It is commonly present in pasteurised, sterilised or otherwise heat-treated milk, and in milk products. UHT milk contains 50–750 mg/l of lactulose, while sterilised milk has higher lactulose content. The lactulose content clearly correlates with the negative organoleptic properties (cooked flavour, darker colour); therefore it is used as an indicator, which can differentiate pasteurised milk, sterilised milk and UHT milk. The lactulose content in condensed milk is up to 1%, which corresponds to about 10% of isomerised lactose. Lactulose is partly hydrolysed to fructose and galactose, and these monosaccharides isomerise to produce small amounts of glucose and tagatose, respectively. Isomerisation of lactulose (2,3-enolisation) yields 4-deoxy-D-*glycero*-hexo-2,3-diulose as an intermediate product and 3-deoxy-D-*glycero*-pentos-2-ulose and formic acid as the main final products. Dehydration of 3-deoxy-D-*glycero*-pentos-2-ulose yields small amounts of furfuryl alcohol.

Amadori compounds have been identified in various processed fruit and vegetable products, for example, in commercial carrot products (juices, baby foods, tinned and dehydrated carrots). While these products showed fairly low rates of amino acid modification (up to 5%), dehydrated carrots contained Amadori products corresponding to a lysine derivatisation of up to 58% and nearly 100% derivatisation of γ-aminobutyric acid. Besides the Amadori

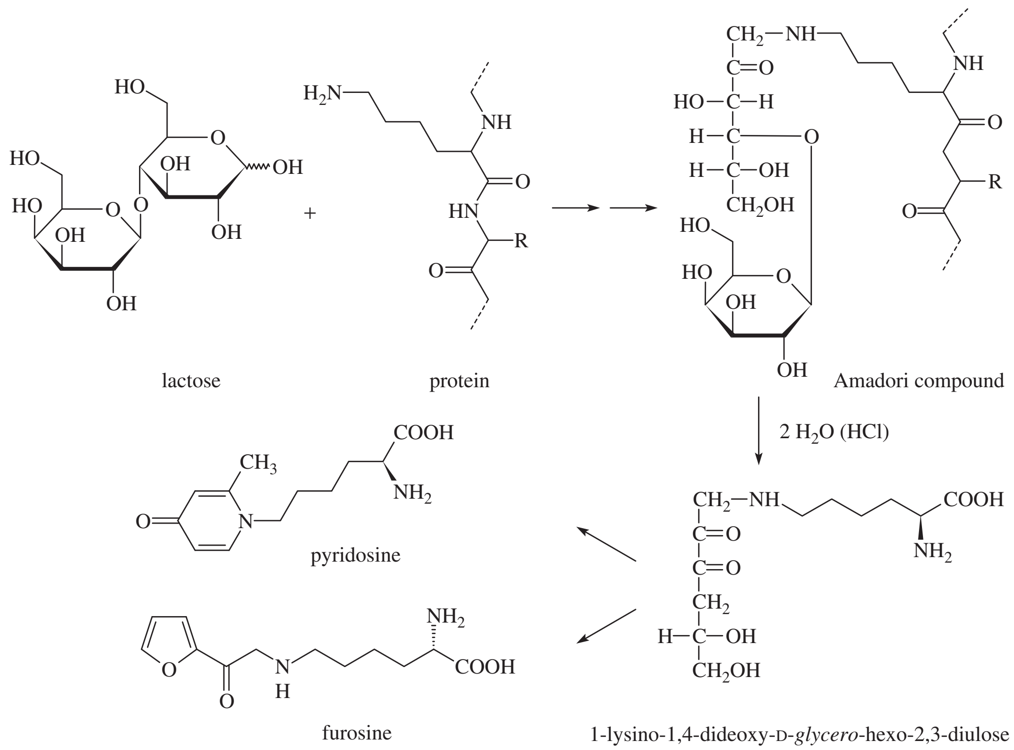


Figure 4.102 Formation of furosine and pyridosine from lactose and milk proteins.

products formed during the early stage of the Maillard reaction, the AGEs N^{ε}-(carboxymethyl)lysine (CML, **4-231**) and 6-(2-formyl-5-hydroxymethylpyrrol-1-yl)-L-norleucine (pyrraline, **4-232**) likewise occurred in all carrot products (except raw carrot).

4.7.5.12.4 Extrusion

Extrusion technology is now widely used with a range of food applications (such as production of biscuits and breakfast cereals). It is a relatively complex process in which food is exposed to comparatively high temperature, high pressure and shear forces for a short period of time. The quality of the final product depends on parameters such as the speed of performance of the extruder, screw speed and screw configuration (shape). High temperature and low water activity of the processed material produce favourable conditions for the Maillard reaction. The negative aspect is the loss of lysine, whereas a positive aspect is the formation of a desirable flavour of the product. Under unfavourable conditions, losses of lysine during extrusion can reach 40–50%. The losses can be minimised in various ways, such as by lowering the temperature, increasing the water content, using non-reducing sugars (saccharose) instead of reducing sugars and changing the geometry of the screw. For example, at a temperature of 210 °C, the increase of the moisture content from 13 to 18% results in roughly seven times lower loss of lysine during the production of biscuits. To maintain the lysine losses under 15% of the original lysine content, the recommended temperature is 180 °C and the water content in the material must be lower than 15%. The addition of reducing sugars is not recommended. Temperature and humidity are key parameters influencing the formation of aromatic compounds during extrusion. The most important fragrant substances in the extruded materials are pyrazines. Their content increases as the temperature increases to 160 °C, but at higher temperatures the levels of pyrazines decrease.

4.7.5.12.5 Microwave cooking

In recent decades, microwave cooking has undergone considerable growth. The highest temperature is achieved not only on the surface of the food (as in classical heating), but also inside the food. This can be a major disadvantage, because there is insufficient heating and drying of the surface, so the crust formation and colour and aroma development are insufficient. To reduce these shortcomings, several principles have been proposed that consist of:

- modifications of recipes
- changes of process parameters
- packaging technology.

An example of recipe modifications is the addition of artificial flavours or coating the surface of food by pre-mixes containing reducing sugars and amino acids. The actual process can be modified by the combination with another type of heating (such as grilling). Changes in packaging technology lie mainly in the use of packaging materials that are capable of absorbing the microwave radiation and can heat the surface of food with which they are in contact, such as a polyester film metallised with aluminium and glued onto paper. The temperature of the packaging material can be influenced by the thickness of the aluminium layer.

4.7.5.12.6 Infrared heating

Infrared heating is successfully used, for example, for cooking meat, and in the production of biscuits or bread. The main advantage in comparison with conventional methods is the shorter cooking time and energy savings. Sensory qualities of products obtained by conventional methods and by infrared heating are comparable; for example, bread forms a crust, but it is slightly thinner.

4.7.6 Caramelisation

Caramelisation of sugars is the process that produces brown to brown–black amorphous products of different composition that are referred to as **caramel**. A solution of caramel is called **couleur caramel** or **sugar couleur**. Caramel is produced by heating sugars or sugars with the addition of substances that accelerate caramelisation (catalysts) to temperatures higher than about 120 °C, typically 150–190 °C, but not exceeding 240 °C.

The raw materials for the production of caramel are mostly saccharose, glucose, fructose, glucose syrup or starch. During the discontinuous (batch) mode of caramel production, these materials are heated at 120–180 °C for 5–10 h in the presence of a catalyst. The choice of the catalyst depends on the intended use of the caramel. According to the technological process used (substances used in accelerating caramelisation), the following types of caramels can be distinguished:

- caramels with a positive electric charge (pH of isoelectric point is 4.0–7.0, in particular 6.0–7.0), produced by the addition of ammonia;
- caramels with a negative electric charge (pH of isoelectric point <3.0, usually around a value of 1.5), produced by the addition of ammonium sulfate or ammonium sulfite;
- caramels with no electric charge (produced in the presence of NaOH) known as spirit caramels.

Caramels are used to dye beer and other alcoholic beverages, soft drinks, vinegar, confectionery, bakery and meat products. Caramels with a positive electrical charge are particularly suitable for colouring beer, because in the presence of alcohol the positively charged colloidal particles of tannin are not precipitated and do not form hazes. Caramels with negative electric charges are used in the manufacture of soft drinks, which require caramel stability at low pH values. Spirit caramels are used for colouring alcoholic beverages such as rum, because they are soluble and stable in the presence of ethanol. Classification of sugar caramels and their uses are given in Table 4.37.

Table 4.37 Classification of sugar couleurs and their use.

Class		Couleur name	Additives	Use
I	CP	Caustic (plain, spirit)	Na_2CO_3, K_2CO_3, NaOH, KOH, H_2SO_4, acetic acid, citric acid	Spirits with high alcohol content
II	CCS	Caustic sulfite	SO_2, H_2SO_4, Na_2SO_3, K_2SO_3, NaOH, KOH	Malt bread, vinegar, bear, spirits, flavoured wines, mead
III	AC	Ammonium	NH_3, $(NH_4)_2SO_4$, Na_2CO_3, H_2SO_4, NaOH, KOH	Beer and other alcoholic beverages, acidic foods
IV	SAC	Sulfite ammonium	NH_3, SO_2, $(NH_4)_2SO_3$, Na_2SO_3, K_2SO_3, Na_2CO_3, K_2CO_3, NaOH, KOH, H_2SO_4	Acidic foods, non-alcoholic beverages

Caramel contains, in addition to high-molecular weight constituents, a variety of substances of low molecular weight, which are formed in the Maillard reaction. These substances largely include unreacted sugars, acids (mainly pyruvic acid), sugar anhydrides, furan and pyran derivatives and sugar fragments. Low molecular weight substances are the main precursors of reactions leading to the formation of brown polymeric melanoidins. Reactions taking place during the caramelisation of sugars are similar to those that occur during the Maillard reaction (such as dehydration, isomerisation and retroaldolisation). Unlike the Maillard reaction, caramelisation, with few exceptions, does not produce nitrogenous compounds. The only exception is caramelisation catalysed by ammonium salts or ammonia in which nitrogen compounds are formed, for example pyrazines, imidazoles and other heterocyclic compounds, but to a lesser extent than in the Maillard reaction.

By analogy with the Maillard reaction, some undesirable compounds can be similarly formed in caramelisation. Possible compounds are, for example, 4(5)-methylimidazole, 2-methylimidazole and 2-acetyl-4(5)-(*arabino*-1,2,3,4-tetrahydroxybutyl)imidazole (see Section 8.2.11.1.5) that may occur in caramels of the class III or IV (Table 4.37). Caramels with a low level of imidazoles can also be obtained by other technologies, for example by rapid continuous production processes or by extrusion of pregelatinised starch or dextrin at a temperature of 150–220 °C or they may be removed by ultrafiltration. 4(5)-Methylimidazole and 2-methylimidazole are classified by the International Agency for Research on Cancer (IARC) as 2B group agents that are possibly carcinogenic to humans. Internationally, JECFA (Joint FAO/WHO Expert Committee on Food Additives) has set the acceptable daily intake (ADI) of class II caramels to160 mg/kg body weight per day and those of class III and class IV to 200 mg/kg body weight per day and

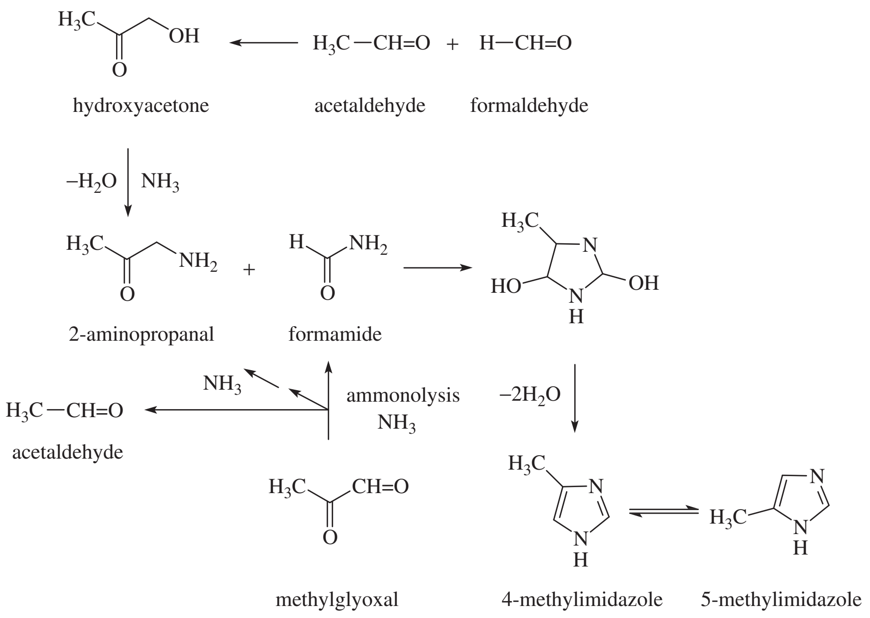

Figure 4.103 Formation of 4(5)-methylimidazole.

the European Commission has limited the 4(5)-methylimidazole content to 250 ppm (mg/kg). ADI of class I caramels has not been specified. For example, the levels of 4-methylimidazole found in commercial cola soft drinks ranged from 0.30 to 0.36 mg/l in 2011. The proposed formation mechanisms of 4(5)-methylimidazole from methylglyoxal and ammonia is given in Figure 4.103. Ammonolysis of methylglyoxal is proposed as the mechanism for forming acetaldehyde and formamide, which subsequently reacts with 2-aminopropanal arising as a product of hydroxyacetone and ammonia, to give 4(5)-methylimidazole. Hydroxyacetone also arises as a degradation product of sugars (and methylglyoxal).

5

Vitamins

5.1 Introduction

Vitamins are a group of low molecular weight organic substances present in minute amounts in natural foods that are essential to normal metabolism; insufficient amounts in the diet may cause symptoms of deficiency. Vitamins are synthesised almost exclusively by autotrophic organisms. Heterotrophic organisms synthesise vitamins only to a very limited extent (e.g. man can synthesise niacin from tryptophan) and or they can be obtained as exogenous substances mainly in food and in some cases through the enteric (intestinal) microflora. Vitamins are necessary for the regulation of human metabolism. They are not a source of energy or a building material, but mostly function as parts of enzymes catalysing biochemical reactions, although they have a number of other functions. Therefore, vitamins are often referred to as **exogenous essential biocatalysts**.[1]

Vitamins are substances with a variety of different chemical structures. In the past, before structures of all the vitamins were known and vitamin preparations were mixtures of various substances, so-called biological units (such as mice or chicken units) were introduced for quantitative purposes. The biological unit of a vitamin was related to the amount of that vitamin that produced a physiological effect to the respective animal within a given time. Later, so-called international units (IU) were derived, related to a particular vitamin weight. International units are often used even today for fat-soluble vitamins in pharmacy and medicine. The level of a vitamin in a food is commonly measured in mass units. In the past, the names associated with a disease caused by deficiency of the vitamin were used (e.g. vitamin A was called antixerophthalmic vitamin or the vitamin against night blindness, and vitamin C was known as antiscorbutic vitamin or the vitamin against scurvy). Upper-case letters (vitamin A or vitamin C) were used later. Subsequently it was discovered that several substances have the same physiological effects, and a numeric index on the upper-case letters began to be used (e.g. vitamins A_1 and A_2). Such designations are still commonly in use, although some vitamins have a simple trivial name (e.g. retinol instead of vitamin A_1 and ascorbic acid instead of vitamin C).

The most common method of classifying vitamins is according to their common physical properties, their solubility in water (in a polar environment) and fat (in a non-polar environment). Vitamins are thus divided into two groups:

- **fat-soluble vitamins**, **lipophilic vitamins** (four vitamins)
- **water-soluble vitamins**, **hydrophilic vitamins** (nine vitamins).

Fat-soluble vitamins are vitamin A, D, E and K. Water soluble vitamins include the B group vitamins or vitamin B complex (which refers to all of the known essential water-soluble vitamins except for vitamin C) and vitamin C. The B group vitamins are thiamine, riboflavin, niacin, pyridoxinal derivatives, pantothenic acid, biotin, folacin and the corrinoids.

Some substances referred to as **provitamins** do not show physiological effects themselves but can serve as precursors from which the body can synthesise vitamins. A provitamin of vitamin A_1 (retinol), for example, is β-carotene. The term vitamin sometimes also includes other biologically active substances whose vitamin effect has not been demonstrated reliably or substances needed by other organisms, for example by microorganisms.

The fat-soluble vitamins have different functions. For example, vitamin A_1 (retinol) is required in the production of the visual pigment rhodopsin; its provitamin (β-carotene) likewise acts as a plant pigment and antioxidant.

The function of hydrophilic vitamins is a catalytic effect, since in all organisms they generally occur as cofactors of various enzymes

[1] Other groups of special biocatalysts are hormones that the body is able to synthesise itself. Between these two groups a sharp boundary exists, both groups were earlier called ergons. A hormone is a substance formed in one organ or part of the body and carried in the blood to another organ or part, depending on the specificity of their effects. Vitamin D_3 (cholecalciferol) is often erroneously considered one of the hormones.

and play a role in the metabolism of nucleic acids, proteins, carbohydrates, fats and products of secondary metabolism. For example, vitamin B_1 (thiamine) is a cofactor of decarboxylases, dehydrogenases and other enzymes.

The body's need for most vitamins is relatively low. The amounts needed to ensure the normal physiological function of humans is dependent on many factors such as age, sex, health status, lifestyle, eating habits and work-related activity. Many countries have recommendations for the daily intake of vitamins, which are continually revised in accordance with contemporary scientific knowledge and dietary guidelines. Presently, Recommended Daily Allowances (RDAs)[2] are set in the EU (upper number) and United States (lower number) as follows: vitamin A (800/900 μg), vitamin D (5/15 μg), vitamin E (12/15 mg), vitamin K (75/120 μg), thiamine (1.1/1.2 mg), riboflavin (1.4/1.3 mg), niacin (16/16 mg), pantothenic acid (6/5 mg), vitamin B_6 (1.4/1.3 mg), biotin (50/30 μg), folacin (200/400 μg), vitamin B_{12} (2.5/2.4 μg) and vitamin C (80/90 mg).

Water soluble vitamins are generally not stored in the body, or are stored only for a limited time and the excess is excreted in the urine. Lipophilic vitamins are stored mainly in the liver. The **reserve capacity**, defined as the time during which the need for the vitamin is covered by the organism reserves, is the longest for corrinoids (3–5 years) and vitamin A (1–2 years). The reserve capacity for folacin is 3–4 months, for vitamins C, D, E and K, riboflavin, pyridoxine and niacin it is 2–6 weeks, and for thiamine, pantothenic acid and biotin it is only 4–10 days. Reserve capacity is affected by the history of vitamin intake, the metabolic need for the vitamin and the health status of the individual.

The need for vitamins can also be affected by the presence of other food components that can interfere with vitamins in the diet. These substances are called **antivitamins** or **vitamin antagonists**. Antivitamins eliminate the biological effects of vitamins, which can lead to symptoms of deficiency. The activity of antivitamins is based on the following basic principles:

- Structural analogues of vitamins react with the apoenzymes (which act as competitive enzyme inhibitors) or with proteins that transport vitamins (the antivitamin of thiamine is oxythiamine and the antivitamin of retinol is citral, also known as geranial).

- Certain enzymes convert some vitamins into inactive substances (e.g. lipoxygenase indirectly catalyses degradation of vitamin A and its provitamins, thiaminases decompose thiamine).

- Some substances (usually proteins, but also low molecular weight substances) form unusable complexes with vitamins (a typical example is the reaction of biotin with the egg protein avidin or the reaction of the amino acid linatin from flax seeds with pyridoxal).

Commonly used technological processes cannot usually remove antivitamins of the first group, the so-called true antivitamins. The remaining two groups of antivitamins can be largely eliminated by suitable processes or culinary practices (such as heat inactivation of enzymes or denaturation of proteins bound in the non-utilisable protein–vitamin complexes.

A disease resulting from a deficiency of one or more vitamins is **hypovitaminosis** (if vitamin is supplied in insufficient quantity) or **avitaminosis** (complete lack of vitamin manifested by some biochemical processes disorder). Deficiency of vitamins was formerly one of the main causes of many diseases and deaths. Pellagra (deficiency of some B-complex vitamins), scurvy (vitamin C), beriberi (thiamine), rickets (vitamin D), pernicious anaemia associated with reduced ability to absorb vitamin B_{12} (corrinoids) and xerophthalmia (vitamin A) are now well-known diseases caused by vitamin deficiency. Excessive intake of one or more vitamins (especially of lipophilic vitamins A and D) also causes an abnormal state resulting from disturbances of biochemical processes and can lead to severe diseases known as **hypervitaminosis**.

In food, vitamins are found in different amounts, which usually ranging from micrograms per kilogram to hundreds or thousands of milligrams per kilogram according to the particular vitamin, food type and method of processing. Vitamins occur as free compounds and in various bound forms, usually bound to proteins or carbohydrates. Physiological activity generally encompasses more than one entity. For example, the activity of vitamin A has about 50 naturally occurring carotenoids, and vitamin C activity involves two basic compounds, L-ascorbic and L-dehydroascorbic acids.

The most important sources of vitamins are mainly the basic foods, such as meat and meat products, milk and dairy products, eggs (especially egg yolk), bread and other cereal products, fruits and vegetables, which should adequately cover the vitamin requirements. Some foods have high or extremely high vitamin contents (e.g. vitamin C in rosehips), but these are eaten irregularly or rarely and are therefore not a significant source of vitamins for most of the population. Other vitamins are limited to a certain group of foods (e.g. corrinoids are found only in foods of animal origin).

The vitamin contents of foods are affected by a number of factors, in addition to the genetic makeup of the given organism. In foods of animal origin, vitamin content depends mainly on conditions during storage and processing of the raw materials. In foods of plant origin, the vitamin content depends particularly upon climatic conditions during growth, especially rainfall, fertilisation, stage

[2]The recommended daily allowance (RDA) for vitamins (and minerals; see Chapter 6) is defined as the minimum daily amount of nutrient required to avoid a deficiency. The Reference Daily Intake or Recommended Daily Intake (RDI), based on the older Recommended Dietary Allowance (RDA), is the daily intake level of a nutrient that is considered to be sufficient to meet the requirements of 97–98% of healthy individuals. The RDI is still used for nutrition labelling. In 1997, RDA became one part of a broader set of dietary guidelines called the Dietary Reference Intake (DRI) used by both the United States and Canada. The current Dietary Reference Intake recommendation is composed of: Estimated Average Requirements (EAR), expected to satisfy the needs of 50% of the people in that age group; Recommended Dietary Allowances (RDA), the daily dietary intake level of a nutrient considered sufficient to meet the requirements of nearly all (97–98%) healthy individuals in each life-stage and gender group (it is usually approximately 20% higher than the EAR); Adequate Intake (AI), where no RDA has been established; and tolerable Upper intake Levels (UL), to caution against excessive intake of nutrients that can be harmful in large amounts.

of ripeness and post-harvest storage and processing. Vitamins, in general, are very unstable compounds and their loss can be induced by a number of factors. During the food manufacturing and cooking processes and during storage of raw materials and foods, the majority of vitamins undergo losses to a greater or lesser extent. Obviously, losses of vitamins depend on the processing procedure, cooking method, cooking time and temperature. Some vitamins are fairly heat-stable, whereas others are heat-labile. For this reason, vitamins are considered indicators of the use of good manufacturing practices (GMPs), procedures that ensure the quality of the manufacturing processes of products for human consumption. Water-soluble vitamins are mainly leached out into the cooking water and will be lost if this extract is thrown away. The highest losses of fat-soluble vitamins are caused by oxidation. The stability of individual forms of vitamins varies, and depends on external factors and on the specific food and technology used.

In the food industry, vitamins are used to enrich many products, by the processes of restitution and fortification (enrichment). Restitution means the return of the vitamin content to the original level found in the raw material; fortification is enrichment to a higher level needed for physiological or other reasons. Some vitamins have also found use as natural dyes (riboflavin and provitamins A, in particular β-carotene) and as antioxidants (provitamins A, vitamin E and vitamin C). Intake of vitamins currently significantly influences the consumption of various concentrated sources of vitamins such as dietary supplements and multivitamin preparations. Intake of vitamins in these concentrated forms may lead, in extreme cases, to hypervitaminosis.

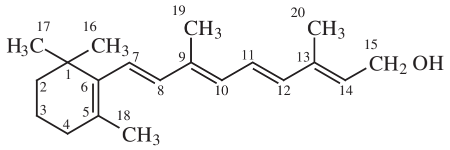
This chapter describes the individual vitamins, their structure, nomenclature, activity in biochemical reactions occurring in the body and their importance in physiology and human nutrition. Their occurrence in foods of animal and vegetable origin and other sources, and their use in food technology, is reported in detail. Another part of the chapter deals with changes in the vitamin contents and their reactions during storage of food materials, and in their culinary and industrial processing. The last part is devoted to biologically active substances that were previously ranked among the vitamins.

5.2 Vitamin A

5.2.1 Structure and terminology

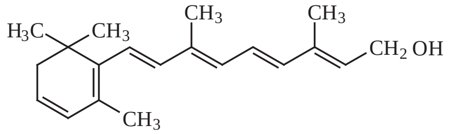
Vitamin A and its provitamins are classified as terpenoids or isoprenoids (see Section 8.2). Provitamins A are tetraterpenes (hydrocarbons) or tetraterpenoids (their oxygen derivatives), which contain 40 carbon atoms in a molecule. They originate, hypothetically, from eight molecules of isoprene (2-methylbuta-1,3-diene). The fission products, known as apocarotenoids, are widespread in living organisms performing many key functions. In animals, apocarotenoids act as vitamins, visual pigments, signalling molecules during cell division, growth and differentiation of tissues and control of reproduction. In plants, apocarotenoids take on the role of hormones, pigments, odorous compounds and perform a series of defensive functions.

The basic and most important biologically active apocarotenoid in animal tissues is all-*trans*-retinol also known as axeroftol or vitamin A_1 (**5-1**). Retinol is an isoprenoid with 20 carbon atoms and five conjugated double bonds in the molecule, more precisely a diterpenic alicyclic alcohol with the so- called β-ionone ring and a side chain of four conjugated double bonds attached to C-6. It is one of 16 possible stereoisomers.



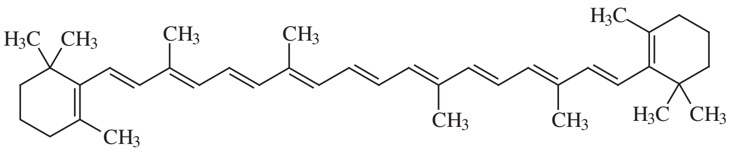
5-1, all-*trans*-retinol

In foods retinol is accompanied by a number of analogues and metabolites, differing in the ionone cycle or side chain structures. Freshwater fish contain, for example, 3,4-didehydroretinol known as vitamin A_2 (**5-2**), which has about 40% of the activity of retinol. Marine fish, birds and mammals do not synthesise this vitamin. Synthetic derivatives related chemically to vitamin A are collectively called **retinoids**. These substances are used for the treatment of various skin conditions, such as severe acne, sun spots, wrinkles and psoriasis. Some retinoids may even help treat or prevent certain forms of skin cancer.

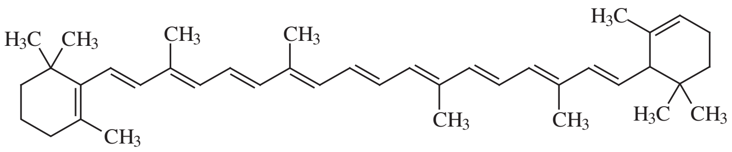


5-2, 3,4-didehydroretinol

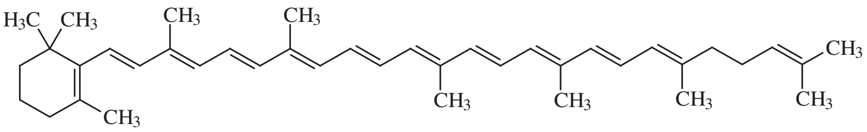
Activity of vitamin A (antixerophthalmic vitamin) have about 50 other naturally occurring compounds from the group of carotenoids, which are called provitamins A. The most important provitamin A is β-carotene (**5-3**). In foods it is often accompanied by other carotenes, namely α-carotene (**5-4**) and γ-carotene (**5-5**) and xanthophylls, such as β-cryptoxanthin (**5-6**) and echinenone (**5-7**) and other provitamins A.



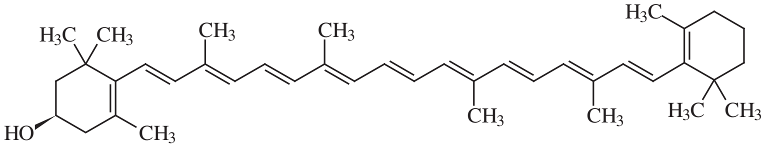
5-3, β-carotene



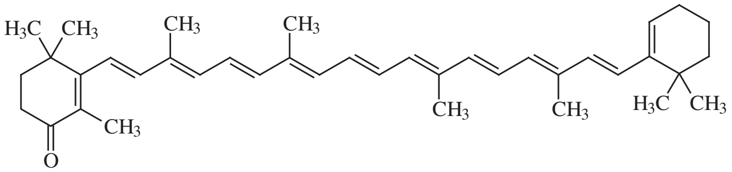
5-4 α-carotene



5-5, γ-carotene



5-6, β-cryptoxanthin

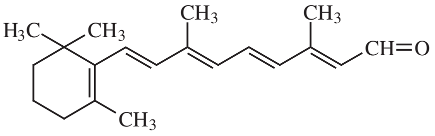


5-7, echinenone

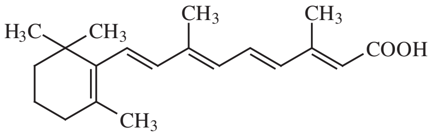
5.2.2 Biochemistry

The building unit of vitamin A and other isoprenoids is not isoprene, but its activated forms isopentenyl diphosphate and dimethylallyl diphosphate. Isopentenyl diphosphate is synthesised either from acetylcoenzyme A (an intermediate of its biosynthesis is mevalonic acid) or, alternatively, from 1-deoxy-D-xylulose 5-phosphate via 2-*C*-methyl-D-erythritol 4-phosphate and isopentenyl diphosphate. Gradual lengthening of the isoprenoid chain yields the immediate precursor of the carotenoids, geranylgeranyl diphosphate, with 20 carbon atoms in the molecule. The subsequent reactions of two molecules of geranylgeranyl diphosphate yield provitamins A (see Section 3.7.4.2).

In animals, birds and fish, provitamins A containing at least one β-ionone ring are transformed largely by central (symmetric) fission of the molecule catalysed by β-carotene-15,15′-dioxygenase to all-*trans*-retinal, also known as retinaldehyde (**5-8**). Two molecules of retinal are formed from one molecule of β-carotene, while other provitamins A provide only one molecule of retinal. Cleavage of β-carotene between the two cyclohexyl rings may also occur on other double bonds. This asymmetric (eccentric) cleavage provides two β-apocarotenals with different chain lengths. Subsequent cleavage of the β-apo-carotenal with the longer chain length gives retinal, but only one molecule per one molecule of β-carotene. Retinal is reversibly reduced to all-*trans*-retinol by retinol dehydrogenase. Together with other biologically active forms of vitamin A, such as all-*trans*-retinoic acid (**5-9**), which is the product of irreversible oxidation of retinal by retinal dehydrogenase, all-*trans*-retinol esters with higher fatty acids (**5-10**), all-*trans*-retinyl β-glucuronide (**5-11**) and other compounds, all-*trans*-retinal is stored mainly in the liver and transported, bound to specific proteins, by plasma. Retinoic acid occurs in a level of about 0.000 1%, in rosehip seed oil (the total oil content in seeds is approximately 9%).



5-8, all-(*E*)-retinal



5-9 all-(*E*)-retinoic acid

In addition to β-carotene, freshwater fish can also convert the xanthophyl lutein (**5-12**), also known as 3,3′-dihydroxy-α-carotene or (3*R*,3′*S*,6′*R*)-β,ε-carotene-3,3′-diol, into vitamin A. Lutein eliminates one molecule of water (C-3′ hydroxyl group) and yields anhydrolutein (**5-13**), which cleaves to the corresponding aldehydes. These aldehydes are reduced to all-*trans*-3,4-didehydroretinol (vitamin A_2) and all-*trans*-3-hydroxyretinol, respectively. The latter compound can dehydrate to form another

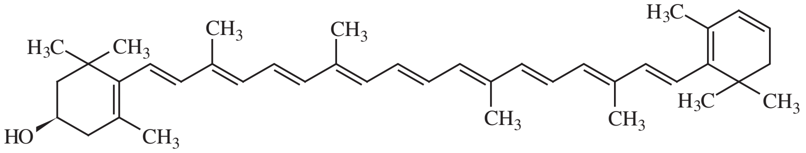
5-12, lutein



5-13, anhydrolutein

molecule of vitamin A_2. Trivial, specific, semi-systematic and systematic names of some provitamins A are given in Table 5.1.

The biochemistry of vision is a very complex process, where all-*trans*-retinol isomerises to 11-*cis*-retinol (**5-14**), which is then enzymatically oxidised to 11-*cis*-retinal (**5-15**). This compound associates with light-sensitive membrane-bound proteins (35–55 kDa) called opsins. Ciliary opsins (*c*-opsins) are typical of vertebrates, while invertebrates usually have rhabdomeric opsins (*r*-opsins). The resulting complexes are visual pigments (photoreceptors), which initiate a cascade that converts light (photons) falling on the retina into neural signals. Light destabilises opsins, which leads to protein conformation changes and isomerisation of 11-*cis*-retinal to all-*trans*-retinal. In order to function, each eye needs, in addition to opsins, the so-called shielding pigment that shields the retina from excess incoming light and exposes the photoreceptors to light coming from only a certain direction, thus ensuring the perception of directional light. Melanin (see Section 9.3.1.1) is a typical shielding pigment of vertebrates; invertebrates mainly have pteridines (see Section 9.3.4) and phenoxazines (see Section 9.3.7) at their disposal. During biological inactivation (catabolism), retinol is oxidised at carbon C-4 to a hydroxyl- or oxoderivative or the side chain can be shortened or hydroxylated at the C-5 methyl group of the β-ionone ring.

5-15, (11*Z*)-retinal

5.2.3 Physiology and nutrition

Absorption of the individual provitamins is not always quantitative. It is dependent on food composition and method of cooking, especially on the presence of lipids and their concentration. For example, the amount of β-carotene needed for the formation of 1 μg of retinol is 4 μg (if β-carotene is present in milk, margarine, vegetable oils or animal fats), 8 μg (in cooked leafy vegetables or carrot cooked in fat) or even 12 μg (if present in carrot boiled in water). The provitamin in raw carrot is almost non-utilisable.

The recommended daily dose of retinol in children is 0.4–0.6 mg and 0.8–1.0 mg in adults. On average it is 0.9 mg or 3000 IU, which is equivalent to 1.8 mg (3000 IU) of β-carotene in vitamin preparations or to 10.8 mg (18 000 IU) of β-carotene in foods. For pregnant and lactating women, the recommended daily dose is 1.0–1.2 and 1.2–2.0 mg, respectively.[3] About 50% of the vitamin A requirement is covered (in some countries for the most part) by provitamins in food of plant origin. About 40% of the required amount is provided by provitamins from vegetables, 20% by retinol and provitamins from meat and meat products, 15% by retinol and provitamins from milk and dairy products, 8% by fruit provitamins, 8% by retinol from fats (vegetable oils contain only provitamins) and 6% by retinol and provitamins from eggs. The biological activity of 9-*cis*-retinol is 21%, of 11-*cis*-retinol 24%, of 13-*cis*-retinol 75%, of 9,13-di-*cis*-retinol 24%, of 11,13-di-*cis*-retinol 15% and of all-*trans*-retinal 90% of the activity of all-*trans*-retinol.

Avitaminosis manifests itself as disturbed vision (night blindness) and keratinisation of mucous membranes (which line the respiratory tract, intestines, urinary tract and epithelium of the eye), the inhibition of growth, and in deformation of bones and reproductive organs. Reduced absorption of vitamin A can lead to hypovitaminosis, for example, in vegans.

High doses of vitamin A result in increased liver reserves of vitamin A and hypervitaminosis symptoms (acute or chronic intoxication with various symptoms including strumigenicity). Some individuals have genetically conditioned susceptibility to retinol, which is manifested by intolerance even at doses only slightly higher than normal doses. Excessive intake of provitamin A β-carotene by vegetarians and children (hypercarotenosis or carotenaemia or xanthaemia) does not produce symptoms of hypervitaminosis (an excessive intake of provitamins from carrots or other vegetables worsens their resorption), but may manifest itself through the presence of β-carotene in plasma and by temporary yellow–orange discolouration of the skin, which dissipates when materials containing β-carotene are eliminated from or reduced in the diet.

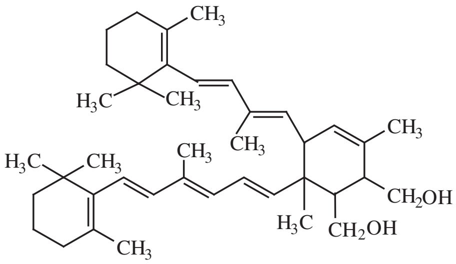
Provitamins A exhibit anticarcinogenic effects, because they are part of the control mechanisms that scavenge free radicals (toxic forms of oxygen). Their antioxidant potential is relatively low. Other carotenoids that do not act as provitamins A have significantly higher antioxidant activities, such as lycopene, zeaxanthin and lutein. The enzymes that oxidise fatty acids (lipoxygenases or linoleate: O_2 oxidoreductases, formerly known as lipoxidases) are antivitamins A.

5.2.4 Use

To enrich foods with vitamin A (e.g. table oils, margarine, butter, dairy products and flour), synthetic and relatively stable retinyl acetate or retinyl palmitate (**5-10**) are used, β-carotene (**5-4**) is used as a lipophilic dye.

5.2.5 Occurrence

Retinol does not occur in foods of plant origin, higher fungi or microorganisms (bacteria, yeasts and moulds), but these materials often contain carotenes and xanthophylls that show the activity of provitamin A. Animals are unable to synthesise carotenoids *de novo*; they only convert plant pigments into substances of a different structure or store them as such (Table 5.2). These reactions generate retinol, 3,4-didehydroretinol and a retinol dimer known as kitol (**5-16**), which can be obtained from whale liver oil in particular. The latter substance has little or no biological activity, but is transformed into retinol upon heating to temperatures above 200 °C. Also, some rosy pink pigments of fish (such as salmon) and some crustaceans (such as shrimps), and meat and feathers



5-16, kitol

[3]The total content of vitamin A is expressed in International Units (IU) and earlier it was in retinol equivalents (RE). Thus 1 IU is equal to 0.3 μg of retinol, 0.6 μg of β-carotene or 1,2 μg of other provitamins A (such as α-carotene, γ-carotene, β-cryptoxanthin and echinenone) and 1 RE is equal to 1 μg of retinol, which is equivalent to 3.33 IU of vitamin activity of retinol or 10 IU of vitamin activity derived from β-carotene. Vitamin A in vitamin preparations is often in the form of more stable retinyl acetate; 1 IU is equivalent to 0.33 μg of retinyl acetate. In animal materials, the amount of vitamin A (expressed in RE) equals the sum of μg of retinol and μg of β-carotene/6 or IU of retinol/3.33 IU + IU of β-carotene/10. In plant materials, it is equal to the sum of μg of β-carotene/6 and μg of other retinoids/12.

Table 5.2 Retinol and provitamins A contents of some foods.

Food	Edible portion (mg/kg or mg/l)		Food	Edible portion (mg/kg or mg/l)	
	Vitamin A	Provitamin A		Vitamin A	Provitamin A
Meat	0.1	0.4	Carrots	-	20-95
Liver	30-400	300	Parsley (root)	-	0.1
Milk	0.3 -1.0	0.1-0.6	Parsley (curly)	-	30-260
Cheeses	1.6-3.2	0.3-8.0	Cabbage	-	3.0-74
Eggs	0.5-1.5	0.1-2.0	Savoy cabbage	-	50
Fish	0.5	0.7	Broccoli	-	25

Mango	-	20	Beans	-	3.0-5.0

of some birds (such as flamingos) are transformed carotenoids (xanthophylls). The main pigment of the fish and crustaceans is astaxanthin (see Section 9.9.2.4.3), feathers of flamingos contain canthaxanthin and astaxanthin as the main components, together with some minor pigments (echinenone, phoenicoxanthin and phoenicopterone, see Section 9.9.3).

5.2.5.1 Foods of animal origin

The main forms of vitamin A include retinol esterified with higher fatty acids and free retinol or retinal. Precursors, or provitamins A, occur in food of animal origin in relatively small quantities. The most common ester of retinol is palmitate, and esters with other fatty acids are also found in variable amounts. For example, the main component in milk is palmitate followed by oleate and stearate. Other fatty acid esters (caprylate, caproate, linoleate, laurate, arachidonate, linolenate, myristate, palmitoleate, pentadecanoate, gadoleate and heptadecanoate) and free retinol are also present in smaller amounts. One particularly rich source of vitamin A is liver. For example, the retinol content in pork liver is about 30 mg/kg, and the liver of polar bears contains up to 60 g/kg of retinol. There is here a clear correlation with their diet, which consists mainly of seals. Milk (as well as meat) contains relatively little vitamin A (the vitamin content is proportional to the fat content). Dairy products and butter are good sources of vitamin A because of their high fat content.

5.2.5.2 Foods of plant origin

The most important provitamin A is β-carotene. Leafy vegetables such as spinach and cabbage are very rich sources of provitamins A as they contain 10–30 mg/kg retinol equivalents (RE), mainly in the form of β-carotene. Provitamins A form about 25% of total carotenoid pigments present in these vegetables. The classic source of β-carotene is carrots, containing about 20 mg/kg RE. The tomato has lycopene as the main pigment, which is not a provitamin A and the amount of β-carotene is relatively low (about 6 mg/kg). Tomatoes also contain small amounts of γ-carotene (1 mg/kg). There is a high content of β-carotene in the orange varieties of tomatoes (Table 5.2). Some fruits (such as apricots and mango) are also good sources of vitamin A precursors. Margarine is usually fortified with synthetic retinyl acetate or palm oil (that contains mainly α-carotene), so that the vitamin content is the same as in butter.

5.2.5.3 Other sources

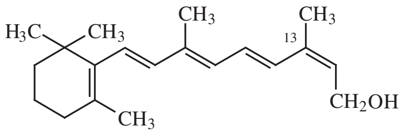
Fish liver oil is a very abundant source of vitamin A. Cod liver oil contains 10–100 g/kg of retinol (or its esters). Liver oils of freshwater fish contain about 40 mg/kg of retinol and 110 mg/kg of 3,4-didehydroretinol, the ratio of these vitamins A is highly variable.

5.2.6 Reactions

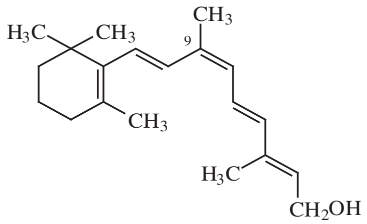
Naturally occurring all-*trans* isomers of provitamin A and retinol are unstable compounds. They isomerise very easily during food storage, especially when exposed to light and higher temperatures (cooking, baking and other thermal operations). They are also sensitive to oxidation (lipoxygenases, oxygen in the air or chemical agents). These compounds likewise react with free radicals and thus inhibit unwanted radical oxidation reactions. Similarly to lipid oxidation, a range of products are formed due to the combined effect of various factors.

5.2.6.1 Retinol

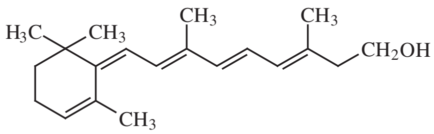
Retinol and its derivatives isomerise to a mixture of products in which 13-*cis*- (**5-17**) and 9-*cis*-stereoisomers (**5-18**) dominate. These isomers of retinol generally have a less intense colour than all-*trans* isomers. At the same time, and especially in acidic media, there is a shift of the double bonds towards the β-ionone ring with the formation of a positional isomer, retrovitamin A, also known as α-retinol (**5-19**). Retrovitamin A partially dehydrates to all-*trans* anhydroretinol (anhydrovitamin A, **5-20**).



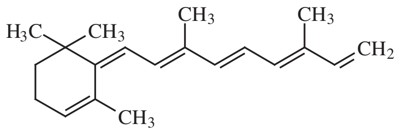
5-17, (13*Z*)-retinol



5-18, (9*Z*)-retinol

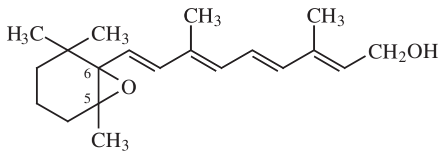


5-19, α-retinol



5-20, all-(*E*)-anhydroretinol

Oxidation of the β-ionone ring of retinol yields unstable hydroperoxides as the primary products. Their subsequent reactions produce relatively stable epoxides, such as all-*trans*-5,6-epoxyretinol (**5-21**), and oxidation of the hydroxymethyl group produces all-*trans*-retinal. Other oxidation products include compounds with shorter side chains. These oxidation products of retinol or the corresponding free radicals yield polyene polymers. Similar reactions *in vivo* lead to the yellow–brown aging pigment lipofuscin (see Section 3.6.1). Retinol esters are more stable to oxidation than free retinol. Tocopherols exhibit protective effects.

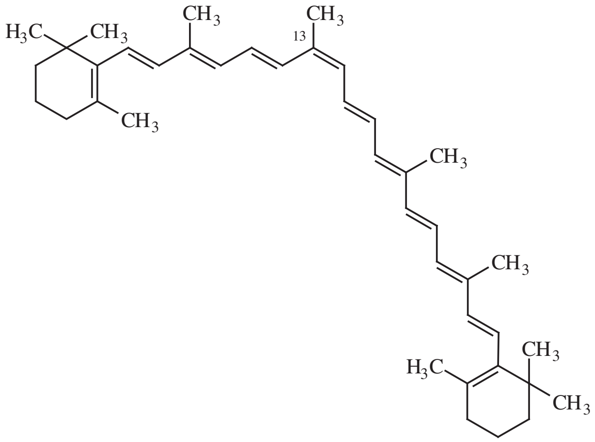


5-21, all-(*E*)-5,6-epoxyretinol

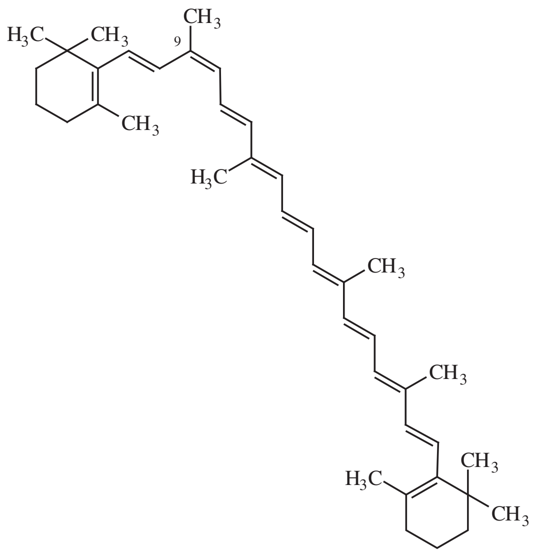
5.2.6.2 β-Carotene

Similarly to retinol, isomerisation, oxidation and degradation of β-carotene and other provitamins A may occur during food storage and processing through the combined effects of light, heat, oxygen, hydroxonium ions and other factors. Some stereoisomers of β-carotene, such as 13-*cis*-β-carotene (**5-22**) and 9-*cis*-β-carotene (**5-23**), appear as minor natural pigments in fruits and vegetables, especially in green species where photosynthesis occurs. This is explained by the presence of chlorophylls that act as photosensitisers and catalyse photoisomerisation of β-carotene to 13-*cis*- and 9-*cis*-isomers.

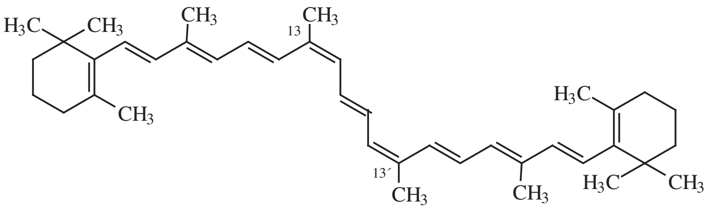
Stereoisomers of β-carotene are also formed during storage of flour under normal conditions and in particular at higher



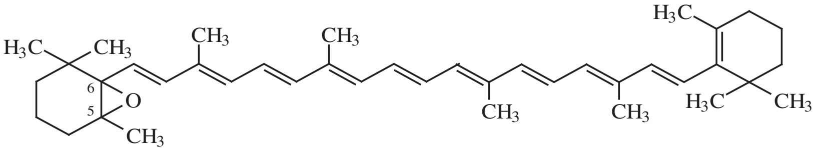
5-22, (13*Z*)-β-carotene



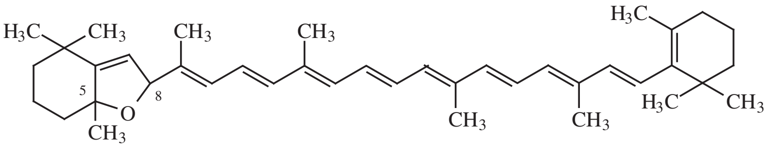
5-23, (9*Z*)-β-carotene



5-24, di-(*Z*)-β-carotene



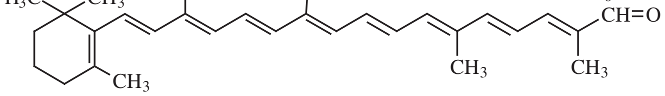
5-25, β-carotene-5,6-epoxide



5-26, β-carotene-5,8-epoxide

temperatures common in cooking, baking, frying and extrusion. Frying of foods or extrusion of cereals (at temperatures of 180–200 °C) yields 13-*cis*-β-carotene (as the major product) and other stereoisomers, such as 9-*cis*-β-carotene, 15-*cis*-β-carotene, 13,13′-di-*cis*-β-carotene (**5-24**), 9,9′-di-*cis*-β-carotene, 9,13′-di-*cis*-β-carotene and other products. Oxidation products, such as 5,6-epoxide (**5-25**), are formed at the same time.

In acidic media, 5,6-epoxides isomerise to dihydrofuran derivatives, also known as 5,8-epoxides (**5-26**), other products include diepoxides, β,β-carotene-3,3′-diol (zeaxanthin), β,β-carotene-4-one (echinenone) (**5-7**) and their degradation products, such as β-apo-8′-carotenal (**5-27**), β-apo-10′-carotenal, β-apo-12′-carotenal, β-apo-14′-carotenal and numerous other aldehydes. The main product is 5,8,5′,8′-diepoxide (also known as 5,8,5′,8′-diepoxy-5,8,5′,8′-tetrahydro-β,β-carotene or aurochrome or ξ-carotene), and other products include 5,6,5′,6′-diepoxide (5,6,5′,6′-diepoxy-5,6,5′,6′-tetrahydro-β,β-carotene) and 5,6,5′,8′-diepoxide (5,6,5′,8′-diepoxy-5,6,5′,8′-tetrahydro-β,β-carotene or luteochrome).



5-27, β-apo-8′-carotenal

5.2.6.2.1 Reactions with free radicals

Carotenoids react with free radicals, they deactivate them and thus act as antioxidants. They exhibit antioxidant effects in proportion to their concentration in systems containing lipids and also *in vivo*. The mechanism of the antioxidant action of carotenoids differs from the mechanism of action of vitamin E or synthetic phenolic antioxidants. In heterogeneous systems, such as emulsions, there are no significant differences between individual carotenoids. In homogeneous systems, such as anhydrous fats and oils, individual carotenoids differ somewhat in their antioxidant properties.

It is assumed that the hydroperoxyl radical ROO• generated by autoxidation of lipids is not reduced to hydroperoxide as in the case of phenolic antioxidants, but is captured by the conjugated polyene system, represented by the formula **5-28**, with the formation of relatively stable β-carotene radicals, these being stabilised by resonance:

$$\text{R–O–O}^\bullet + \beta\text{-carotene} \rightarrow \text{R–O–O–}\beta\text{-carotene}^\bullet$$

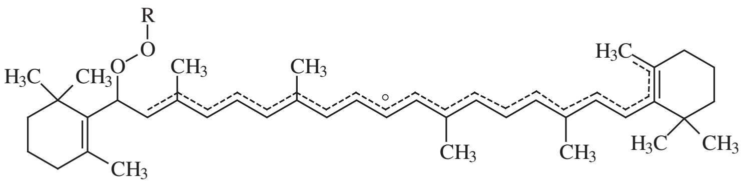
These radicals break down to alkoxyl radicals (RO•) and stabilise through the formation of epoxides, carbonyl compounds and a number of other products (Figure 5.1):

$$\text{R–O–O–}\beta\text{-carotene}^\bullet \rightarrow \text{R–O}^\bullet + \beta\text{-carotene epoxide}$$
$$\beta\text{-carotene epoxide} \rightarrow \text{polar products}$$

The main products of the reaction outlined in Figure 5.1 are 5,6- and 5,8-epoxides, 19-oxomethyl-10-nor-β,β-carotene, 12-formyl-11-nor-β,β-carotene, its isomer 13,15′-epoxyvinyleno-13,15′-dihydro-β,β-carotene and 13,14-epoxide that is transformed into 11,15′-cyclo-12,15-epoxy-11,12,15,15′-tetrahydro-β, β-carotene.

Under anaerobic conditions and in the presence of small amounts of oxygen, when carotenoids show higher antioxidant activity, β-carotene reacts with another hydroperoxyl radical with the formation of stable polar products:

$$\text{R–O–O–}\beta\text{-carotene}^\bullet + \text{R–O–O}^\bullet \rightarrow \text{polar products}$$



5-28, resonance stabilised R–O–O–β-carotene radical

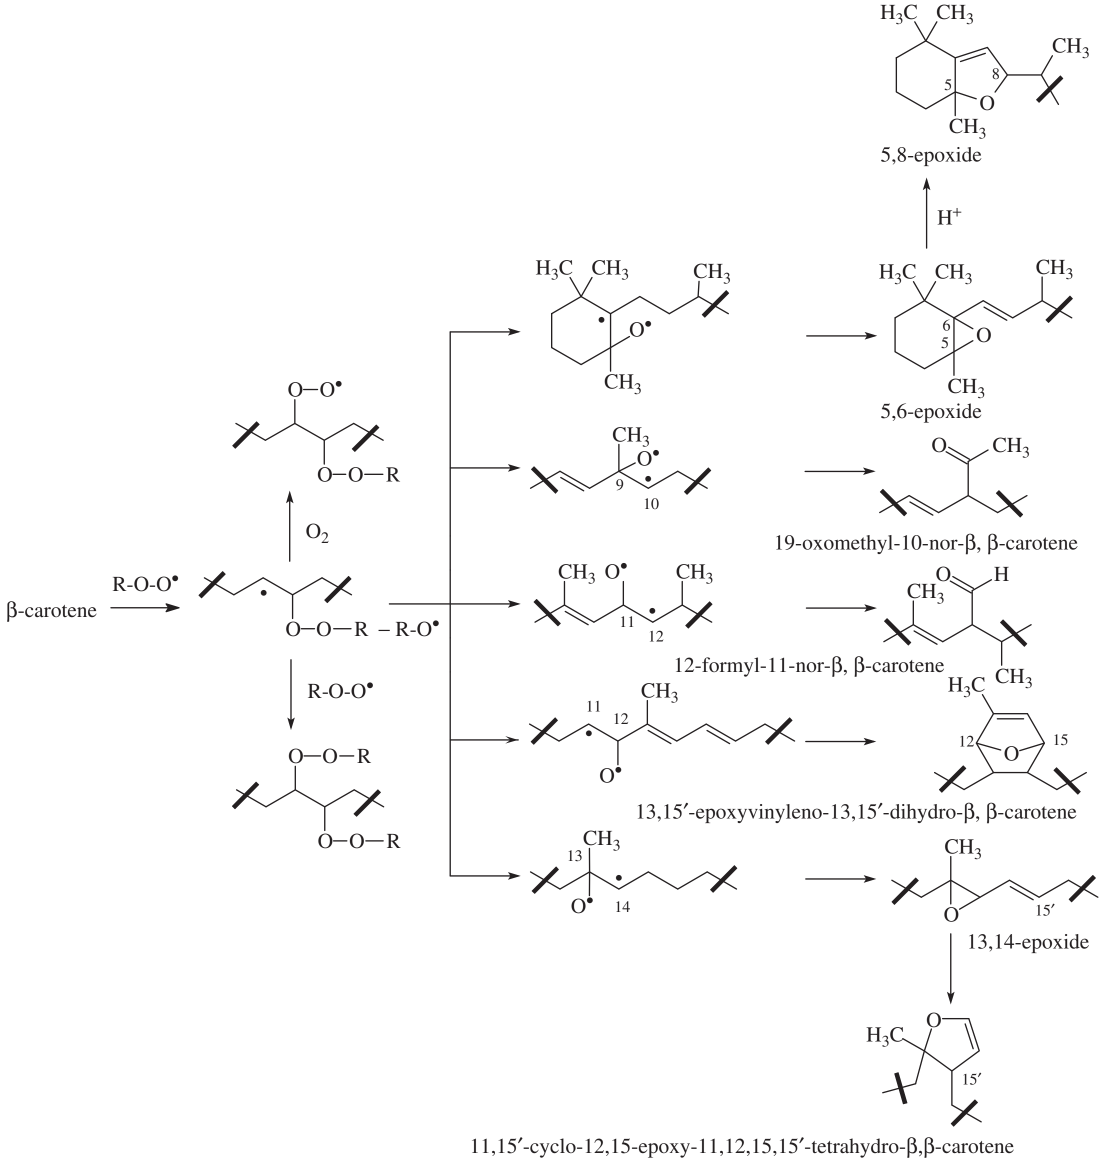


Figure 5.1 Reaction of β-carotene with lipid hydroperoxyl radicals (R = lipid residue).

At higher partial pressure of oxygen (e.g. during storage of fat in contact with air) unstable peroxyl radicals can form:

$$\text{R–O–O–}\beta\text{-carotene}^\bullet + O_2 \rightarrow \text{R–O–O–}\beta\text{-carotene–O–O}^\bullet$$

Alternatively, stable polar products are formed:

$$\text{R–O–O–}\beta\text{-carotene–O–O}^\bullet \rightarrow \text{polar products and radicals}$$

In reactions involving the hydroperoxyl radical R–O–O$^\bullet$, the alkoxyl radical RO$^\bullet$ formed by decomposition of hydroperoxides can also react with β-carotene.

β-Carotene also deactivates singlet oxygen ($^1O_2$; see Section 3.8.1.8.4). In other words, β-carotene acts as a singlet oxygen quencher and prevents lipid oxidation initiated by singlet oxygen. Singlet oxygen is usually generated by the interaction of air oxygen

(triplet oxygen, $^3O_2$) with various photosensitisers. The reaction products are oxygen in the triplet state and β-carotene in the excited triplet state (^{3}β-carotene*):

$$^1O_2 + \beta\text{-carotene} \rightarrow {}^3O_2 + {}^3\beta\text{-carotene}^*$$

β-Carotene is more effective in the presence of tocopherols, which ensure its protection against oxidation. Degradation of β-carotene and other carotenoids produces a series of low molecular weight products such as various hydrocarbons and oxygen compounds (e.g. epoxides and ketones), which are important flavour constituents of many foods.

5.2.7 Changes in foods

Natural provitamins A and vitamin A, β-carotene in foods of plant origin as well as esters of retinol in foods of animal origin, are relatively stable substances in the absence of air. At higher temperatures and in the light (e.g. during food preservation), they may isomerise to **neocarotenes**, which still exhibit vitamin A activity if they have preserved at least one β-ionone ring, but are less intensely coloured. Autoxidation (oxidation that occurs in the open air or in the presence of oxygen) of these substances is particularly rapid in dehydrated food. Retinoids also react with lipid oxidation products (fatty acid oxidation products), which similarly generate less coloured products.

5.2.7.1 Meat and meat products

During normal processing of meat and offal, vitamin A and provitamins A are very stable.

5.2.7.2 Milk and dairy products

During pasteurisation, in UHT milk and during milk drying, up to 6% of vitamin A is lost, and further losses occur during storage. In UHT milk, these losses are 3–7% over 4 weeks. In the presence of oxygen and in light (during storage in inappropriate containers), however, vitamin losses may reach up to 20–30% per hour. Dried milk powder is very stable and vitamin losses, even during prolonged storage, do not exceed 10%. The vitamin content in cheeses is higher than in milk (up to 50% or more, according to the fat content). Storage of butter results in only small losses of carotenoids and retinol.

5.2.7.3 Cereals and cereal products

The changes to the provitamins A content of grains are negligible. During storage of flour, provitamins A react with fatty acid hydroperoxides produced by the action of lipoxygenases. During dough mixing and proofing, hydroperoxides oxidise carotenoids and the range of reactions depends on many factors, such as water content. The result is a desirable lighter colour of the final product (e.g. of bread). On the other hand, the loss of carotenoids (up to 75%) is undesirable in the production of pasta. The addition of ascorbic acid, which inhibits lipoxygenase, has a colour stabilising effect. Losses, often higher than 9%, happen in the production of extruded cereal products. The so-called bleaching of flour is also done by chemical oxidising agents such as halogenides and peroxides (see Section 11.4.2.2.1).

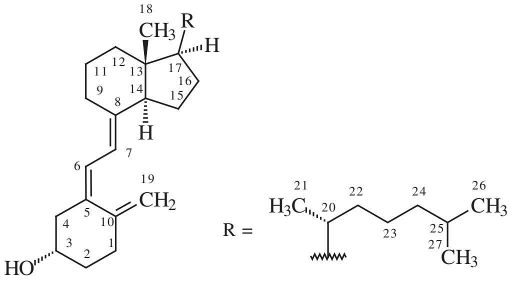
5.2.7.4 Fruits and vegetables

The extent of degradation reactions of carotenoid compounds in preserved fruits and vegetables after blanching and deaeration (removal of air) is usually small. For example, the retention of carotenoids in canned apricots, peaches and plums ranges from 85 to 100% after one year of storage, depending on the type of fruit and storage temperature. In the presence of oxygen a number of isomerisation and fission products of carotenoids arise. Carotenoid substances in dried fruits and vegetables are easily oxidised (the extent of oxidation depends, for example, on water activity, temperature and oxygen content in the atmosphere). During storage of dried carrots in air, there may be up to 50% loss of the carotenoids. There are also extensive losses of carotenoids in the production of fruit wines and spirits. Decomposition of carotenoids, however, also leads to a series of flavour active compounds that can have an impact on odour and taste of the product.

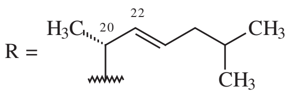
5.3 Vitamin D

5.3.1 Structure and terminology

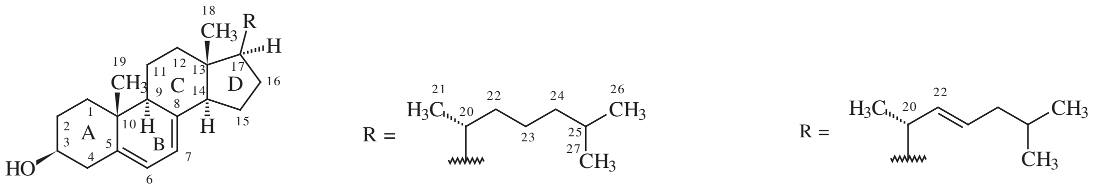
Vitamin D is the common name for a group of closely related lipophilic 9,10-secosteroids of which the most important are vitamin D_3, which is known as cholecalciferol (9,10-seco-$\Delta^{10(19),5,7}$-dehydrocholestatriene-3 β-ol, **5-29**) and vitamin D_2, known as ergocalciferol (9,10-seco-$\Delta^{10(19),5,7,22}$-ergostatetraene-3β-ol, **5-30**).



5-29, cholecalciferol (vitamin D_3)



5-30, ergocalciferol (vitamin D_2)



5-31, 7-dehydrocholecalciferol (provitamin D_3) **5-32**, ergosterol (provitamin D_2)

Vitamins D are produced by ultraviolet (UV) irradiation of their precursors, provitamins D. Provitamins D are cyclopentaperhydrophenanthrenes with C-18 and C-19 methyl groups, C-3 hydroxyl group and a C-5(6), C-7(8) system of conjugated double bonds in ring B, which differ from each other in length and arrangement of the side chain at position C-17. Provitamin D_3 is 7-dehydrocholesterol, also known as 7-procholesterol (**5-31**), provitamin D_2 is ergosterol (**5-32**). In the past, vitamin D_1 was the name for a mixture of vitamin D_2 with lumisterol, a byproduct resulting from irradiation (photodegradation) of ergosterol (Table 5.3). Vitamin D_4 is 22-dihydroergocalciferol, which is produced by irradiation of 22-dihydroergosterol. Irradiation of 7-dehydrositosterol yields sitocalciferol, which is also known as vitamin D_5.

5.3.2 Biochemistry

Provitamins D, similarly to provitamins A, are terpenoids. Gradual lengthening of the isoprenoid chain gives an immediate C_{15} precursor of some steroids, farnesyl diphosphate. Condensation of two molecules of farnesyl diphosphate and subsequent reactions yield provitamins D and other steroids. Through a sequence of reactions, humans and other animals synthesise 7-dehydrocholesterol, which is one of the precursors in the biosynthesis of cholesterol, from lanosterol. UV irradiation of 7-dehydrocholesterol (provitamin D_3) present in the skin cells,[4] at the wavelength range 280–320 nm (with a maximum at 295–297 nm), brings about a photochemical reaction (due to energy absorption by the system of π-electrons), which yields, as the first intermediate, the so-called precholecalciferol (previtamin D_3) with an opened ring B, which spontaneously isomerises, with the migration of hydrogen, to cholecalciferol (Figure 5.2). Precholecalciferol shows about 35% of the activity of cholecalciferol.

[4]Electromagnetic radiation is classified into ultraviolet A radiation (in short UV-A) with a wavelength of 315–400 nm, ultraviolet B radiation (UV-B, 315–280 nm) and ultraviolet C (germicidal) radiation (UV-C, 280–100 nm).

Table 5.3 Nomenclature of major vitamins D and of their precursors.

Trivial name	Systematic name
7-Dehydrocholesterol	7-Dehydrocholest-5-en-3β-ol

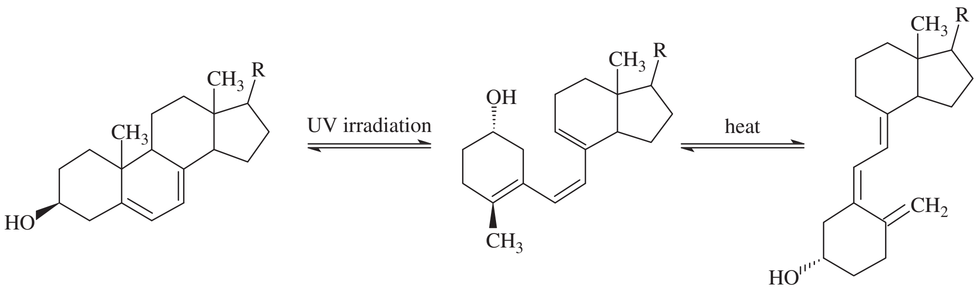
(*R*)-1,24,25-Trihydroxycholecalciferol, calcitetrol	(5*Z*,7*E*)-9,10-Secocholesta-5,7,10(19)-trien-1,3β,24,25-tetrol
Lumisterol	(*E*)-9β,10α-Ergosta-5,7,22-trien-3β-ol
Ergosterol	(*E*)-Ergosta-5,7,22-trien-3β-ol
Ergocalciferol, ercalciol, vitamin D_2	(5*Z*,7*E*,22*E*)-9,10-Secoergosta-5,7,10(19),22-tetraen-3β-ol



provitamin D previtamin D vitamin D

Figure 5.2 Formation of vitamins D from provitamins D.

Cholecalciferol binds to a specific globulin in blood plasma (vitamin D-binding protein, DBP) and is transported to the liver. Therefore, its concentration in blood plasma is relatively low (<20 nmol/l). In the liver it is stored and, according to requirements, is oxidised to 25-hydroxycholecalciferol, known as calcidiol (Figure 5.3), which is the main circulating metabolite of cholecalciferol. Its concentration in plasma depends on many factors such as the duration of exposure to sunlight and the season. Cholecalciferol is metabolised in the kidneys to a number of dihydroxysubstituted vitamins D_3. The major metabolites are the hormones 1α,25-dihydroxycholecalciferol (known as calcitriol) and (24*R*)-24,25-dihydroxycholecalciferol. The biological efficiency of 1α,25-dihydroxycholecalciferol is about ten times higher than that of cholecalciferol. Along with two other hormones, calcitonin and parathyroid hormone (parathormone, parathyrin), act in the metabolism of calcium and phosphorus. Synthesis of 24,25-dihydroxycholecalciferol is part of a detoxification mechanism, (24*R*)-1,24,25-trihydroxycholecalciferol is a starting compound for catabolism (so-called 24-oxidation) in the target cells, where calcitroic acid is formed as a product. Many other metabolites are known, such as (*S*)-1,25,26-trihydroxycholecalciferol and 1α,25-dihydroxycholecalciferol-26-lactone.

Because of the possibility of its biosynthesis in the body and its biological function (it is an antirachitic vitamin connected with the metabolism of calcium and phosphorus, which are necessary for growth, development and maintenance of bone structure), some reports state that vitamin D_3 is more a hormone than a vitamin, but these statements are wrong and do not reflect the definitions of either a vitamin or a hormone. Cholecalciferol is a vitamin in the true sense of the word, and its metabolite 25-hydroxycholecalciferol (or other deltanoids) is appropriately described as a prehormone. The hormonally active form of vitamin D_3 (hormone) is 1α,25-dihydroxycholecalciferol. Prehormone is a glandular secretory product, having little or no inherent biological potency that is converted peripherally into an active hormone (a prohormone is an intraglandular precursor of a hormone). According to recent research, vitamin D acts not only in the metabolism of calcium and phosphorus, but also in cell differentiation, and plays an important part in the immune system.

Cholecalciferol, ergocalciferol and metabolites of these vitamins ingested via foods are resorbed in the intestines and, bound to DBP, are transported to the liver by the lymphatic vascular system, where they are stored or metabolised.

Commonly used and recommended trivial and systematic names of key vitamins D and related steroids are listed in Table 5.3.

5.3.3 Physiology and nutrition

The vitamin D content of foods is still often given in international units (IU). One IU corresponds to the 0.025 μg of vitamin D_3 or vitamin D_2. Both vitamins have the same biological activity. The most important form of vitamin D is cholecalciferol. The recommended daily dose of vitamin D, which is 2.5–10 μg (there is greater need for the upper limit in babies, children, pregnant

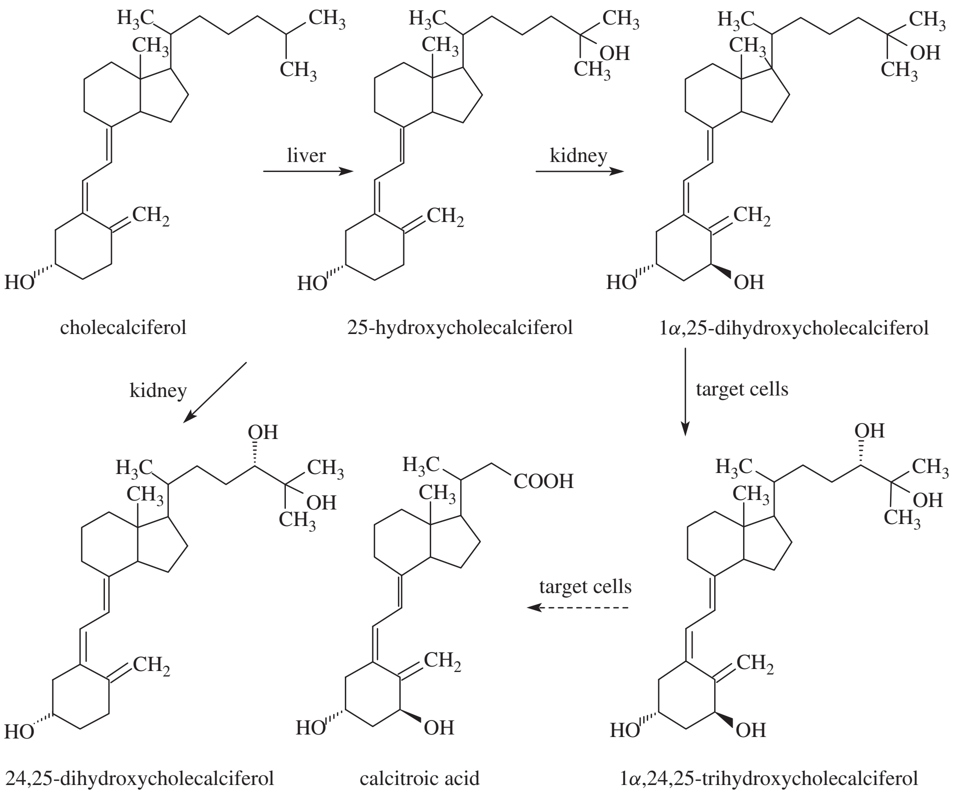


Figure 5.3 Metabolism of cholecalciferol.

and lactating women) is accounted for by the vitamin D_3 obtained through biosynthesis from provitamin 7-dehydrocholesterol in conjunction with the vitamin D_3 and vitamin D_2 contained in foods.

Hypovitaminosis manifests itself as rickets (changes to the skeleton) in children, and in adults by softening and deformation of developed bones caused by defective mineralisation (osteomalacia). Doses higher than the daily requirement similarly negatively result in a variety of symptoms. Long-term high doses of vitamin D may even cause hypercalcaemia, which is due to excessive skeletal calcium release and is characterised by its elevated level in the blood. Calcium is then stored in various organs, for example, in the heart and lungs.

5.3.4 Use

A common practice in some countries is the fortification of margarines by ergocalciferol or dehydrocholecalciferol, and milk and breakfast cereals are likewise often fortified. Ergocalciferol is the main form of vitamin D found in the fortified foods and pharmaceutical preparations. It is produced industrially by photoisomerisation of ergosterol. Some of the earlier procedures of feed enrichment (e.g. yeast for feed purposes) by ergocalciferol were based on irradiation of materials rich in ergosterol.

5.3.5 Occurrence

5.3.5.1 Foods of animal origin

Mammals, birds and fish synthesise cholecalciferol in the same way as man. Cholecalciferol is therefore found naturally in foods of animal origin, where it is also accompanied by its precursor (7-dehydrocholesterol) and related metabolites, such as calcidiol. Notable concentrations of cholecalciferol are found in the liver fats of marine fish (halibut, 30 mg/kg; mackerel, 15 mg/kg; cod, 2.5 mg/kg). Another valuable source is the meat of fatty fish (such as herring, mackerel and salmon).

Lower amounts of vitamin D_3 (cholecalciferol and metabolites) are present in the meat and offal of livestock and in other animal products, such as milk, dairy products and eggs (Table 5.4). Vitamin levels in these foods are, of course, determined by many factors. The cholecalciferol content of milk in the winter, for example, is about four times lower than in the summer.

Table 5.4 Vitamin D content of some foods of animal origin.

Food	Edible portion (μg/kg or μg/l)	Food	Edible portion (μg/kg or μg/l)
Meat	3	Butter	10–20
Liver	2–11	Cheeses	8
Milk	1	Eggs	30–50
Cream	4	Sea fish	50–450

Ergosterol (provitamin D_2) is the main sterol of most fungi, and therefore is naturally present (together with small amounts of vitamin D_2, vitamin D_3 and its metabolites) in cheeses that have molds on the rind or throughout (e.g. blue cheeses such as Roquefort and Gorgonzola).

5.3.5.2 Foods of plant origin

7-Dehydrocholesterol, cholecalciferol, calcitriol and calcidiol can be found in some plant species of the Solanaceae family (also known as the nightshade or potato family) originating in South America. These plants (such a *Solanum glaucophyllum*, syn. *S. malacoxylon*) are calcinogenic plants responsible for producing the enzootic calcinosis of cattle and sheep in Argentina, Brazil, Paraguay and Uruguay. The disease is characterised by the calcification of soft tissues, especially the aorta, heart, lungs and kidneys.

The presence of ergosterol in oil seeds, grains and cereal products (up to hundredths of micrograms per kilogram) is an indicator of microbial contamination. Similarly, ergosterol can be present for the same reason in some vegetables. The content in carrots is reportedly about 0.7 μg/kg, and in cabbage and spinach is about 0.1 μg/kg. Ergosterol is also the main sterol of the plant parasitic fungus ergot (*Claviceps purpurea*), commonly found on grains of rye or sometimes on other grasses such as quack grass (*Elytrigia repens*), and causing a devastating and sometimes deadly syndrome called ergotism in humans and other animals through consumption of contaminated foods and feeds (see Section 12.3.1.2.1).

5.3.5.3 Other sources

The content of ergosterol in the species and strains of yeast *Saccharomyces cerevisiae* (active dried yeast, a type of yeast used to make dough rise in baking) varies within wide limits from 600 to 1500 μg/kg (dry matter).

An important source of ergocalciferol may be higher fungi (of the phylum Basidiomycota that covers most of fungi often referred to as mushrooms), which also contain the provitamin D_2 ergosterol. Ergocalciferol is produced from ergosterol by direct solar radiation with the same mechanism that yields cholecalciferol from 7-dehydrocholesterol (via the corresponding previtamin) in humans. Therefore, mushrooms are the only non-animal-based food containing vitamin D and are hence the only natural vitamin D sources for vegetarians. Cultivated shiitake mushrooms (*Lentinula edodes*) and common mushrooms, white button mushroom (*Agaricus bisporus*), however, have a significantly lower content of ergocalciferol (about 2–3 μg/kg) than wild mushrooms (chanterelle, *Cantharellus cibarius*, around 130 μg/kg, and penny bun, *Boletus edulis*, about 30 μg/kg fresh weight). Generally, the content of ergocalciferol in wild mushrooms depends on many factors, such as climatic conditions and colour of the stalk. Ergocalciferol represents about 90% of the vitamin content, with the remainder being previtamin D_2, 25-hydroxyergocalciferol, ergosta-5,7-dienol (22,23-dihydroergosterol) and ergosta-7-enol. The content of provitamin D_2 (ergosterol) in fungi varies considerably. For example, its content in white button mushrooms is

560 mg/kg, in shiitake mushrooms 849 mg/kg, in oyster mushrooms (*Pleurotus ostreatus*) 680 mg/kg and in chanterelle mushrooms 463 mg/kg fresh weight. Ergosterol usually represents 60–70% of the sterols present.

The concentration of vitamin D_2 in cultivated mushrooms increases if they are exposed to sunlight or artificial UV-B (315–280 nm) or UV-C (280–100 nm) light. After exposure to a UV-B light, the concentration of vitamin D_2 in shiitake mushrooms was increased to 36.7, 68.6 and 106 mg/kg for the pileus, middle, and gill parts, respectively. The concentrations of vitamin D_2 produced in white button mushrooms after exposure to UV-C irradiation were 40.6–141 mg/kg, depending on irradiation doses and time of irradiation.

5.3.6 Reactions

Compounds belonging to the vitamin D group are oxylabile, similar to other lipophilic vitamins. It would therefore be expected that these compounds yield autoxidation products. Thermal transformation (at temperatures around 200 °C) produces both pyroisomers and isopyroisomers of vitamins D (Figure 5.4), isomerisation in acidic media provides isovitamins D and isotachysterols (Figure 5.5).

5.3.7 Changes in foods

Some vitamin D reactions, such as formation of oxidation products and isomers, can also be expected in foods. The irradiation of foods may produce photodegradation products that also occur during the industrial production of ergocalciferol from ergosterol. The most important product of ergosterol irradiation is previtamin D_2, but tachysterol, lumisterol and other products are formed as byproducts (Figure 5.6).

5.4 Vitamin E

5.4.1 Structure and terminology

Vitamin E, formerly also known as antisterile vitamin, has eight basic structurally-related derivatives of chroman-6-ol (2*H*-1-benzopyran-6-ol). Structural bases common to all compounds with the reported activity of vitamin E (so-called vitagens E) are tocol (**5-33**) and tocotrienol (**5-34**), which contain a

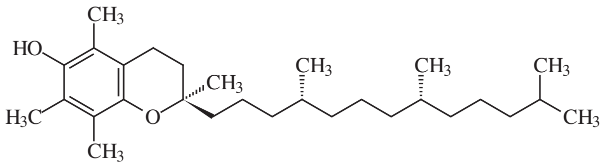
hydrophobic chromane ring with a saturated or unsaturated isoprenoid side chain of 16 carbon atoms. The systematic name of tocol is (2*R*,4′*R*,8′*R*)-3.4-dihydro-2-methyl-2-(4′,8′,12′-trimethyltridecyl)-2*H*-1-benzopyran-6-ol and for tocotrienol is (2*R*,3′*E*,7′*E*,4′*R*,8′*R*,11′*E*)-3,4-dihydro-2-methyl-2-(4′,8′,12′-trimethyltrideka-3′,7′,11′-trienyl)-2*H*-1-benzopyran-6-ol.

The chromane ring is derived from the diterpenic alcohol phytol, with the systematic name (2*E*,7*R*,11*R*)-3,7,11,15-tetramethylhexadec-2-en-1-ol, but in addition to the hydroxyl groups in position C-6 it contains another methyl group at position C-2. The presence of these functional groups is essential for the biological activity of all vitamers. Four forms of vitamin E with a saturated terpenoid side chain derived from the tocol are called **tocopherols** (**5-33**); four forms with unsaturated side chains derived from tocotrienol are called **tocotrienols** (**5-34**). Tocopherols and tocotrienols are collectively known as **tocochromanols**. By virtue of the phenolic hydrogen on the 2*H*-1-benzopyran-6-ol nucleus, the individual compounds exhibit varying degrees of antioxidant activity, depending on the site and number of methyl groups and the type of isoprenoid side chain. The structurally related, but biologically inactive, 5,7-dimethyltocol was formerly called ζ-tocopherol, 5-methyltocol was ε-tocopherol and 7-methyltocol was η-tocopherol.

Owing to the presence of three chiral centres (position C-2 of the chromane ring and position C-4′ and C-8′ in the side chain of tocol), each tocopherol can exist in eight diastereoisomeric forms. In nature, however, only (2*R*,4′*R*,8′*R*)-isomers of tocopherols exist. They are also known as (*RRR*)-isomers, 2ᴅ, 4′ᴅ,8′ᴅ-tocopherols, d-tocopherols and (+)-tocopherols. One representative is, for example, (*RRR*)-α-tocopherol, abbreviated to α-T (**5-35**). Tocotrienols containing three double bonds in the side



5-35, (2*R*,4′*R*,8′*R*)-α-tocopherol

chain may occur in eight different *Z* (*cis*) and *E* (*trans*) isomers and their combinations. In nature only all-*trans* geometric isomers occur. α-Tocotrienol is often called α-T-3 or α-TT for short.

Some vegetable oils also contain small amounts of 3,4-dehydrotocopherols (3,4-dehydrochromenols, **5-36**) and analogues of tocotrienols, tocomonenols and tocodienols that have a partially saturated terpenoid side chain. α-Tocomonoenol (**5-37**) occurs, for example, in crude palm oil (40 mg/kg), with α-tocomonoenol (17.6 mg/kg) and γ-tocomonoenol (118.7 mg/kg) being found in roasted pumpkin seed oil and δ-tocomonoenol was identified in the freeze-dried peel and pulp of kiwi fruits. α-Tocomonoenol, denoted by α-T_1, is similar to α-tocopherol, but with a double bond at the side chain. There are only two known naturally occurring isomers. One with a double bond at C-11′, whereas the other has a double bond at C-12′. Tocomonoenols also have three chiral centres at carbons C-2, C-4′ and C-8′ and all naturally occurring tocomonoenols have the *RRR* configuration. Rhizomes of plants from the genus *Dioscorea* (Dioscoreaceae), known as yams, are a common food in tropical areas and are widely used as a staple medicinal food, for example in the promotion of the health of postmenopausal women. The oestrogenic activity of yams *D. alata* was attributed to α-tocopherol, γ-tocopherol-9 (**5-38**), hydro-Q_9 chromene (**5-39**), coenzyme Q_9 and 1-feruloylglycerol.

5.4.2 Biochemistry

Vitamin E, as well as vitamin K, plastoquinones and ubiquinones, is formed, in principle, from shikimic acid via 4-hydroxyphenylpyruvic and homogentisic acid. The terpenoid side chain is synthesised from isopentenyl diphosphate, or more precisely from geranylgeranyl diphosphate, which is gradually reduced to phytyl diphosphate. The primary product of biosynthesis is δ-tocopherol; other tocopherols are products of its methylation. The biosynthesis of tocotrienols lies in the condensation of homogentisic acid with geranylgeranyl diphosphate. Vitamin E is only synthesised by plants and some cyanobacteria.

The most important lipophilic antioxidant that acts in eucaryotic cells to protect unsaturated lipids against free radical damage is vitamin E, especially α-tocopherol. Along with β-carotene and coenzyme Q, it protects the structure and integrity of biomembranes, such as the cytoplasmic cell membrane (or plasmolema) and intracellular membranes of organelles (nucleus, mitochondria, lysosome and endoplasmic reticulum). It is also employed in the protection of lipoproteins present in plasma. It is transported in the bloodstream by association with the lipid phase of low density lipoprotein (LDL) particles (see Section 3.6.1). Each LDL particle contains six molecules of vitamin E.

Other functions of vitamin E are not yet fully established. Vitamin E probably furthermore directly contributes to the structure of biological membranes and modulation of their properties, because the vitamin specifically interacts with arachidonic acid and has some regulatory function in its metabolism (conversion of arachidonic acid into leucotrienes). Deficiency of vitamin E is manifested in females by placental disorders and in males by disorders of maturation of gametes.

5.4.3 Physiology and nutrition

An adequate intake of vitamin E is believed to prevent oxidation of lipids in biomembranes. Vitamin E is therefore a factor that slows the collection of changes known as the aging process, and is applied in the prevention of cardiovascular diseases and cancer (oncogenesis).

The need for vitamin E is not yet precisely known. It depends greatly on polyunsaturated fatty acid intake through the diet. For people whose average daily intake of these fatty acids is between 14 and 19 g, the recommended daily intake of vitamin E is 15 mg. More (*RRR*)-α-tocopherol (0.5–0.6 mg) is needed for each additional gram of fatty acids taken in. For pregnant women, the recommended daily intake is higher by 2 mg, and for lactating women by 5 mg. The current increasing intake of unsaturated fats

with low oxidation stability highlights the need for a revision of these recommendations. A real need is about 20–30 mg per day. Ideas of the need for higher intake (of around 50 mg, but also up to 100 mg daily) have no basis in scientific knowledge or even in clinical trials.

The international unit of activity (IU) is defined as an activity of 1 mg of synthetic all-*rac*-α-tocopheryl acetate (D,L-α-tocopheryl acetate) that is often used for food fortification and in multivitamin tablets. The biological activity of tocopherols and tocotrienols and their stereoisomers is difficult to determine, and is expressed in a relatively wide range. (*RRR*)-α-Tocopherol is generally considered the most effective substance, and its esters have similar effects. β-Tocopherol has about 50% the activity of α-tocopherol, γ-tocopherol about 10% and δ-tocopherol approximately 3% of the α-tocopherol activity.

Synthetic α-tocopherol exhibits, unlike natural α-tocopherol, lower biological activity, because it consists of the C-2 enantiomers, (2*R*)-α-tocopherol and (2*S*)-α-tocopherol. In short, synthetic α-tocopherol is (2*RS*)-α-tocopherol (D,L-α-tocopherol or 2-*ambo*-α-tocopherol). Synthetic α-tocopherol can also be a racemic mixture of all possible stereoisomers and it then consists of (2*RS*)-, (4′*RS*)- and (8′*RS*)-α-tocopherol (or 2-*ambo*-, 4′-*ambo* and 8′-*ambo*-α-tocopherol), which is called all-*rac*-α-tocopherol.

Commercial vitamin products often contain esters of α-tocopherol (acetate or hydrogen succinate), which are more stable to oxidation compared with free α-tocopherol. However, esterification of the C-6 hydroxyl group (**5-33**) results in the formation of biologically inactive compounds, but these esters are rapidly hydrolysed to the biologically active α-tocopherol under the action of non-specific esterases.

The presence of double bonds in the molecule of the tocotrienols results in a decrease in their biological activity of about one-third compared with tocopherols. Biological activity of any significance is shown only by α-tocotrienol (about 30% of the activity of α-tocopherol) and β-tocotrienol (about 5% of the activity of α-tocopherol).

Vitamin requirements are mainly fulfilled by plant lipids, especially oils, and in some countries by margarine enriched with tocopherols. Other foods of both plant and animal origin are also important additional sources. Although they contain fewer vitamins, they are consumed regularly and in high quantities (e.g. bakery products, meat, eggs and some vegetables).

Vitamin E deficiency is relatively rare, but occasionally occurs in newborns and adolescents. It manifests with similar symptoms as selenium deficiency, because the specific selenoproteins are also involved in transport of tocopherols and protect the tocopherols against oxidation. Manifestation of vitamin E deficiency is mainly through degenerative nerve and muscle (neuromuscular) changes known as myopathy and encephalomalacia. Consumption of excessive amounts of tocopherols occurs only rarely.

5.4.4 Use

For fortification of foods and feeds (such as with vitamins and lipid antioxidants) and for pharmaceutical purposes, synthetic racemic α-tocopherol and its esters or a mixture of natural D-tocopherols obtained as a byproduct of refining (deodorisation) of oils from deodorisation condensates are used. The material produced should be protected from oxidation by addition of a phenolic antioxidant. Tocopherols β, γ and δ can also be converted into α-tocopherol by methylation (tocotrienols by methylation and hydrogenation of the side chain).

5.4.5 Occurrence

Vitamin E is found primarily in foods of plant origin, and to a lesser extent (with a few exceptions) in foods of animal origin. Other sources do not have any practical significance (Table 5.5).

All eight biologically active tocopherols and tocotrienols occur in foods. Unsubstituted tocol does not occur in nature. Unsubstituted tocotrienol (also called desmethyl tocotrienol) was recently isolated from heated rice bran together with so-called didesmethyl tocotrienol, which lacks the C-2 methyl group. The main compounds are α-, β-, γ- and δ-tocopherol and α-, β- and γ-tocotrienol. Tocotrienols are also found in the form of esters.

5.4.5.1 Foods of animal origin

In animal tissues, the composition of vitamers E is affected mainly by the feed composition. Vitamin content also varies according to the season. The main component (more than 90% of vitamin E) is always α-tocopherol. Animal fats contain much less vitamin E than vegetable oils. The total content of vitamin E in butter is up to 50 mg/kg (γ-tocopherol content is up to 10% of the total vitamin E content), in pork fat 6–30 mg/kg (about 5% as γ-tocopherol, 5% as α-tocotrienol), in beef tallow up to 20 mg/kg and in chicken fat up to 25 mg/kg. Unlike other lipophilic vitamins, vitamin E does not occur in large quantities in fish oils. The content in cod liver oil is only 0.25 mg/kg.

5.4.5.2 Foods of plant origin

In cereals, vitamin E is located mainly in the germ and bran, so white flours have lower vitamin content than whole grain flours.

Table 5.5 Vitamin E content of selected food commodities.

Food	Edible portion (mg/kg or mg/l)	Food	Edible portion (mg/kg or mg/l)
Meet	2.5–7.7	Soybeans	2.7–13
Liver	4–14	Apples	1.8–7.4
Milk	0.2–1.2	Oranges	2.4–2.7
Butter	10–50	Cabbage	0.2–11
Cheeses	3.0–3.5	Spinach	16–25
Eggs	5–30	Tomatoes	3.6–4.9

The total vitamin E content is about 15–50 mg/kg. Details of the main forms of vitamin E in cereals and pseudocereals are shown in Table 5.6. The main form of vitamin E in the green parts of plants is α-tocopherol, located in the plastids; γ-tocopherol is the major form of vitamin E in cells that do not have chloroplasts where photosynthesis does not occur (e.g. in seeds).

Vegetable oils have a somewhat lower content of vitamin E than oils from germs. Virgin (crude) oils, contain higher amounts of vitamin E than refined oils. The vitamin E content in crude rapeseed oil, for example, is 360–1000 mg/kg; the refined oil vitamin content is 140–850 mg/kg. Crude and refined sunflower oils have vitamin E contents of 270–1240 and 270–900 mg/kg, respectively. Among the common vegetable oils, soybean oil contains the highest amount of vitamin E (530–2000 mg/kg); 11% of the vitamin is in the form of α-tocopherol, over 60% in the form of γ-tocopherol and more than 20% as δ-tocopherol, with tocotrienols present in negligible quantities. The vitamin E content of olive oil is about 160 mg/kg.

Germ oils contain large amounts of vitamin E. For example, wheat germ oil contains 1650–3000 mg/kg of vitamin E, which consists of about 61% of α-tocopherol, 23% of β-tocopherol, 5% of γ-tocopherol, 2% of δ-tocopherol and approximately 8% of tocotrienols, of which β-tocotrienol is the dominating form (Table 5.6).

The content of vitamin E in fruits and vegetables usually does not exceed 10 mg/kg. The main vitamin form is α-tocopherol. Apples contain, on average, 1.8 mg/kg of α-tocopherol, but 6.1 mg/kg are found in the skin. The vitamin content in cabbage is about 0.9 mg/kg, of which only 0.1 mg/kg represents α-tocopherol, the rest is δ-tocopherol. Carrots contain about 2.5 mg/kg of α-tocopherol, 0.2 mg/kg of β- and γ-tocopherol and 0.1 mg/kg of δ-tocopherol. Lettuces contain about 3.2 mg/kg of α-tocopherol, 1.5 mg/kg of β-tocopherol and 2 mg/kg of γ-tocopherol. Potatoes contain very little vitamin E (about 0.1 mg/kg of α-tocopherol in the flesh and skin). Even tubers from transgenic plants (containing a gene or genes transferred from another species) accumulate approximately 10–100-fold less α-tocopherol than leaves or seeds. Relatively high amounts of vitamin E are found, of course, in potatoes fried in oil; for example, potato chips with reduced fat content (20.8%) contain about 55 mg/kg of α-tocopherol.

5.4.6 Reactions

Tocopherols and tocotrienols are monoethers of the respective hydroquinones and are therefore readily oxidised, for example by ferric ions, lipid hydroperoxides and other oxidants. This creates the corresponding quinones (tocopheryl quinones or tocoquinones). Tocopheryl quinones can be reduced to tocopheryl hydroquinones (tocohydroquinones). The most important reactions are those with oxidised lipids (Figures 5.7 and 5.8).

Biological activity of vitamin E is related to antioxidant effects; the most effective antioxidant (*in vivo*) is α-tocopherol. In food lipids, the situation is more complicated, because the antioxidant activity of tocopherols and tocotrienols depends on many factors. One important aspect is the amount and composition of unsaturated fatty acids. Under typical storage conditions, tocopherols are more effective antioxidants, for example, in animal fats (the main fatty acid is oleic acid) compared with vegetable oils that contain higher amounts of linoleic acid (e.g. soybean and sunflower oils).

The antioxidant activity of vitamin E in emulsions depends on the structure of the emulsions and the presence of other antioxidants, such as 3,5-di-*tert*-butyl-4-hydroxytoluene (BHT) and ascorbyl palmitate. Temperature plays an important part, as does, particularly, the presence of oxygen and the stability of the radicals of tocopherols produced as intermediates in reactions with oxidised lipids. At 80 °C in the presence of air, δ-tocopherol, for example, is the only vitamin form which partially withstands heating for 6 h, when used as an antioxidant to protect linoleic acid against autoxidation. In an atmosphere containing only 10% oxygen (half of the amount of oxygen in air), β- and γ-tocopherols are also present, but α-tocopherol and all tocotrienols are absent. At 60 °C in the absence of oxygen, all tocopherols and tocotrienols are present.

For all these reasons, therefore, the following relative order of antioxidant efficiency of tocopherols in food is generally given, which is the opposite to the order of their biological activities

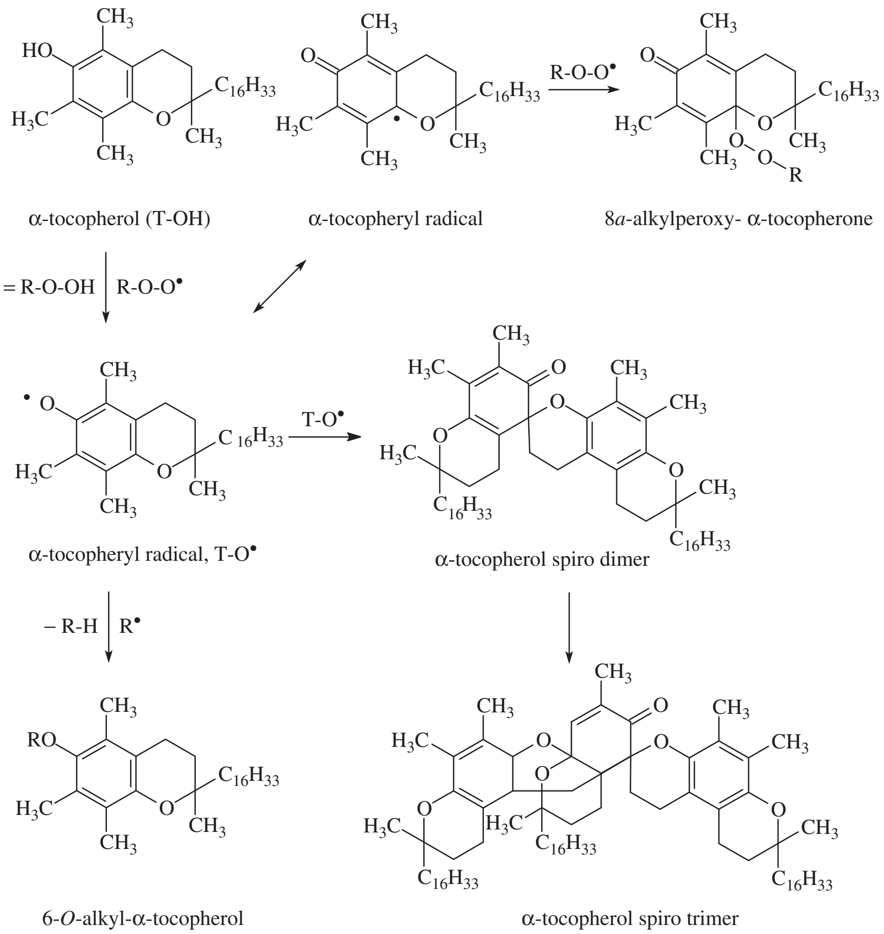

Figure 5.7 Main reaction products of α-tocopherol with oxidised lipids.

(tocotrienols are less effective than the corresponding tocopherols):

$$\delta\text{-T} > \gamma\text{-T} > \beta\text{-T} > \alpha\text{-T or } \delta\text{-T} > \gamma\text{-T} = \beta\text{-T} > \alpha\text{-T}$$

The mechanism of the antioxidant effect of vitamin E is similar to the effect of other lipophilic antioxidants. Tocopherols react with a number of free radicals including active oxygen species. One tocopherol molecule can react with two hydroperoxyl radicals. Autoxidation of lipids is inhibited by reaction of tocopherols (abbreviated as T–OH) with hydroperoxyl lipid radicals (R–O–O$^\bullet$) with the formation of hydroperoxides (R–O–OH) and radicals of tocopherols (tocopheroxyl radicals, T–O$^\bullet$). This reaction interrupts the radical chain autoxidation reaction of lipids during the propagation phase:

$$\text{R–O–O}^\bullet + \text{T–OH} \rightarrow \text{R–O–OH} + \text{T–O}^\bullet$$

The resulting tocopheroxyl radical is not sufficiently reactive and therefore cannot split other lipid (fatty acid) molecules. In the termination phase of the chain autoxidation, the tocopheroxyl radical stabilises by irreversible reactions with other radicals, mostly with the second hydroperoxyl radical:

$$\text{T–O}^\bullet + \text{R–O–O}^\bullet \rightarrow \text{stable products}$$

Both reactions occur in lipids containing low concentrations of tocopherols and also in the presence of sufficient amounts of oxygen. Alternatively, other reactions take place. In the presence of large quantities of tocopherols, some tocopheroxyl radicals react with each other to form a dimer or trimer:

$$\text{T–O}^\bullet + \text{T–O}^\bullet \rightarrow \text{tocopherol dimer}$$

With an adequate supply of oxygen, the hydrocarbon radicals (R$^\bullet$), formed in the initial phase of the autoxidation chain reaction, preferentially yield hydroperoxyl radicals (ROO$^\bullet$). When there is a limited supply of oxygen (with a low partial pressure of oxygen) and in the absence of antioxidants, hydrocarbon radicals react with each other and form lipid dimers (R–R). In the presence of tocopherols, there is a competitive reaction of the hydrocarbon radicals with tocopheroxyl radicals that are stabilised by the formation of hydrocarbons (R–H) and other stable products:

$$\text{R}^\bullet + \text{R}^\bullet \rightarrow \text{R–R}$$
$$\text{R}^\bullet + \text{T–OH} \rightarrow \text{R–H} + \text{T–O}^\bullet$$
$$\text{R}^\bullet + \text{T–O}^\bullet \rightarrow \text{stable products}$$

Figure 5.8 shows, as an example, the most important products of α-tocopherol in reactions with oxidised lipids. The main products,

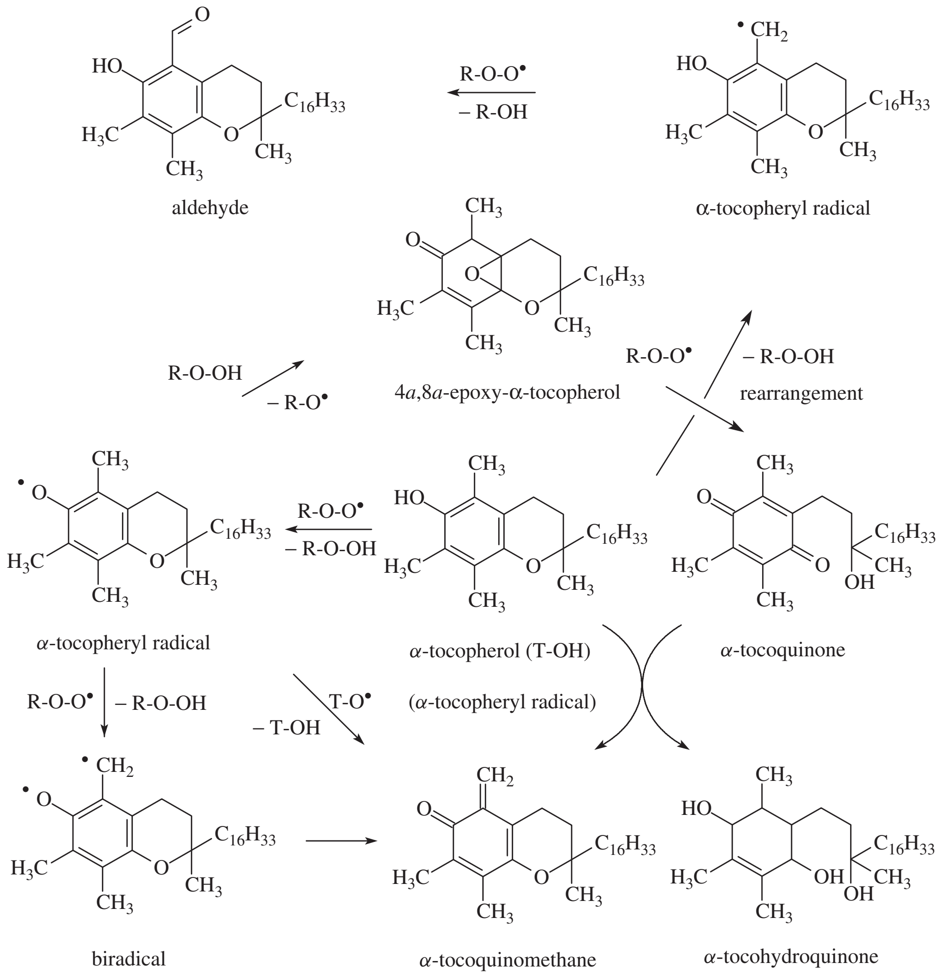

Figure 5.8 Minor reaction products of α-tocopherol with oxidised lipids.

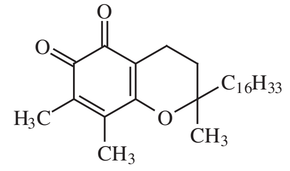
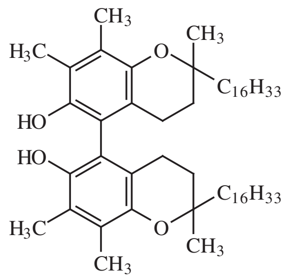
formed by reaction of tocopheroxyl radicals with hydroperoxyl radicals, are 8a-alkylperoxy-α-tocopherons.[5] To a lesser extent the recombination of tocopheroxyl radicals with hydrocarbon radicals (and alkoxyl radicals, RO•) also occurs. The reaction products are the corresponding 6-*O*-alkyl-α-tocopherols. Dimers (which show reducing effects as well as tocopherols), trimers and other products, such as epoxides, quinones, hydroquinones, qinomethanes[6] and other compounds are likewise formed as minor products.

Similarly to α-tocopherol, other tocopherols and tocotrienols also react with oxidised lipids Some reaction products of γ-tocopherol, such as tocopherol red (tocored, **5-40**, arising during bleaching of vegetable oils), C–C dimer (**5-41**), C–O–C dimer (**5-42**) and trimer (**5-43**), do not arise from α-tocopherol.



5-40, tocopherol red



5-41, γ-tocopherol C–C-dimer

Tocopherols can also react with singlet oxygen as quenchers (analogously to β-carotene) with the formation of various oxidation products. The primary reaction is probably 1,4-cycloaddition of oxygen to form endoperoxides (Figure 5.9). If the phenolic group of the tocopherols is located at the lipid–water interface, tocopheroxyl radicals present in the lipid phase can be reduced

[5]For example, oxidised linoleic acid esters (hydroperoxyl radicals of this acid) yield a mixture of (9*R*,8a*R*)-, (9*R*,8a*S*)-, (9*S*,8a*R*)-, and (9*S*, 8a*S*)-9-(8a-peroxy-α-tocopheron)-(10*E*,12*Z*)-octadeca-10,12-dienoate together with (13*R*,8a*R*)-, (13*R*,8a*S*)-, (13*S*,8a*R*)-, and (13*S*,8a*S*)-13-(8a-peroxy-α-tocopheron)-(9*Z*, 11*E*)-octadeca-9,11-dienoate.

[6]Quinomethanes (formerly known under incorrect names quinone methides or quinomethides) are methylidenecyclohexadienones and dimethylidenecyclohexadienes, formally derived from quinones by replacement of one or both of the quinone oxygen atoms by a methylidene group.

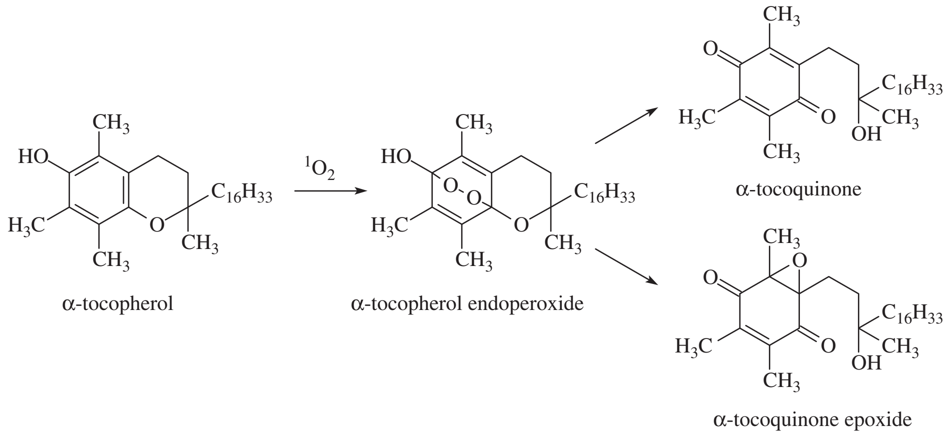


Figure 5.9 Oxidation of α-tocopherol by singlet oxygen.

back to tocopherols by water-soluble ascorbic acid, which thus also protects vitamin E against oxidation *in vivo*.

5.4.7 Changes in foods

5.4.7.1 Fats and oils

The refining of edible oils reduces the vitamin content to 10–50% of the original amount. The major losses occur during the deacidification step (removal of free fatty acids), if this step is performed by chemical methods (due to oxidation of vitamin E in the alkaline medium). High losses of vitamin E also appear during oil bleaching (oxidation on the surface of bleaching earths catalysed mainly by ferric ions). Losses during the deodorisation step are mainly caused by volatilisation of vitamin E with water vapour under reduced pressure. Hydrogenation of fats using nickel catalysts (Raney nickel) leads to losses of 30–50%.

5.4.7.2 Other foods

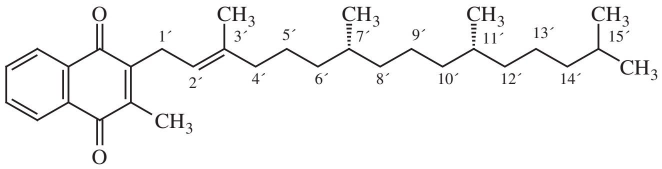
In the absence of oxygen and oxidised lipids (their hydroperoxides), vitamin E is relatively stable during normal culinary and industrial processing of foods. During processing and storage of meat, meat products, milk, dairy products and cereals, the losses usually do not exceed 10% of the original amount. For example, the loss of vitamin E during pasteurisation of milk is about 5%. Stored grains lose about 10% of their vitamin content per month. The largest losses occur during frying and baking. In fats that are used repeatedly for frying food, tocopherols are virtually absent, because they are volatile along with the water vapour and decompose at higher temperatures. An analogous situation is in fried, frozen and stored products, such as pre-fried potato chips (French fries). In general, the vitamin E content gradually decreases even under refrigerated storage of foods containing higher amounts of polyunsaturated fatty acids. Drying of fruits or vegetables results in a loss of 50–70% of vitamin E.

5.5 Vitamin K

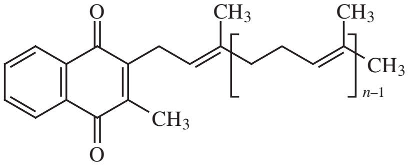
5.5.1 Structure and terminology

All naturally occurring compounds that show vitamin K activity (the coagulation vitamin) are derivatives of menadione (2-methyl-1,4-naphthoquinone) with an isoprenoid unsaturated side chain at the C-3 position of the aromatic ring. Today, essentially two types of active substances are recognised. The other compounds with vitamin K activity are synthetic derivatives.

Vitamin K_1, also known as vitamin $K_{1(20)}$, phylloquinone or phytylmenaquinone, contains a hexahydrotetraprenyl chain (2-methyl-3-phytyl-1,4-naphthoquinone, **5-44**). Phylloquinone occurs in foods of plant origin. The side chain derived from phytol has 20 carbon atoms (four isoprenoid units, of which three are reduced). The isomer with a *cis*-configuration in the side chain is not biologically active. The systematic name of vitamin K_1 is (2′*E*,7′*R*,11′*R*)-2-methyl-3-(3′,7′,11′,15′-tetramethylhexadecyl)naphtho-1,4-quinone. The second compound with the activity of vitamin K is vitamin K_2 (**5-45**), also known as vitamin $K_{2(n)}$, menaquinone, menaquinone-*n*, MK-*n* or 2-methyl-3-multiprenyl-1,4-naphthoquinone ($n = 0$–13). The most common menaquinones contain 4–10 isoprene units, such as MK-7, additionally called pharnoquinone. Vitamin K_2 is produced by many bacteria and actinomycetes. A multiprenyl side chain



5-44, phylloquinone



5-45, menaquinone (n = 0–13)

with an all-*trans* configuration is the most common substituent. The bacteria usually produce menaquinone with different chain lengths. The main menaquinone of *Escherichia coli* is, for example, MK-8, *Staphylococcus aureus* produces menaquinones MK-0 to MK-9. One or more isoprenoid groups in the side chain can be hydrogenated. Some bacteria also produce related 2-demethylmenaquinones. Yeasts do not produce vitamin K_2, but only related coenzymes Q.

Vitamin K_3 (menadione, MK-0, 2-methyl-1,4-naphthoquinone) is a synthetic substance. The product of menadione reduction, known as menadiol (2-methylnaphthalene-1,4-diol), and derived compounds, such as the fat-soluble menadiol diacetate or menadiol dibutyrate and the water-soluble sodium salt of menadiol diphosphate, are referred to as vitamin K_4. Activity of vitamin K was also detected in the synthetic monoamino analogues and diamino analogues of menadiol, for example, in 1-amino-4-hydroxy-3-methylnaphthalene (vitamin K_5), 1,4-diamino-2-methylnaphthalene (vitamin K_6) and 1-amino-4-hydroxy-2-methylnaphthalene (vitamin K_7).

5.5.2 Biochemistry

Phylloquinone and menaquinone are derived from chorismic acid, which results from 3-phosphoenolpyruvic acid (a product of glycolysis) and D-erythrose 4-phosphate (a product of the pentose and Calvin cycles) as a starting compound for the biosynthesis of phenylalanine, tyrosine and tryptophan. It is transformed into isochorismic acid; other carbon atoms are derived from 2-oxoglutaric acid. The side chain is provided by phytyl diphosphate or by polyprenyl diphosphates, which are formed from geranylgeranyl diphosphate. The final reaction is a methylation at C-2.

Vitamin K in birds and mammals occurs in the reduced form (as a hydroquinone) and acts as an essential factor for the carboxylation of certain proteins (transformation of bound glutamic acid into γ-carboxyglutamic acid). Carboxyglutamic acid residues impart important properties to the relevant proteins, such as the ability to bind calcium ions and phospholipids, which are necessary for their activation and for them to function in blood clotting. The best known reaction is the conversion of inactive prothrombin into the active proteolytic enzyme thrombin.

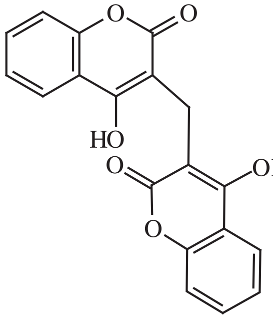
The main transport form in plasma is vitamin $K_{1(20)}$, which is bound to very low density lipoproteins (VLDL). In the liver, about 90% of vitamin K is represented as menaquinones MK-7 to MK-12.

5.5.3 Physiology and nutrition

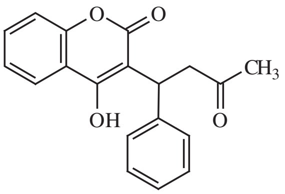
The daily requirement of vitamin K is estimated to be between 0.01 mg (for babies) and 0.14 mg (for adults). The daily intake by food is estimated at 0.3–0.5 mg, but only about 30–70% of dietary vitamin is absorbed in the intestines. According to some data, about 40–50% of the daily requirement of the vitamin is provided by foods, and under normal circumstances intestinal microflora produces the rest.

A deficiency in the production of vitamin K may occur during intestinal dysbiosis (an impaired balance of the intestinal microflora), in inflammatory intestinal diseases (such as Crohn's disease), in intestinal absorption disorders and with an inadequate production of bile. Deficiency can be manifested by blood clotting disorders (this is rare in humans). Chickens are particularly sensitive to the lack of vitamin K, mainly due to the use of antibiotics that inhibit the activity of intestinal microflora. Vitamin K is therefore added to feed mixtures to prevent bleeding into the muscles and skin.

Vitamin K antagonists (anticoagulants) are typically coumarins, and particularly dicoumarol (also known as melitoxin, **5-46**), which is produced in larger concentrations in the mouldy clover from 2-coumaryl-CoA under the action of fungi enzymes. Warfarin, that is 3-(3-oxo-1-phenylbutyl)-4-hydroxycoumarin (**5-47**), which also shows a significant anticoagulant effect, is used as a rodenticide (a chemical intended to kill rodents), but also in human medicine to prevent increased blood clotting, which can lead to embolisms. The mechanism of action of anticoagulants is that of competitive inhibition of the conversion of 2,3-epoxyvitamin K into vitamin K in the liver.



5-46, dicoumarol

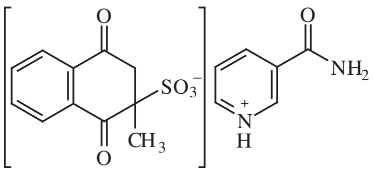


5-47, warfarin

5.5.4 Use

Vitamin K_3 and its water soluble forms, such as salts or complexes of its addition product with sodium hydrogen sulfite (trihydrate of sodium salt), and its complex with nicotinamide (**5-48**) or with

other amino compounds, are used as additives in the fattening of chickens.



5-48, menadionbisulfite/nicotinamide complex

5.5.5 Occurrence

5.5.5.1 Foods of animal origin

Meat and meat products have a moderately high vitamin K content. Liver is high in vitamin K (Table 5.7). In pigs' liver, for instance, more than ten active substances have been identified, of which vitamin $K_{1(20)}$ (0.012 mg/kg), MK-4 (0.011 mg/kg), MK-7 (0.016 mg/kg), MK-8 (0.025 mg/kg), MK-9 (0.006 mg/kg) and MK-10 (0.008 mg/kg) occur in significant quantities. Menaquinones MK-10 to MK-13, originally synthesised by bacteria in the rumen and subsequently absorbed, have been found in beef liver.

5.5.5.2 Foods of plant origin

Vitamin $K_{1(20)}$ is the only form of vitamin K that is found in foods of plant origin. It is a normal constituent of specialised cells for photosynthesis (chloroplasts), whereas in foods of animal origin, more active forms of vitamin K are present. Rich sources of vitamin K are mainly green leafy vegetables. For example, green cabbage leaves from the edge of the cone contain 3–6 times higher amounts of vitamin K than the yellow leaves inside the cones. Vegetable oils are also good sources of vitamin K. Fruits, potatoes and cereals are low in vitamin K.

Table 5.7 Vitamin K content of some foods.

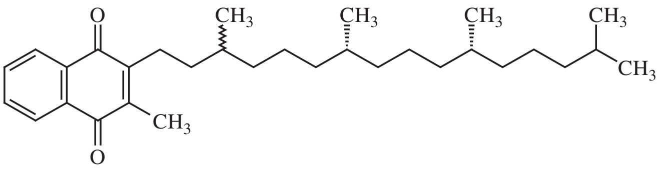
Food	Edible portion (mg/kg or mg/l)	Food	Edible portion (mg/kg or mg/l)
Pork liver	0.08	Cabbage	1.1–2.5
Beef liver	0.14	Broccoli	1.5–1.8
Pork meat	0.03	Spinach	2.0–14.4
Beef meat	0.04	Beans	0.1–0.5
Chicken meat	0.60	Peas	0.4
Fish (rainbow trout)	0.04	Tomatoes	0.02–0.06
Fish (Baltic herring)	0.01	Carrot	0.01–0.05
Eggs	0.02	Potatoes	0.01–0.02
Milk (fresh)	0.01–0.03	Strawberry	0.01
Yogurt (plain)	0.01	Soybean oil	1.39–2.90
Cheese (Edam type)	0.49	Rapeseed oil	1.14–1.88
Cheese (Emmental type)	0.08–0.09	Olive oil	0.3–0.8
Bread	0.004	Sunflower oil	0.09

5.5.5.3 Other sources

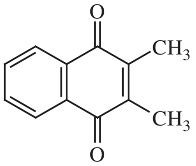
Vitamin K_2 is produced mainly by the bacteria *Escherichia coli* and bacteria of the genus *Bacillus*. In bacteria and actinomycetes it occurs at levels of about 600–1700 mg/kg dry matter. The synthetic menadione and its derivatives are transformed by bacteria into MK-4 with a tetraprenyl side chain. This form of vitamin K also occurs in the tissue of animals whose feed was fortified with this vitamin.

5.5.6 Reactions

Adverse reactions and loss of vitamin K activity occurs under exposure to light (photodegradation to a number of products), in reactions with reducing agents and in alkaline media. The hydroquinone forms of the vitamin are oxidised to quinones by the air oxygen. Oxidation of phylloquinone (e.g. by hydrogen peroxide in an alkaline medium) yields 2,3-epoxide. During hydrogenation of vegetable oils, the side chain of phylloquinone is also partly hydrogenated. The hydrogenated fat contains the original phylloquinone, partly 2′,3′-dihydrophylloquinone (dihydrovitamin K_1, **5-49**) and decomposition products of phylloquinone, such as 2,3-dimethyl-1,4-naphthoquinone (**5-50**). The original vitamin content is decreased by 50% or more.



5-49, dihydrovitamin K_1



5-50, 2,3-dimethyl-1,4-naphthoquinone

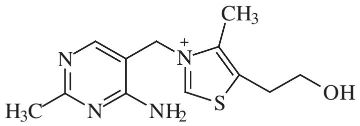
5.5.7 Changes in foods

During storage and thermal processing of foods, vitamins K are relatively stable. Significant losses, however, occur when food is exposed to daylight. The vitamin content in vegetable oils decreases during frying (for 30 min at 190 °C), for example, to 85–90% of the original amount. If oil is exposed to daylight at ambient temperature, the vitamin content decreases to 50% in one day.

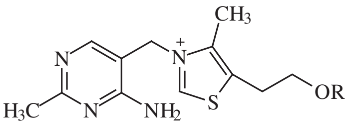
5.6 Thiamine

5.6.1 Structure and terminology

Thiamine (vitamin B_1, also formerly known as aneurine) contains a pyrimidine ring (4-amino-2-methylpyrimidine) attached by the methylene group at C-5 to the nitrogen of 5-(2-hydroxyethyl)-4-methylthiazole. Thiamine (**5-51**) occurs primarily as a free compound and in the form of phosphate esters (**5-52**), the monophosphate, diphosphate (pyrophosphate called cocarboxylase) and triphosphate.



5-51, thiamine (free base)



5-52, thiamine phosphates

thiamine phosphate, R = PO_3H_2
thiamine diphosphate, R = $P_2O_6H_3$
thiamine triphosphate, R = $P_3O_9H_4$

5.6.2 Biochemistry

Thiamine is synthesised *de novo* by all higher plants and many microorganisms. However, some microorganisms synthesise only the pyrimidine moiety (using 5-aminoimidazole ribonucleotide, known as AIR; an intermediate in the metabolism of purines) or only the thiazole part (from histidine and pyridoxol), and the remaining part of the thiamine molecule is obtained from the environment. Animals do not synthesise thiamine. Free thiamine obtained from food (esters of thiamine after prior hydrolysis) is esterified to thiamine diphosphate, the active form of thiamine, in cells of various organs by pyrophosphokinase. Thiamine diphosphate is a cofactor of many important enzymes (such as decarboxylases, dehydrogenases, transketolases and carboligases) associated primarily with the metabolism of carbohydrates and branched chain aliphatic amino acids. Thiamine diphosphate bound to proteins is then esterified to thiamine triphosphate.

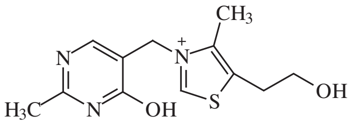
5.6.3 Physiology and nutrition

Thiamine is a cofactor of enzymes involved in energy metabolism, therefore the required amount of the vitamin is mainly related to the amount of utilisable carbohydrates (D-glucose) received in the food. For every 4200 kJ (1000 kcal) of energy derived from carbohydrates, an intake of 0.4–0.6 mg of thiamine is recommended. For adults with a daily energy intake of 12 600 kJ (3000 kcal), the recommended intake of thiamine is 1.2 mg (for infants typically 0.3 mg, 0.7–1.2 mg for children, 1.2–1.5 mg for males, 1.0–1.1 mg for women, 1.4 mg for pregnant women and 1.5 mg for lactating women).

Thiamine is, like some other vitamins, produced by intestinal microflora. The level of vitamin delivered in this way is too low, so in practice the required amount is only obtained through food. The most important sources of thiamine are whole grain cereal products that supply about 40% of the vitamin requirements (bread covers about 20%). Other important sources are meat and meat products (18–27%), milk and dairy products (8–14%), potatoes (10%), legumes (for reasons of low consumption, about 5%), vegetables (up to 12%), fruits (about 4%) and eggs (about 2%). Other foods supply the requirements for this vitamin to a lesser extent.

Thiamine deficiency is manifested by non-specific symptoms such as muscle fatigue, anorexia, weight loss and irritability. The reason is the partial oxidation of glucose to pyruvic acid. Vitamin deficiency may appear as a result of its increased demand (e.g. during pregnancy, lactation and sport activities), through significantly inadequate or faulty nutrition, artificial (parenteral) nutrition over a long period of time, reduction in the diet, haemodialysis, treatment with antibiotics, which suppress the intestinal flora that synthesise B group vitamins, and chronic alcoholism. A deficient intake brings about alcoholic cardiomyopathy, the Wernicke–Korsakoff syndrome (encephalopathy and psychosis) or beriberi (a neurological and cardiovascular disease).

Thiamine has a high specificity, which means that even small changes of the molecule lead to a reduction of the vitamin effect, inefficiency and in some cases even to an antivitamin effect. A well-known thiamine antagonist is oxythiamine (**5-53**), which contains as a substituent of the pyrimidine ring hydroxyl group instead of an amino group. Oxythiamine is formed from thiamine in strongly acidic media and therefore occurs, for example, in acid protein hydrolysates used as soup seasonings. Oxythiamine easily forms diphosphate, which is a competitive inhibitor of thiamine in enzymatic reactions.



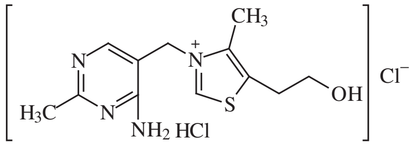
5-53, oxythiamine (free base)

Thiaminases are enzymes that are significant antivitamins, as are some low molecular weight substances from plant foods, such as phenolic compounds in blueberries, red currants, red cabbage and Brussel sprouts. Higher activity of thiaminase I is seen in raw meat and some fresh raw sea fish, molluscs, the raw offal of farm animals and some plants. Thiaminase II is an enzyme present in many bacteria.

5.6.4 Use

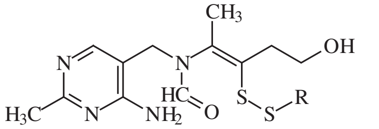
In some countries, white wheat flour, breakfast cereals and rice are fortified with thiamine. For further processing in the pharmaceuticals and food industries, the most commonly used

compound is synthetic thiamine chloride hydrochloride, also called thiamine hydrochloride (**5-54**).



5-54, thiamine chloride hydrochloride

Vitamin activity is also seen in some lipophilic thiamine derivatives with an opened thiazole ring (disulfides derived from the thiol form of thiamine). Oxidative cleavage of the thiazole ring in alkaline solution yields thiamine thiol, which can react with other thiols, forming thiamine alkyl disulfides known as allithiamines (**5-55**). A number of allithiamines occur in plants, especially in members of the genus *Allium* (family: Amaryllidaceae, subfamily: Allioideae). Thiamine allyl disulfide is a lipid-soluble form of thiamine that occurs naturally in garlic. In higher quantities it forms via the heating of thiamine with garlic extract at a temperature of about 60 °C. Garlic extract contains allicin, a diallyl disulfide that is produced by degradation of the amino acid (+)-*S*-allyl-L-cysteine sulfoxide (known as alliin). Allithiamines are biologically active compounds as, on reductive cleavage of the disulfide bridge, they spontaneously dehydrate to yield thiamine. Some synthetic allithiamines (such as thiamine propyl disulfide) have been used for the prevention and treatment of thiamine deficiency.



5-55, allithiamines

thiamine allyl disulfide, R = CH_2–CH=CH_2
thiamine propyl disulfide, R = CH_2–CH_2–CH_3

5.6.5 Occurrence

Free thiamine and its phosphoric acid esters occur in all foods, but only in some are they present in significant amounts (Table 5.8). In general, higher concentrations of thiamine (1–10 mg/kg) are found in foods that are rich in carbohydrates, which undergo intensive metabolism of sugars (cereals and legumes, as well as in pork meat and liver).

5.6.5.1 Foods of animal origin

Animal tissues contain approximately 80–90% of the vitamin as thiamine diphosphate bound to proteins. Pork and chicken meat also contain higher concentrations of thiamine triphosphate (70–80% of the total vitamin content). A particularly rich source of thiamine is pork meat (which contains about ten times more thiamine than other types of meat), ham and other pork meat products, as well as other types of meat, milk, dairy products and eggs.

Thiamine is present in milk mainly as a free compound and the diphosphate is partly bound to proteins. Cows' milk contains about 50–75% of free thiamine and 18–45% of phosphorylated thiamine, which is more labile than free thiamine. About 5–17% of thiamine phosphates are bound to proteins. These forms contribute to about 90% of the activity of free thiamine.

5.6.5.2 Foods of plant origin

In cereals, legumes and generally all plant seeds, the most common form of thiamine is free thiamine. In cereals, which are the most important source of thiamine due to their large consumption, thiamine is found mostly in the outer layers (aleurone layer) of the grain and in the germ, which are removed during the milling process, and thus a large proportion of the thiamine is in the bran. White flours, therefore, contain about ten times less thiamine than whole grain flours. Whole grain cereal products that are rich in thiamine, however, also contain relatively high concentrations of fibre and phytates (see Section 6.2.2.3), which inhibit intestinal absorption of thiamine. Brown rice (or hulled rice), which is unmilled or partly milled, contains a higher amount of thiamine than white rice, which is milled (with the bran and germ removed). Parboiled rice contains a higher amount of thiamine than white rice, as it is absorbed during the process of parboiling. In this process, the harvested rice (rice with husk) is hydrated and then steamed, before drying. Once dried completely, the husk is removed. As a result, the majority of thiamine is absorbed in the inner parts of the grain. Eating brown and parboiled rice is therefore important in preventing of avitaminosis. Another important source of thiamine is potatoes and legumes.

5.6.5.3 Other sources

Brewer's yeast is a rich source of thiamine, because the cells absorb thiamine present in the malt (containing about 160 mg/kg thiamine). Thus this means that in beer, the thiamine concentration is very low (0.01–0.06 mg/l).

5.6.6 Reactions

Thiamine is among the least stable of the vitamins. The reaction catalysed by thiaminase I, which is, for example, present in raw fish, lies in the cleavage of the thiamine molecule by an exchange reaction with nitrogen bases (such as nicotinic acid) or thiols (such as cysteine). Thiaminase II (found in some microorganisms) catalyses thiamine hydrolysis with the formation of the same products that form by non-enzymatic hydrolysis (Figure 5.10).

Thiamine is relatively stable in acidic solutions (pH < 5). Thiamine diphosphate is unstable in weakly acidic and neutral solutions, and its hydrolysis yields thiamine monophosphate and thiamine. In neutral and alkaline solutions, thiamine exists as the free base, which is very unstable. It is hydrolysed to 4-amino-5-hydroxymethyl-2-methylpyrimidine and 5-(2-hydroxyethyl)-

Table 5.8 B group vitamins content of common foods.

Food	Edible portion (mg/kg or mg/l)

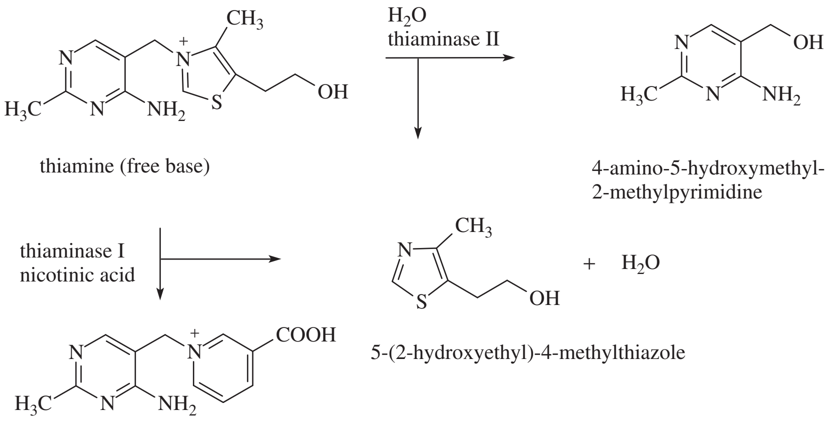

Figure 5.10 Degradation of thiamine by thiaminases.

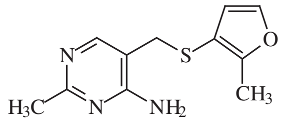
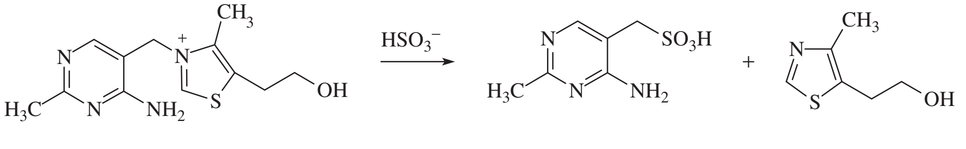
4-methylthiazole and 4-amino-5-aminomethyl-2-methylpyrimidine arises as a minor product. Another non-volatile product, 2-methyl-4-amino-5-(2-methyl-3-furylthiomethyl)pyrimidine (**5-56**), is formed from the pyrimidine moiety of thiamine and a degradation product of thiamine 2-methyl-3-furanthiol. Similarly, the thiamine molecule splits into two parts by the action of sulfur dioxide or hydrogen sulfites (Figure 5.11). This cleavage produces 5-(4-amino-2-methyl-4-pyrimidinyl)methanesulfonic acid and 5-(2-hydroxyethyl)-4-methylthiazole. In aqueous solutions, the thiazole ring of thiamine opens to form thiamine thiol, which exists as a salt in alkaline solutions (both forms also arise in foods). Thiamine thiol is easily oxidised to thiamine disulfide and thiochrome results as a minor product along with some other compounds (Figure 5.12).

A large number of other decomposition products of thiamine arise in aqueous solutions during boiling and by photodegradation.



5-56, 2-methyl-4-amino-5-(2-methyl-3-furylthiomethyl) pyrimidine

More than 70 degradation products have been identified. In addition to simple compounds, such as hydrogen sulfide, ammonia, formaldehyde, acetaldehyde, formic acid and acetic acid, dozens of other minor sulfur compounds are formed: aliphatic sulfides, aliphatic carbonyl compounds with a thiol group, furans containing sulfur in the molecule (including the previously mentioned meaty aroma character imparting compound 2-methyl-3-furanthiol), thiophenes, thiazoles and alicyclic and heterocyclic bicyclic sulfur



thiamine (free base) | 5-(4-amino-2-methylpyrimidinyl)-methane sulfonic acid | 5-(2-hydroxyethyl)-4-methylthiazole

Figure 5.11 Degradation of thiamine by sulfur dioxide.

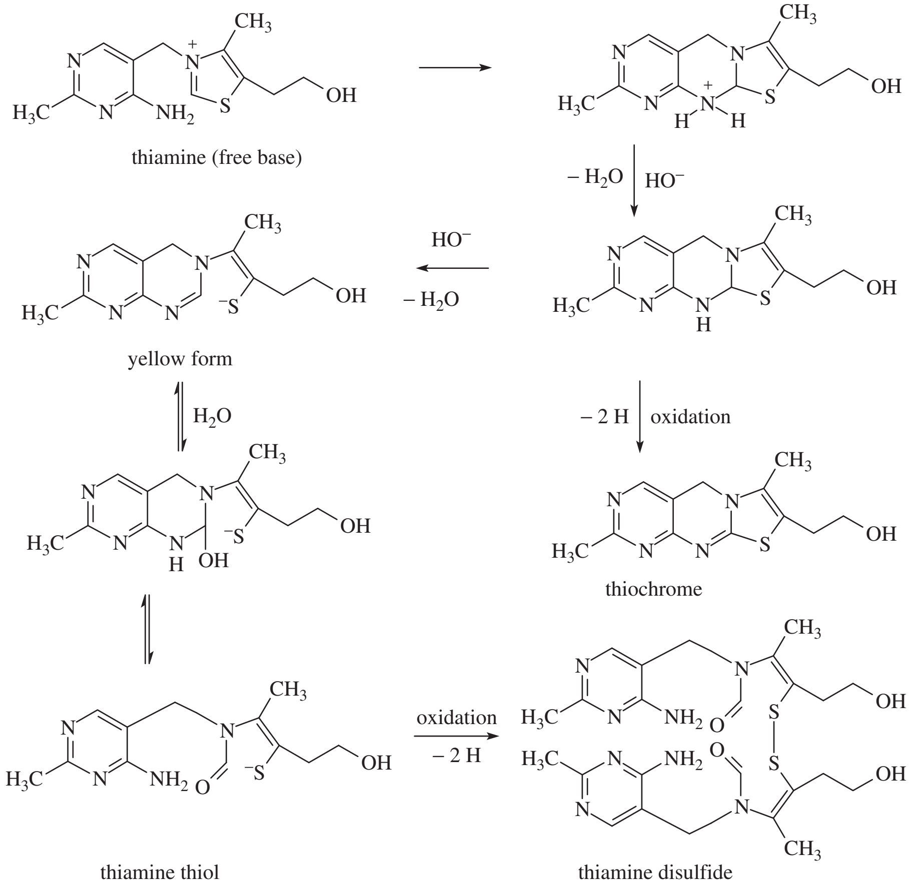


Figure 5.12 Formation of thiamine thiol, thiamine disulfide and thiochrome.

compounds. An important precursor of many decomposition products is 5-hydroxy-3-mercaptopentan-2-one (Figure 5.13). Many of these products become significant flavour components of meat and other foods. Thiamine is therefore often used as a component in mixtures (traditionally mixtures of proteins or amino acids with sugars and other ingredients) called reaction flavours (also known as process flavours) that are powerful, highly concentrated foundations for flavour compounds or seasonings and can be used directly in processed foods. A particularly significant product of thiamine decomposition is bis(2-methyl-3-furyl)disulfide. Its threshold concentrations are extremely low ($2 \cdot 10^{-5}$ μg/kg). This disulfide also appears as a product of thiamine degradation during storage of multivitamin tablets or thiamine tablets, and is responsible for their distinctive odour.

Some reactions of thiamine, such as decarboxylation of α-oxocarboxylic acids, are features of primary metabolism (decarboxylation of pyruvic acid to acetaldehyde in glycolysis and transformation of pyruvic acid to acetyl-CoA prior to its entry into the citric acid cycle) that depend on thiamine diphosphate as a coenzyme. The thiamine ring has an acidic hydrogen and is thus capable of producing the carbanion that acts as a nucleophile towards carbonyl groups. Analogous reactions proceed non-enzymatically and can thus be included among the so-called Maillard reaction. In neutral solutions, for example, thiamine reacts with reducing sugars and other carbonyl compounds (Figure 5.14). Its reaction with glucose yields glucothiamine as a primary product. Reaction with furan-2-carbaldehyde, which is one of the main degradation products of ascorbic acid in acidic solutions, explains the decomposition of thiamine in the presence of vitamin C.

Some amino acids, such as glycine, alanine, valine and glutamic acid, catalyse the thiamine degradation in alkaline solutions. The products are hydrogen sulfide and dethiothiamine (**5-57**). With cysteine and other thiols (and cystine and other disulfides), thiamine reacts to form mixed thiamine disulfides. Such mixed disulfides are the previously mentioned allithiamines (**5-55**). Analogously, thiamine reacts with proteins containing cysteine thiol groups or disulfide bonds in the side chains. These reactions explain the protective effect of thiamine on protein degradation (Figure 5.15).

5.6.7 Changes in foods

5.6.7.1 Meat and meat products

Thiamine decomposes during all food technology and culinary processes, such as frying (by 10–50%), cooking and stewing (50–70%). The losses depend on the size of the processed material, the fat and water content and the method of heat treatment used. The nitrite used in meat curing reacts with thiamine, which is partly decomposed to form elemental sulfur, thiochrome and probably oxythiamine (**5-53**). Freezing and refrigerated storage does not substantially affect the stability of thiamine, but leads to the slow decrease of its content. Frozen meat should be thawed before cooking, but the liquid that drips out during the thawing should be used because it is very rich in thiamine and other nutrients.

5.6.7.2 Milk and dairy products

During pasteurisation, sterilisation (including UHT heating) or drying of milk under normal manufacturing conditions, the loss of thiamine is in the range of 10–20%. The losses are not too high during storage of heat-treated milk either and, of course, are proportional to storage time and temperature. Stability of thiamine in dried milk depends on the conditions during storage, mainly on temperature and the presence of oxygen. Losses usually do not exceed 20%.

5.6.7.3 Cereals and cereal products

Thiamine, like other vitamins, is not evenly distributed in cereal grains. A higher amount of thiamine is found in the outer layers, and the concentration in flour is dependent on the degree of milling (known as flour extraction rate). For example, if the thiamine content of the original wheat is 3.87 mg/kg (expressed on a 13% moisture basis), the thiamine content in the 85% straight run flour (yield of 85%, expressed as a percentage of the wheat represented) is 3.42 mg/kg, in the 80% straight run flour 2.67 mg/kg and in the 70% straight run flour only 0.70 mg/kg, which is 18% of the original amount. Losses during storage of flour are relatively small (usually about 10% according to the conditions and length of storage).

During bread baking, the total losses are relatively small (about 20% of the amount in the flour), but in the crust they reach up to 90%. There are losses of up to 80% in the baking of biscuits. Higher losses result for products where alkaline baking agents (such as carbonates of alkali metals) are used. During grain extrusion, losses are relatively high (20–80%), depending on temperature, water content and the presence of oxygen. Retention of thiamine generally decreases with increased temperature and decreased water content. Cooking of pasta leads to approximately 40% loss of thiamine, which is largely caused by vitamin leakage into the water.

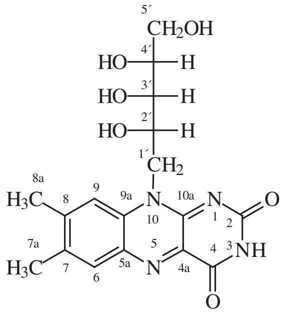
5.6.7.4 Fruits and vegetables

Losses during the cooking of root vegetables are usually around 25% and in leafy vegetables are about 40%. The addition of sulfites, used to prevent enzymatic browning reactions in peeled potatoes or dried fruits and vegetables, results in extensive or total destruction of thiamine.

5.7 Riboflavin

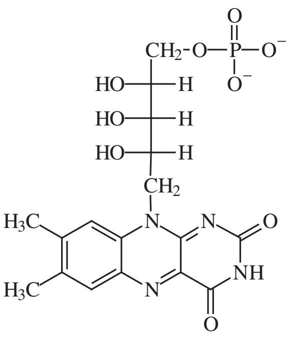
5.7.1 Structure and terminology

The basis of the yellow–green riboflavin structure (vitamin B_2, formerly also known as vitamin G, lactoflavin, ovoflavin or uroflavin) is an isoalloxazine nucleus, to which is bound the alditol ribitol at position *N*-10 (**5-58**). Riboflavin exists in an oxidised (flavoquinone) and a reduced form (flavohydroquinone).

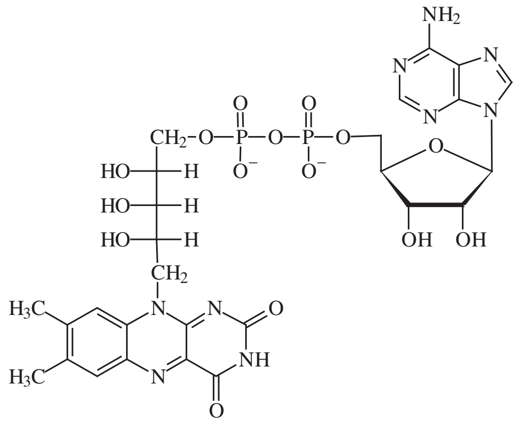


5-58, riboflavin (oxidised form)

Riboflavin, 7,8-dimethyl-10-(1′-D-ribityl)isoalloxazine, likewise occurs as a free compound, but predominantly exists in the form of riboflavin 5′-phosphate (flavin mononucleotide, FMN, **5-59**) and flavin adenine dinucleotide (FAD, **5-60**). These compounds, known as covalently bound riboflavin, are cofactors of enzymes known as flavoproteins, where carbons in positions C-6 or C-8a are involved in covalent bonding of flavins to apoproteins. The corresponding salts are present under physiological pH values. One-electron

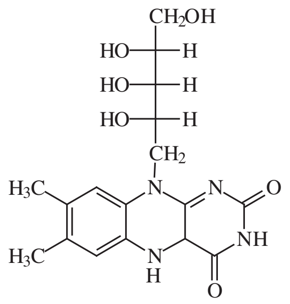


5-59, FMN



5-60, FAD

reduction of riboflavin generates two forms of riboflavin radicals, a red anion and a blue neutral molecule (called flavosemiquinone, Figure 5.16). A reduced, almost colourless form that acts in the enzyme catalysed reduction–oxidation (redox) reactions is 1,5-dihydroriboflavin (another name is dihydroflavin or leucoflavin), which spontaneously oxidises by air oxygen to riboflavin. Another reduced form (generated by two-electron reduction in some enzymatic reactions) is 4*a*,5-dihydroriboflavin (**5-61**).



5-61, 4*a*, 5-dihydroriboflavin

5.7.2 Biochemistry

Riboflavin is synthesised by a variety of microorganisms and plants. The starting substrate is a guanosine 5′-triphosphate (GTP). Animals only transform riboflavin received in food into FMN and FAD. The flavin enzymes are structurally and functionally similar to pteridine enzymes. Flavoproteins containing FMN and FAD cofactors are involved in both one-electron and two-electron redox reactions. One-electron acceptors are haem proteins or proteins containing sulfur and iron; a two-electron donor is, for example, the reduced form of nicotinamide adenine dinucleotide (NADH). Oxygen reacts with the flavins in several ways. For example, it acts as a one-electron acceptor, which yields the superoxide radical or as an acceptor of two electrons, which creates hydrogen peroxide. Most of the enzymes catalysing dehydrogenation, oxygen activation (hydroxylation, monooxygenation) and transmission of electrons are part of the respiratory chain located in the mitochondria. Some enzymes (such as glucose oxidase) are involved in other metabolic processes. In aerobic and some aerotolerant bacteria, riboflavin is involved in the biosynthesis of 5,6-dimethylbenzimidazole, which is a component of vitamin B_{12}.

5.7.3 Physiology and nutrition

The daily requirement of this vitamin is between 0.4 mg (for infants) and 1.7 mg (for adolescents and adult men). In women, the daily requirement is somewhat lower (1.2–1.3 mg), while in pregnant and lactating women it ranges from 1.6 to 1.8 mg or more. It is estimated that nearly 40% of the dietary vitamin comes from milk and dairy products, about 20% from meat and meat products, 15% from cereals, with less than 10% from eggs and the same amount (10%) from vegetables. Riboflavin from foods of animal origin is more easily absorbed in the digestive tract than that from foods of plant origin, where covalently bound forms that are not easily hydrolysed by proteases dominate. Riboflavin deficiency, or ariboflavinose, is relatively rare. It manifests itself mainly in non-specific inflammatory changes (lesions) of the eye, mouth, skin (dermatitis) or mucous membranes. It is usually associated with other vitamin deficiencies such as pellagra.

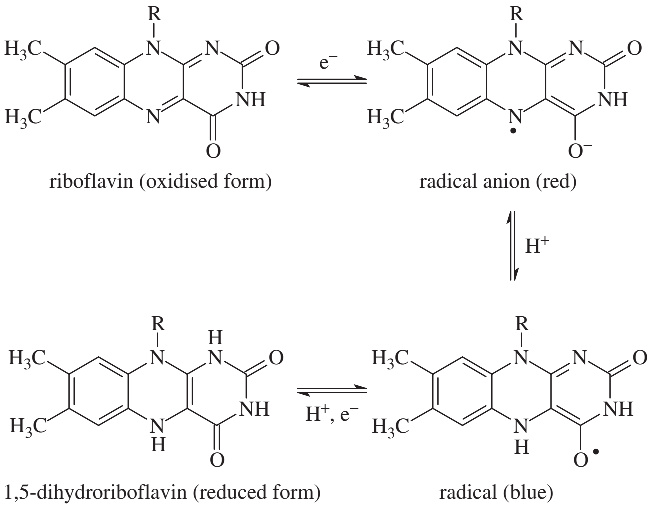


Figure 5.16 Oxidised and reduced forms of riboflavin (see **5-53** for R).

5.7.4 Use

Like thiamine, riboflavin is also used for the fortification of certain foods, such as wheat flour and breakfast cereals. Because of its yellow–orange colour, it is also used as a colouring for certain foods, especially cereal products, ice creams and sugar-coated pills. Hydroxyl groups of ribitol can be easily esterified by carboxylic acids. For example, riboflavin-2′,3′,4′5′-tetrabutyrate has been used as an antioxidant.

5.7.5 Occurrence

5.7.5.1 Foods of animal origin

Riboflavin, mostly as FMN and FAD and less frequently as the free vitamin, is found in all foods, and its distribution is similar to the distribution of thiamine. In milk (and also in eggs), however, the prevailing form is as riboflavin (about 82%). Riboflavin in milk is in part bound to α_S-casein and β-casein, about 14% of riboflavin is in the form of FAD and 4% in the form of FMN. Smaller quantities of some other flavins, such as 10-(2-hydroxyethyl)flavin, 7*a*-hydroxyriboflavin (7-hydroxymethylriboflavin) and its 8*a*-isomer (8-hydroxymethylriboflavin) are also found in milk. A higher vitamin content is found particularly in meat and offal, cheeses and some sea fish (Table 5.8).

5.7.5.2 Foods of plant origin

In addition to riboflavin, FMN and FAD, a large number of other riboflavin derivatives (esters and glycosides) that exhibit similar biological activity, are found in higher plants and microorganisms. For example, the yellow ester of malonic acid (5′-malonylriboflavin) was found in oats (*Avena coleoptiles*, Poaceae) growing in the dark. Riboflavin is present in smaller quantities than thiamine in bread and other cereal products, while whole grain products have a higher riboflavin content.

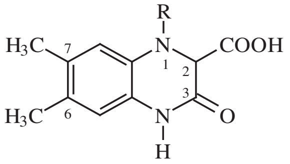
5.7.5.3 Other sources

Unlike thiamine, which remains in the yeast cells during fermentation, a significant amount of riboflavin is present in beer (approximately 0.5 mg/l). Brewer's and baker's yeast is, therefore, a rich source of riboflavin. Derivatives of riboflavin with the C-5′ hydroxyl group of ribitol oxidised to a carbonyl group (called riboflavinal) or a carboxyl group (riboflavinic acid) are present in some edible mushrooms (Basidiomycetes).

5.7.6 Reactions

Flavin coenzymes are very susceptible to enzymatic or chemical hydrolysis. FAD is hydrolysed in acidic solutions to FMN. In acidic solutions, the phosphate group of FMN migrates from the C-5′ position to C′-4, C′-3 and C′-2 positions and subsequent hydrolysis of phosphates yields free riboflavin.

Riboflavin is a very stable vitamin in the absence of light, and in neutral and weakly acidic solutions is practically stable. Even during the production of acid protein hydrolysates (hydrolysis with 20% hydrochloric acid at temperatures above 100 °C), vitamin retention is around 20%. In alkaline media, urea and 1-(3-carboxy-6,7-dimethyl-2-oxo-(2*H*)-quinoxaline-1-yl)-1-deoxy-D-ribitol, also known as 1,2-dihydro-6,7-dimethyl-3-oxo-4-D-ribitol-1-yl-2-chinoxaline carboxylic acid (**5-62**), are formed as reaction products.



5-62, 1,2-dihydro-6, 7-dimethyl-3-oxo-4-D-ribitol-1-yl-2-chinoxaline carboxylic acid (see **5-55** for R)

In neutral and alkaline solutions in the light, all flavins and especially free riboflavin and FMN have complex photochemical properties, act as photosensitisers of type I (free radical generation), type II (oxidation by singlet oxygen) and are degraded to a variety of products (see Section 3.8.1.8.4). Depending on the pH of the solution, excited triplet riboflavin is degraded into non-volatile lumichrome, lumiflavin and other products. The main product of riboflavin photodegradation, after cleavage of the ribitol side chain as 1-deoxy-D-*erythro*-pent-2-ulose (1-deoxy-D-ribulose) in acidic and neutral media, is lumichrome (7,8-dimethylalloxazine). In neutral and alkaline media, the reaction products are lumiflavin, 7,8,10-trimethylisoalloxazine, and D-erythrose (Figure 5.17). Both flavins formed by photodegradation of riboflavin are more effective oxidising agents than riboflavin itself. Flavins also transmit the absorbed light energy to air oxygen (triplet oxygen), which yields singlet oxygen. Singlet oxygen then oxidises flavins, which undergo photolytic fission (photodegradation) and similarly oxidises other organic compounds. For example, the reaction between riboflavin and singlet oxygen yields butane-2,3-dione (biacetyl) (Figure 5.18).

Riboflavin acts as a photosensitisers very often with milk (and also with wine and beer) when exposed to direct sunlight in unsuitable containers (see Section 3.8.1.8.4). Singlet oxygen and

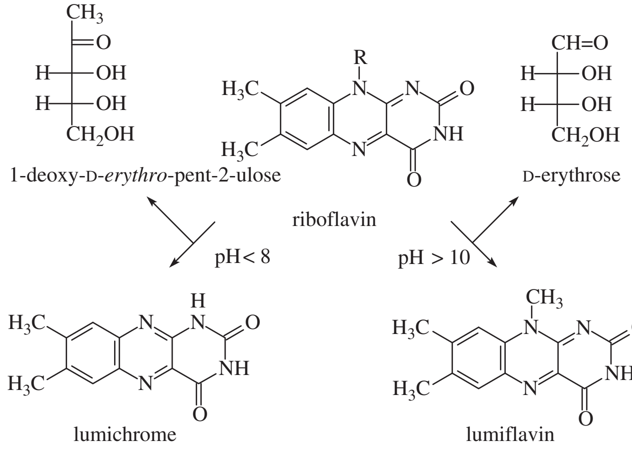


Figure 5.17 Photolysis of riboflavin (see **5-53** for R).

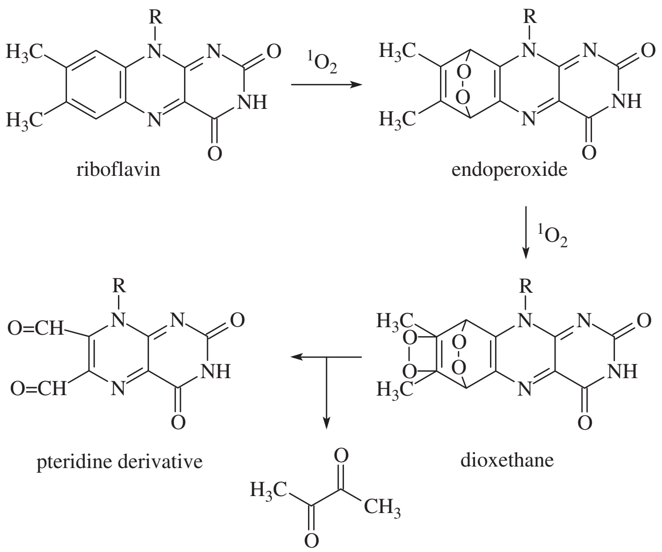

Figure 5.18 Oxidation of riboflavin by singlet oxygen (see **5-53** for R). Jung, Oh, Kim, Kim and Min, 2007, fig 3. Reproduced by permission of the American Chemical Society.

riboflavin degradation products, in particular lumiflavin, cause destruction of vitamin C and oxidise other important substances, such as retinol, essential fatty acids and essential amino acids, and especially methionine.

5.7.7 Changes in foods

Riboflavin is very stable during the thermal processing of foods, but decomposes when exposed to light. To prevent the photochemical degradation of riboflavin, foods containing higher amounts of riboflavin should not be exposed to direct sunlight, and should be stored in opaque or coloured containers.

5.7.7.1 Meat and meat products

Riboflavin is slightly soluble in water (mainly in the reduced form), therefore losses during cooking meat are not very significant (they usually do not exceed 10%), but are caused mainly by extraction into water. During freezing and the refrigerated storage of meat, vitamin loss is also low. For example, the vitamin loss after 15 months of storage of meat is only about 15%.

5.7.7.2 Milk and dairy products

Riboflavin in milk is very stable during normal technological operations (such as pasteurisation and sterilisation); losses do not exceed 5%. For example, retention in UHT milk is about 98%. Losses during storage of UHT milk are also small (about 10%). A significant loss of riboflavin in milk occurs when milk is exposed to direct sunlight. One hour's storage of milk in the sun results in a degradation of about 20–40% of the vitamin present. Diffused daylight also has a similar effect. Riboflavin photosensitisation in milk induces two distinctive off-flavours, which make it less acceptable to consumers. The first off-flavour is the so-called sunlight flavour, giving a burnt and oxidised odour to milk that is caused by methionine oxidation to volatile sulfur compounds, such as methional, methanthiol and dimethyldisulfide. The other off-flavour is a cardboard or metallic flavour, which develops in milk with a prolonged exposure to light. This off-flavour is attributed to some secondary fatty acid oxidation products that include aldehydes, especially (*E*)-non-2-enal, ketones, alcohols, hydrocarbons and other compounds. Fermented milk products contain, in most cases, higher concentrations of riboflavin than the original milk, because the vitamin is synthesised by the microorganisms used. During the drying of milk, about 2% of riboflavin is lost.

5.7.7.3 Cereals and cereal products

Cereals contain a considerable amount of riboflavin. The vitamin content in flour depends, as with other water-soluble vitamins, on the degree of milling (flour extraction rate). Its content is higher in dark flours than in white flours. Losses during cooking are also small (up to 10%); higher losses (up to 30%) are found in flours fortified with riboflavin. Losses in cooked pasta products (to a large extent caused by leaching) reach, according to the type of pasta, 35–55%.

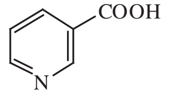
5.7.7.4 Fruits and vegetables

Riboflavin losses in canned fruits and vegetables are in the range of 25–70%, according to the type of processed material. The main losses are caused by leaching. For example, cooked vegetables lose 30–40% of their riboflavin content by leaching into the water used for cooking.

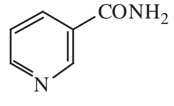
5.8 Niacin

5.8.1 Structure and terminology

Niacin, also formerly known as PP factor (Pellagra Preventive factor) or vitamin PP is a common name for nicotinic acid (pyridine-3-carboxylic acid, **5-63**) and its amide nicotinamide (niacin amide, also formerly known as vitamin B_3, **5-64**). Both compounds have the same biological activity.



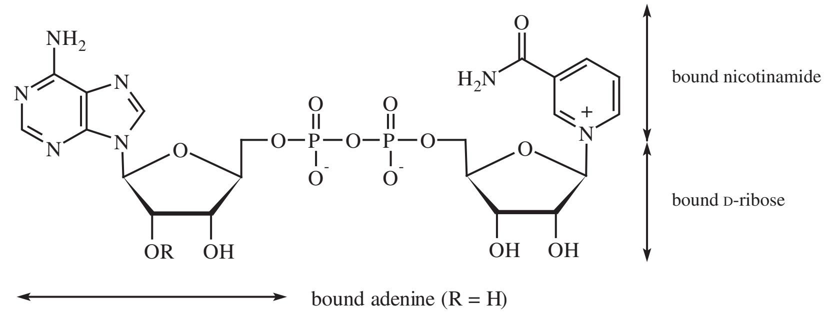
5-63, nicotinic acid



5-64, nicotinamide

5.8.2 Biochemistry

Nicotinamide is part of nicotinamide adenine dinucleotide, NAD (oxidised form is NAD^+ and reduced form is NADH) and its phosphoric acid ester nicotinamide adenine dinucleotide phosphate, NADP ($NADP^+$ and NADPH, **5-65**), which are



5-65, NAD^+, R = H
$NADP^+$, R = PO_3H_2

cofactors (coenzymes) of several hundreds of different enzymes. In the older literature, these substances are known as diphosphopyridine nucleotide (DPN^+, DPNH) and as triphosphopyridine nucleotide (TPN^+, TPNH).

Both cofactors are involved in respiratory electron transfer systems (Figure 5.19), for example, in most redox reactions of the citric acid (Krebs) cycle. NAD is most often involved in degradation (catabolism) of sugars, fats, proteins and ethanol, while NADP is involved mainly in biosynthetic (anabolic) reactions, such as synthesis of macromolecules, fatty acids and cholesterol. Dinucleotides, in addition of their activities in redox reactions, participate in post-translational modifications of some proteins and other reactions.

$NAD(P)^+$ from the diet is first hydrolysed to a mixture of nicotinic acid and nicotinamide. Nicotinic acid can then be transformed into nicotinamide and then to $NAD(P)^+$ in the body. These dinucleotides are *de novo* synthesised by bacteria and some plants from aspartic acid and 1,3-dihydroxyacetone phosphate (glycerone phosphate). Quinolinic acid is an intermediate. It arises from tryptophan in some microorganisms and in animals.

Biosynthesis and catabolism of $NAD(P)^+$ produce various derivatives of niacin, such as N^1-methylnicotinamide (a product of catabolism in humans and animals) and *N*-methylnicotinic acid (1-methylpyridinium-3-carboxylate), known as trigonelline (Figure 5.20), which is a product of catabolism in plants and fungi. Previously, trigonelline was known under the names caffearin, coffearin or gynesine. Trigonelline was first found in fenugreek seeds (*Trigonella foenum-graecum*, Fabaceae)[7] and subsequently in many other plant species, such as legumes, cereals and potatoes. Trigonelline is a biologically active compound involved in the induction of leaf movement, it acts as an osmoprotectant and probably serves as a reserve source of nicotinic acid.

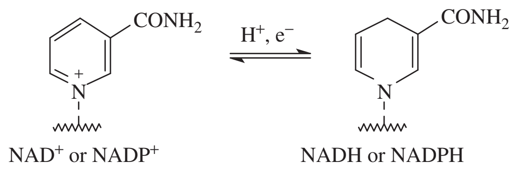


Figure 5.19 Oxidation of NADH and NADPH and reduction of NAD^+ and $NADP^+$.

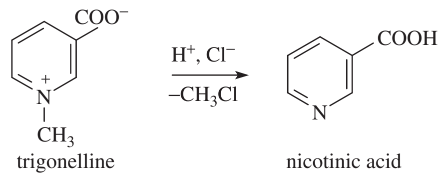

Figure 5.20 Pyrolysis of trigonelline.

5.8.3 Physiology and nutrition

The need for niacin is not precisely known, since it depends on many factors, such as the amount of protein (tryptophan and leucine) consumed. Leucine is an inhibitor of NAD biosynthesis from tryptophan. The recommended daily dose for children is 2–12 mg, 14 mg for women, 16 mg for men and 18 mg for pregnant and lactating women.

The niacin requirement is mainly provided by meat and meat products (about 40% or more), milk (about 10%), cereal products (about 20%), potatoes (about 10%) and other foods. Meat and meat products supply about 50% of the needs for tryptophan, milk and eggs about 25%. Lack of the vitamin, known as pellagra, is manifested mainly by skin damage, digestive tract disorders and later by mental disorders (dementia).

Man has a significant but limited ability to synthesise niacin in a somewhat complicated way using tryptophan and enzymes containing vitamin B_6 as a cofactor. It is reported that 34–86 mg (mean 60 mg) of tryptophan is required for biosynthesis of 1 mg of niacin. The possibility of biosynthesising niacin from tryptophan explains the beneficial effect of milk and eggs as a protection against pellagra. Both foods are good sources of tryptophan, although they contain low concentrations of niacin.

Some pyridine derivatives act as antagonists of niacin. Antagonists occurring in foods may include 3- and 4-acetylpyridine that arise as products of the Maillard reaction. *N*-Methylpyridinium cation generated by the thermal degradation of trigonelline inhibits gastric acid secretion and induces phase II detoxifying enzymes.

[7]The plant comes from the Mediterranean region and is now cultivated worldwide and used as a spice (it is a common ingredient of many curries and other spice mixtures), medicinal plant and animal feed. For example, mixed with summer savoury (*Satureja hortensis*) of the mint family (Lamiaceae), fenugreek seed is a component of chubrica, a favourite spice of Bulgarian cuisine.

5.8.4 Use

In some countries, nicotinic acid is added to white wheat flour and to other cereal products. The complex with menadione bisulfite, which shows the activity of niacin and vitamin K, has been used in animal nutrition. Nicotinamide in combination with ascorbic acid is used as a meat colour stabiliser, but has not found wider application in the meat industry (under anaerobic conditions, metmyoglobin in raw meat is reduced back to myoglobin by enzymes that contain NAD as a cofactor).

5.8.5 Occurrence

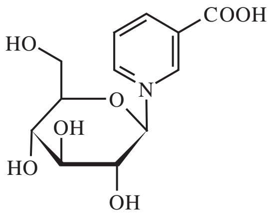
Distribution of niacin in foods is similar to other B group vitamins (Table 5.8). Niacin is present in small amounts in all foods, usually in a bound form.

5.8.5.1 Foods of animal origin

Foods of animal origin mainly contain nicotinamide, mostly in the form of NAD and NADP. The richest source is offal, meat and meat products, eggs and especially egg yolk (which contains approximately 60 mg/kg of niacin). Milk contains a surprisingly low amount of niacin; the niacin content of cheeses is higher.

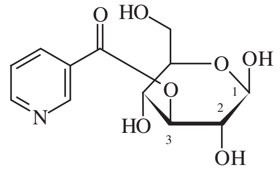
5.8.5.2 Foods of plant origin

The main form of this vitamin in foods of plant origin is nicotinic acid. Plants contain a number of nicotinic acid derivatives, such as *N*-(β-D-glucopyranosyl)nicotinic acid (**5-66**), the ester 1-*O*-nicotinoyl-β-D-glucopyranose and other nicotinoyl derivatives of glucose.



5-66, *N*-(*β*-D-glucopyranosyl)nicotinic acid

Cereals often have, at first sight, a considerable niacin content. Wheat contains about 30–70 mg/kg of niacin, and whole wheat flour and brown rice contain about 30–60 mg/kg. However, milling and peeling have a great influence on the vitamin content, because niacin is largely located in the germ and bran. For example, wheat grains containing niacin at a level of 57 mg/kg give 80% and 70% straight-run flours that have a vitamin content of 19 and 10 mg/kg, respectively. The same vitamin level (about 10 mg/kg) is found in white bread and white rice. Nicotinic acid in maize and sorghum grains is largely covalently bound to macromolecular glycopeptides and is generally not available to mammals. Partial hydrolysis of these glycopeptides gives 3-*O*-nicotinoyl-β-D-glucopyranose (**5-67**). The lack of bioavailability of nicotinic acid in maize, which leads to pellagra, is probably due to this type of binding. The biological availability of nicotinic acid in maize is significantly improved by pre-treatment of the maize flour with lime milk, a procedure used in Mexico for the preparation of tortillas. For example, the total amount of the vitamin in raw maize grains is about 30 mg/kg, of which less than 2% are bioavailable. Boiling in water increases the vitamin utilisation to 16%, but when cooked in lime milk, vitamin utilisation is 100%. Legumes, fruits, vegetables and potatoes have average amounts of niacin.



5-67, 3-*O*-nicotinoyl-β-D-glucopyranose

5.8.5.3 Other sources

A surprisingly rich source of niacin is roasted coffee. Green coffee beans contain a large amount of the alkaloid trigonelline, which is demethylated on roasting forming nicotinic acid (Figure 5.20). The content of niacin in roasted coffee is about 25 times higher than in green (unroasted) coffee and reaches up to 2% of dry matter. Together with other compounds, it also contributes to the bitter taste of roasted coffee. Decarboxylation of trigonelline gives a small amount of the *N*-methylpyridinium cation, transmethylation yields methyl nicotinate and other reactions yield a number of volatile flavour-active pyrroles and pyridines. The caffeine content is virtually unchanged during roasting, so the ratio of caffeine to trigonelline serves as a criterion of the degree of coffee roasting.

5.8.6 Reactions

Nicotinic acid is very stable when heated in aqueous solutions, and is stable in acidic and alkaline media. Nicotinamide is very stable in neutral solutions, in acidic and alkaline solutions it is hydrolysed to nicotinic acid.

5.8.7 Changes in foods

5.8.7.1 Meat and meat products

When processing raw meat and offal, the content of free nicotinamide increases due to the enzymatic hydrolysis of NAD and NADP. Vitamin losses during the thermal processing of meat usually do not exceed 10%, while losses due to draining from improper thawing can amount to 50%. Partial hydrolysis of nicotinamide to nicotinic acid may also occur.

5.8.7.2 Milk and dairy products

Losses in milk are very small (up to 5%). In the manufacture of cheeses, the majority of the niacin goes into the whey (the liquid

part of milk that remains after the manufacture of cheeses). Losses during maturation and storage of cheeses are negligible. The niacin content of yoghurts is slightly higher than in milk because it is produced by the microorganisms that are present.

5.8.7.3 Cereals and cereal products

The loss of the vitamin does not usually exceed 10% in baked cereal products. The use of alkalising baking ingredients, such as baking powders based on ammonium bicarbonate, can increase the bioavailability of niacin due to its release from unavailable forms.

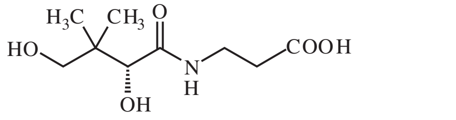
5.8.7.4 Fruits and vegetables

Typically, losses of niacin in preserved fruits and vegetables and in cooked potatoes do not exceed 30–40%; the main reason for any loss is leakage into water.

5.9 Pantothenic acid

5.9.1 Structure and terminology

Pantothenic acid (formerly also known as vitamin B_5, **5-68**) occurs in nature only as the (+)-D-form, that is the (*R*)-enantiomer. (*R*)-Pantothenic acid is composed of (+)-D-pantoic acid, also known as (*R*)-pantoic acid, the systematic name of which is (*R*)-2,4-dihydroxy-3,3-dimethylbutanoic acid. Pantoic acid is linked by an amide bond to the 3-aminopropionic acid (β-alanine). The (*S*)-enantiomer of pantothenic acid, which is the (−)-L-isomer, is not biologically active and is an antimetabolite of (*R*)-pantothenic acid, as are some other structural analogues. The main biologically active natural form of pantothenic acid is coenzyme A (CoA, HS-CoA or CoASH, **5-69**)[8] and a protein called acyl-carrier protein (ACP, **5-70**).



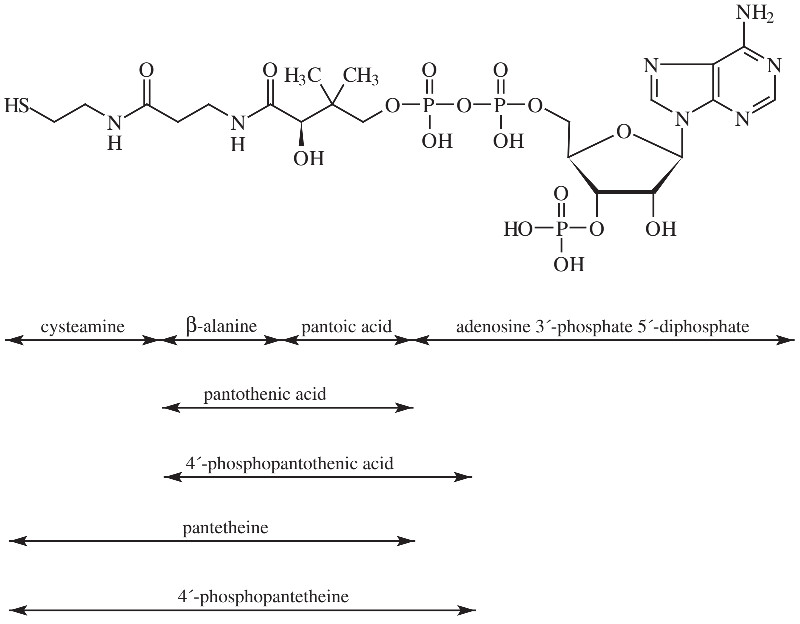
5-68, (*R*)-pantothenic acid

Pantothenic acid can be accompanied by its biologically active higher homologue known as homopantothenic acid (**5-71**), which contains 4-aminobutanoic acid (γ-aminobutyric acid) instead of β-alanine and acts as an antagonist of pantothenic acid.

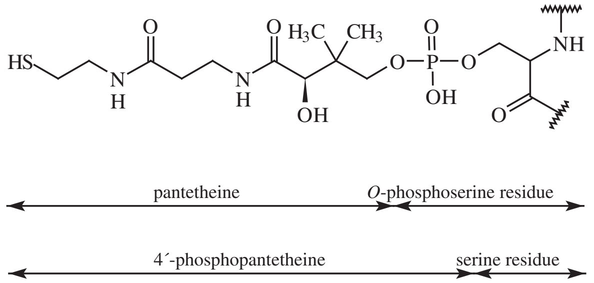
5.9.2 Biochemistry

Pantothenic acid is an essential nutritional factor for a range of yeasts, lactic acid and propionic acid bacteria and other microorganisms. Some bacteria and plants synthesise this acid *de novo* from pantoic acid and β-alanine. The biosynthesis of pantoic acid uses 3-methyl-2-oxobutanoic (2-oxoisovaleric) acid, which is a precursor of valine, the donor of the hydroxymethyl group is 5,10-methylenetetrahydrofolic acid, and decarboxylation of aspartic acid yields the β-alanine.

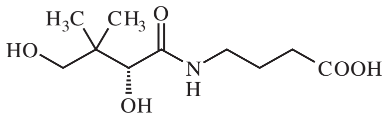
[8]Coenzyme A is the active component of transacylases transporting the residues of carboxylic acids. The most common substance is acetyl-CoA, which carries acetyl groups. In acetyl-CoA, acetic acid is bound as a thioester to the thiol group of cysteamine. Other acyl coenzymes A include malonyl-CoA, succinyl-CoA, and other coenzymes that play a role in the metabolism of proteins, fats and sugars. ACP plays a fundamental role in biosynthesis of fatty acids and polyketides.



5-69, coenzyme A

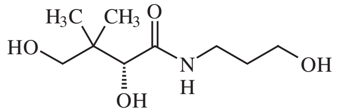


5-70, ACP



5-71, (*R*)-homopantothenic acid

Animals (and also some yeasts and bacteria) do not synthesise pantothenic acid as they only convert exogenous vitamin obtained from food into both metabolically active forms, coenzyme A and ACP. Exogenous coenzyme A is first hydrolysed to pantothenic acid and pantetheine (via 4′-phosphopantetheine); exogenous (*R*)-panthenol (**5-72**) is oxidised to pantothenic acid.



5-72, (*R*)-panthenol

5.9.3 Physiology and nutrition

The recommended daily intake of pantothenic acid in infants under 6 months of age is 1.7 mg, and is 2 mg in children from 6 to 12 months, 3 mg in children from 4 to 8 years, 4 mg in children from 9 to 13.5 years, 5 mg in adolescents and men and 6 mg in women (7 mg in lactating women). Normal dietary intake of this vitamin is 6–12 mg per day. Cases of deficiency, which us manifested mainly by skin irritation and paraesthesia (a tingling and itching sensation), are not common.

It is known that homopantothenic acid improves the metabolism of glucose in the brain and the higher functions of the brain and it has been used in Japan to enhance mental functions, especially in Alzheimer's disease. A rare side-effect is an abnormal brain function resulting from the failure of the liver to eliminate toxins (hepatic encephalopathy). This condition was reversed by pantothenic acid supplementation, suggesting that it was due to pantothenic acid deficiency caused by the antagonist homopantothenic acid.

5.9.4 Use

Pantothenic acid or its salts are added to foods only occasionally. Calcium and sodium pantothenate are more stable and less hygroscopic than the free acid. Salts of pantothenic acid and less polar (*R*)-pantothenyl alcohol or (*R*)-panthenol (**5-72**) are used to fortify animal feed for farm animals (mainly poultry) and also in pharmacy and cosmetics. Proportionally, owing to increasing consumption of cooked foods and ready-to-eat meals in developed countries, more extensive fortification of foods can be expected.

5.9.5 Occurrence

Pantothenic acid is found in virtually all foods of plant and animal origin, usually in relatively small amountss (Table 5.8). Only a small proportion of the total vitamin content is free acid; bound forms such as coenzyme A, acyl-coenzymes A and ACP are mostly present. The pantothenic acid levels in individual foods is highly variable.

5.9.5.1 Foods of animal origin

Relatively large amounts of the vitamin occur in meat, and particularly in offal, eggs and some types of cheese. There is a low vitamin content in milk.

5.9.5.2 Food of plant origin

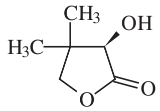
The pantothenic acid content in wheat flour is strongly influenced by the degree of milling. There is a higher vitamin level in wholegrain flour, cereal products and legumes, whilst about ten times lower vitamin content is typically found in fruits and vegetables. Homopantothenic acid occurs in cooked rice at concentrations of about 20 mg/kg.

5.9.5.3 Other sources

Similarly to the other B group vitamins, relatively large amounts of pantothenic acid are found in yeasts. Homopantothenic acid occurs in dried yeasts in a concentration of 8500 mg/kg.

5.9.6 Reactions

The stability of pantothenic acid in aqueous solutions depends greatly on the pH value. The vitamin is most stable in weakly acidic (pH 4–5) solutions, but in acidic and alkaline media the amide linkage is hydrolysed and pantothenic acid yields pantoic acid (or its salt) and β-alanine. The enzyme pantothenase of some bacteria specifically cleaves pantothenic acid into the same products. In acidic solutions, pantoic acid spontaneously dehydrates to form lactone, (*R*)-2-hydroxy-3,3-dimethylbutano-4-lactone, which is called pantoyllactone or pantolactone (**5-73**). Analogously, products of panthenol hydrolysis are pantoic acid



5-73, (*R*)-pantolactone

and 3-aminopropane-1-ol (β-alanol). Solutions of coenzyme A and pantetheine are relatively stable in solutions of pH 2–6. Both compounds are easily oxidised to form disulfides, pantethine or the disulfide form of coenzyme A, respectively.

5.9.7 Changes in foods

Pantothenic acid is relatively unstable during storage and especially during the thermal processing of foods. Losses caused by leaching into the water during operations such as washing, blanching and cooking are often higher than the losses caused by hydrolysis.

5.9.7.1 Meat and meat products

Thermal processing of meat results in losses of pantothenic acid that reach about 12–50%, depending on the conditions. The extent of these losses is contingent on the type of heat treatment, the volume of water used and other factors. Losses in canned meat and in meat products range from 20 to 35%.

5.9.7.2 Milk and dairy products

Pasteurisation of milk does not significantly affect the vitamin content. In the case of UHT milk, the vitamin loss is about 5% of the original level and the loss after 6 weeks of storage of UHT milk is 20–35%. The natural vitamin content in fermented dairy products is affected only slightly by fermentation. Milk powder manufacture and storage of milk powder result in small losses of the vitamin.

5.9.7.3 Cereals and cereal products

A small decrease in pantothenic acid concentration occurs during milling. The vitamin retention in bread is relatively high (up to 90%), while in cooked pasta, according to the type of product and method of preparation, it reaches 55–75%. Losses during the cooking of legumes are 25–56% depending on soaking time. Higher amounts of pantothenic acid can be lost when exposed to alkali agents, such as baking soda.

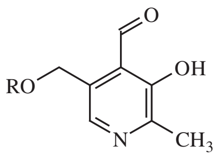
5.9.7.4 Fruits and vegetables

In preserved fruits and fruit juices, the losses of pantothenic acid are on average about 50%. In preserved vegetables, where the vitamin is exposed to vinegar, the losses can reach 45–80%.

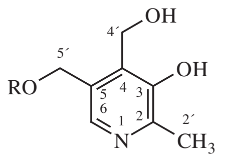
5.10 Pyridoxal, pyridoxol and pyridoxamine

5.10.1 Structure and terminology

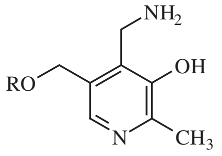
The name vitamin B_6 (formerly known as adermine) refers to three structurally related, biologically active derivatives of 3-hydroxy-5-hydroxymethyl-2-methylpyridine and to their 5′-phosphates. These three forms of vitamin B_6 differ in their substitution at position C-4 of the pyridine ring: the formyl derivative, 4-formyl-3-hydroxy-5-hydroxymethyl-2-methylpyridine, is called pyridoxal (**5-74**); the hydroxymethyl derivative, 3-hydroxy-4,5-bis(hydroxymethyl)-2-methylpyridine, is called pyridoxol or pyridoxine (**5-75**); and the aminomethyl derivative, 4-aminomethyl-3-hydroxy-5-hydroxymethyl-2-methylpyridine, is called pyridoxamine (**5-76**). The residue that results after splitting off the 4′-hydroxyl group is known as the pyridoxyl residue, the pyridoxylidene residue forms by splitting off the oxygen from the aldehyde group of pyridoxal.



5-74, pyridoxal, R = H
pyridoxal 5′-phosphate, R = PO_3H_2



5-75, pyridoxol, R = H
pyridoxol 5′-phosphate, R = PO_3H_2



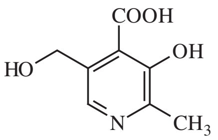
5-76, pyridoxamine, R = H
pyridoxamine 5′-phosphate, R = PO_3H_2

5.10.2 Biochemistry

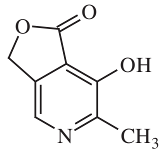
Prokaryotic organisms synthesise a primary form of vitamin pyridoxol 5′-phosphate from 1-deoxy-D-xylulose 5-phosphate (1-deoxy-D-*threo*-pent-2-ulose 5-phosphate) and 2-amino-2-deoxy-D-*threo*-tetronic (2-amino-2-deoxy-D-threonic) acid, known as 4-(phosphohydroxy)-L-threonine or 4-hydroxy-L-threonine 4-phosphate. Phosphohydroxythreonine arises from D-erythrose 4-phosphate, a product of decomposition of D-fructose 6-phosphate. Non-phosphorylated forms (pyridoxal, pyridoxol and pyridoxamine) are produced by hydrolysis of the corresponding phosphates. Animals do not synthesise vitamin B_6 *de novo*, only convert the non-phosphorylated forms in the liver, erythrocytes, and other tissues into the corresponding phosphates and the individual forms of each other. Pyridoxal 5′-phosphate arises by oxidation of pyridoxol 5′-phosphate and transamination of pyridoxal 5′-phosphate provides pyridoxamine 5′-phosphate. Both these forms of vitamin B_6 are catalytically active. Pyridoxal 5′-phosphate

(originally called codecarboxylase) is a cofactor for enzymes catalysing decarboxylation, deamination, racemisation, transamination and transsulfuration of amino acids and also participates in many reactions related to metabolism of fats and sugars.

The dominant forms in animal tissues are pyridoxal 5′-phosphate and pyridoxamine 5′-phosphate. An important metabolite of pyridoxal excreted in the urine is biologically inactive 4-pyridoxic acid (**5-77**) and its lactone, which is called 4-pyridoxolactone (**5-78**). Minor metabolites generated by oxidation in position C-5′are isopyridoxal (aldehyde), the corresponding carboxylic acid and its lactone. Pyridoxol 5′-phosphate is the dominant form in plant tissues.



5-77, 4-pyridoxic acid

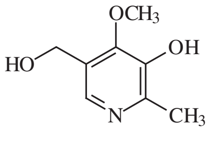


5-78, 4-pyridoxolactone

5.10.3 Physiology and nutrition

The recommended daily intake of vitamin B_6 is 0.3–2.6 mg (the lower limit is for babies and the upper limit for pregnant and lactating women). Vitamin B_6 deficiency manifests by dermatitis and neurological disorders (seizures in children). Long-term high-dose vitamin intake can cause neurological disorders, manifesting as loss of sensation in the feet and poor coordination. Such increased vitamin intake can be only provided by vitamin supplements. It is estimated that about 40% of the required vitamin is provided by meat and meat products, 22% by vegetables, 12% by milk and dairy products, 10% by cereals, 5% by legumes, 8% by fruits and 2% by eggs.

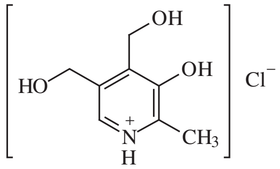
Vitamin antagonists are compounds reacting with the carbonyl group of pyridoxal or substances structurally related. Natural antagonists may be some tryptophan metabolites, hydrazines and hydroxylamines that react to form the respective hydrazones and oximes, which are unavailable forms of vitamin B_6. Some reaction products of pyridoxal with amino acids are also unavailable or available to a small extent. Vitamin antagonists include linatin, an amino acid present in flax seeds and a neurotoxin gingkotoxin (4′-*O*-methylpyridoxol, **5-79**), which is a minor component of gingko leaves (*Ginkgo biloba*, Ginkgoaceae), known as the maidenhair tree.



5-79, gingkotoxin

5.10.4 Use

For the fortification of foods and for food supplements, synthetic pyridoxol hydrochloride (**5-80**) is used. Baby food, and in some countries white wheat flour, are the foods most often fortified.



5-80, pyridoxol hydrochloride

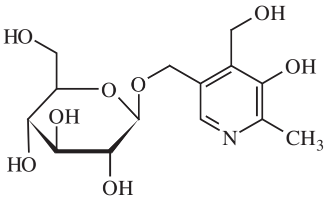
5.10.5 Occurrence

5.10.5.1 Foods of animal origin

Meat, meat products, offal and egg yolk are rich sources of vitamin B_6 (Table 5.8). In foods of animal origin, the main compounds are pyridoxal and pyridoxamine, especially in the form of phosphate esters. For example, in meat the main form is present as pyridoxal 5′-phosphate (about two thirds of this vitamin are prosthetic groups of enzymes) bound to various proteins (such as imine), to a lesser extent as free pyridoxal 5′-phosphate, followed by pyridoxamine 5′-phosphate. In contrast, milk contains only about 10% of vitamin in bound forms. The vitamin content in milk and cheeses is relatively low.

5.10.5.2 Foods of plant origin

Foods of plant origin mainly contain pyridoxol and pyridoxal. Glycosides of pyridoxol are also common. The predominant form is 5′-*O*-(β-D-glucopyranosyl)pyridoxol (**5-81**), which in fruits and vegetables represents 5–80% of the total vitamin content. This form is less available than free pyridoxal. A minor component of pea (*Pisum sativum*, Viciaceae) is 5′-*O*-(β-D-glucopyranosyl)pyridoxol esterified by 3-hydroxy-3-methylglutaric acid at position C-6 of D-glucose. Cereals are good sources of vitamin B_6. A higher vitamin content can be found in whole grain cereal products and cereal germs, as well as in some vegetables, potatoes and legumes.



5-81, 5′-*O*-(β-D-glucopyranosyl)pyridoxal

5.10.5.3 Other sources

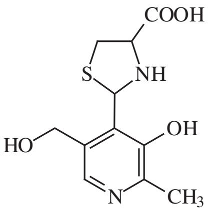
Vitamin B_6 is, like the other B vitamins, present in high concentrations in yeast.

5.10.6 Reactions

Vitamin B_6 is relatively stable in acidic solutions, and less stable in neutral and alkaline solutions, particularly in the light. Pyridoxol is more stable than pyridoxal and pyridoxamine.

Amino acids, peptides and proteins react with pyridoxal and its phosphate in neutral solutions to form imines (formerly known as Schiff bases). This reaction is analogous to reactions of reducing sugars in the Maillard reaction (Figure 5.21). Pyridoxal 5′-phosphate is more reactive than free pyridoxal. Reaction products with amino acids and proteins (imines) isomerise and are hydrolysed to pyridoxamine and the corresponding 2-oxocarboxylic acids (non-enzymatic transamination reaction). The addition of the second amino acid molecule (or thiol) to imines yields *N*,*N*′-substituted diamines. For example, reduction of imines by ascorbic acid or reductones arising in the Maillard reaction yields stable pyridoxylamines (*N*-substituted pyridoxamines). Imines and diamines formed from imines and amino acids are physiologically fully available, pyridoxylamino acids are very resistant to acid hydrolysis and, therefore, less physiologically active. Reaction of pyridoxal 5′-phosphate with proteins generates about 20% of bound forms (8% imines and diamines and 8% of pyridoxylamino acids).

Amino acids containing other reactive functional groups react with pyridoxal to form heterocyclic compounds. Reaction with cysteine during sterilisation of milk gives a thiazolidine derivative (**5-82**). Reaction with tryptophan gives a β-carboline derivative (**5-83**). On a small scale, the Strecker degradation of amino acids yields the corresponding Strecker aldehydes. Hydrogen sulfide produced by the degradation of cysteine reacts with the carbonyl group of pyridoxal analogously to the amino group of amino acid or protein, and an unstable mercaptal forms as an intermediate. It is a precursor of pyridoxylthiol and bis(4-pyridoxyl)disulfide. Reaction with protein-bound cysteine yields mixed disulfides (Figure 5.22). Pyridoxylthiol and the corresponding disulfide show only low activity of vitamin B_6.



5-82, thiazolidine derivative of pyridoxal

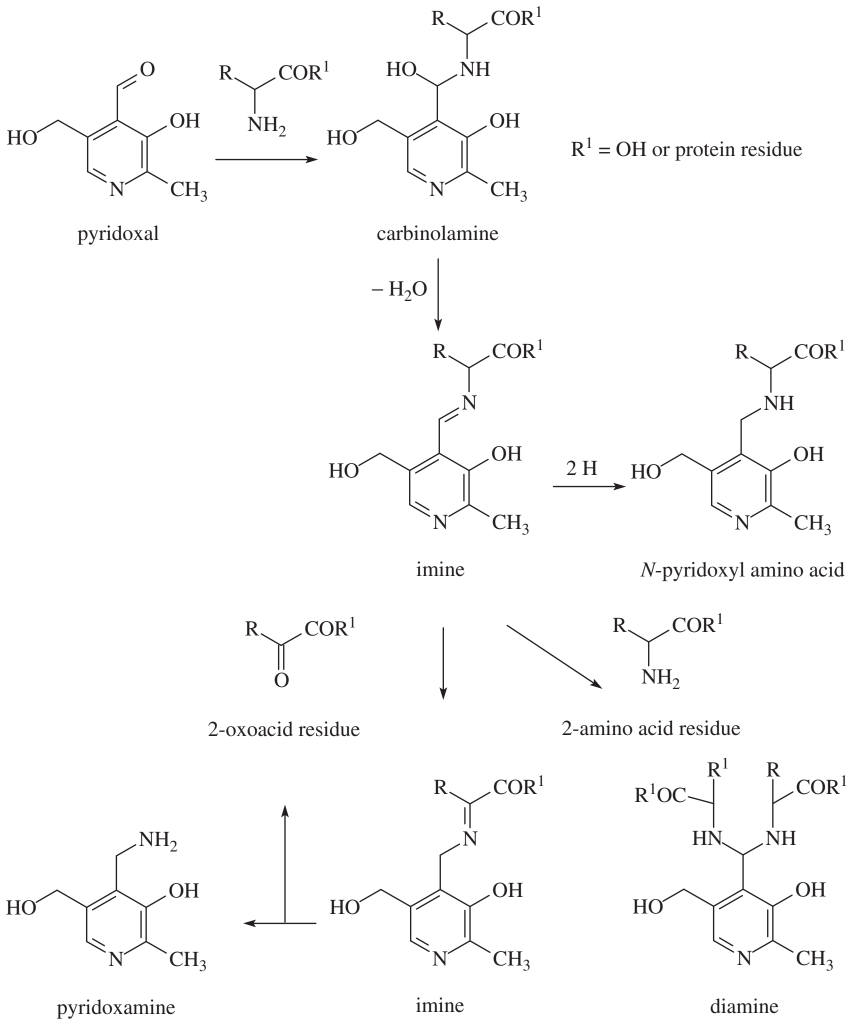


Figure 5.21 Reactions of pyridoxal with amino acids (R^1 = OH) and proteins (R^1 = NHR^2).

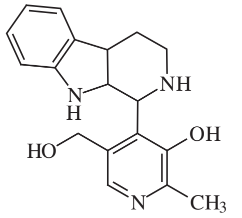

5-83, β-carboline derivative of pyridoxal

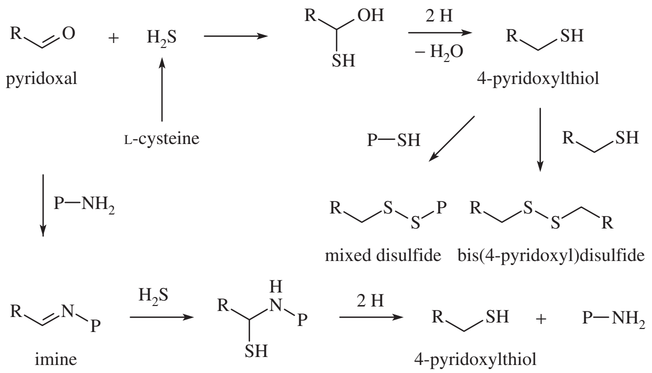

Figure 5.22 Reaction of pyridoxal with thiol group of cysteine and proteins (P = protein residue).

5.10.7 Changes in foods

Vitamin losses during food storage and processing vary considerably in different commodities according to the predominant form of the vitamin. In foods of plant origin that contain less volatile pyridoxol, vitamin losses are usually small. In foods of animal origin containing reactive pyridoxal, losses are higher. Losses are also attributed to vitamin leaching and pyridoxal reaction with proteins.

5.10.7.1 Meat and meat products

Raw meat contains pyridoxal phosphate as the main vitamin form, whereas cooked meat predominantly contains a product of its transamination pyridoxamine phosphate. For example, the main form of vitamin B_6 in raw chicken meat is pyridoxal phosphate (56%), followed by pyridoxamine phosphate (42%) and pyridoxamine (2%). The main form in roasted chicken meat is pyridoxamine phosphate (70%), followed by pyridoxal phosphate (21%), pyridoxol (7%) and pyridoxamine (2%). Vitamin retention in roasted meat is about 45–65%.

5.10.7.2 Milk and dairy products

During conventional methods of milk processing, vitamin losses are small. For example, during pasteurisation the loss is up to 5%, while loss in UHT milk does not exceed 10%. Higher losses are caused by subsequent storage, so that the total losses in UHT milk are about 40–45%. During the heat treatment of milk, pyridoxal is partly transformed into pyridoxamine. Fresh milk mainly contains pyridoxic acid (38%), pyridoxal phosphate (32%), pyridoxal (24%), pyridoxamine (4%) and pyridoxamine phosphate (2%). In pasteurised milk, the main form is pyridoxal (41%), followed by pyridoxal phosphate (24%), pyridoxic acid (20%), pyridoxamine phosphate (9%) and pyridoxamine (6%).

During pasteurisation and especially during drying, pyridoxal reacts with cysteine and lysine (free amino acids and amino acids bound in proteins). For example, milk powder contains 30–70% of the original amount of vitamin. The losses are higher when milk is exposed to sunlight.

5.10.7.3 Cereals and cereal products

The main form of vitamin B_6 in cereals is free pyridoxol and pyridoxol bound to glucose. The vitamin content of flour depends on the degree of milling. In dough and also in bread, the losses are small and do not exceed 15%. Vitamin retention in cooked pasta is 50–70%.

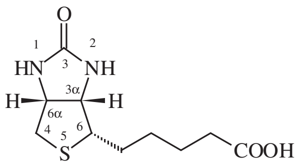
5.10.7.4 Fruits and vegetables

Relatively large losses occur during canning and cooking of vegetables (40–50%), while fruit losses are somewhat lower (approximately 40%).

5.11 Biotin

5.11.1 Structure and terminology

Biotin is composed of an ureido (tetrahydroimidizalone) ring fused with a tetrahydrothiophene ring substituted with pentanoic (valeric) acid. The biotin molecule contains three asymmetric carbon atoms. Only one of eight possible isomers, that is (3*aS*,4*S*,6*aR*)-5-[2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanoic acid, known as *d*-biotin or (+)-biotin (**5-84**), occurs in nature and is biologically active. Biotin was also known as vitamin B_7, vitamin H and previously as bios II, factor X or coenzyme R.

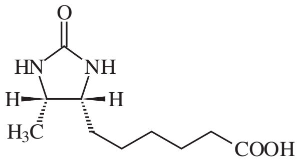


5-84, (+)-biotin

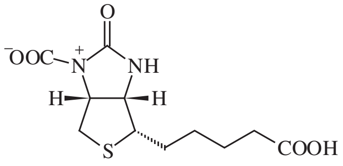
5.11.2 Biochemistry

Most microorganisms, fungi and higher plants synthesise biotin from pimelic acid and alanine. Pimelic acid is a product of oxidative cleavage of higher fatty acids. The primary product of the biosynthesis is dethiobiotin (**5-85**), which reacts with methionine and gives biotin. Biotin is found as a prosthetic group

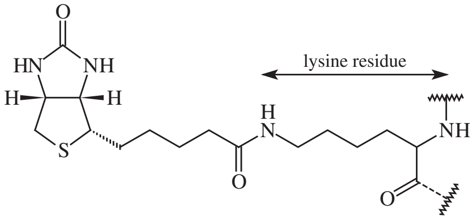
of many enzymes that catalyse the transfer of carbon dioxide. An intermediate of these reactions is *N*-carboxybiotin (**5-86**). Biotin is bound in enzymes through an amide bond provided by the ε-amino group of lysine as the so-called *N*-ε-biotinyl-L-lysine (biocytin, **5-87**). Usually, three groups of enzymes with biotin as a cofactor are recognised: carboxylases, transcarboxylases and decarboxylases. They act in the biosynthesis of fatty acids and the catabolism of branched chain amino acids.



5-85, dethiobiotin

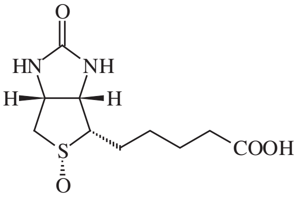


5-86, *N*-carboxybiotin

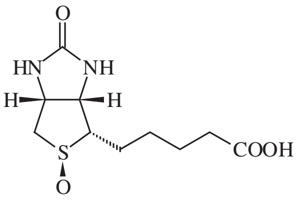


5-87, biocytin

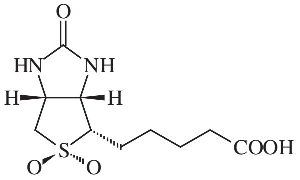
Only free biotin is absorbed from foods. Biotin bound to proteins must be hydrolysed by the enzyme biotinidase (biotinamide amidohydrolase). Excess free biotin is excreted in urine, along with its metabolites (such as the oxidation products biotin sulfoxides, **5-88** and **5-89**). Bound forms of biotin are excreted in the faeces. (+)-Biotin sulfone (**5-90**), also known as *d*-biotin-*d*-sulfone, is the (5*S*)-enantiomer.



5-88, (+)-biotin sulfoxide



5-89, (–)-biotin sulfoxide



5-90, biotin sulfone

5.11.3 Physiology and nutrition

The need for biotin is very low and is usually covered by the vitamin from food and that produced by intestinal microflora. The daily dietary intake is estimated at 50–100 μg, although some sources have reported an even higher intake (150–300 μg). The recommended daily intake for infants (up to 6 months of age) is 5 μg; for infants up to 7–12 months it is 7 μg; for children from 1 year to 3 years, 8 μg; for older children from 4 to 8 years, 12 μg; from 9 to 13 years, 20 μg; for adolescents (14–18 years), 25 μg; for elderly people (also for pregnant women) 30 μg; and for lactating women 35 μg. Spontaneous deficiency is rare and mild. The most common deficiency occurs when the diet is mainly based on the consumption of raw eggs, because raw egg white contains the basic, water-soluble glycoprotein avidin, which forms a very strong complex with biotin in which the vitamin is bound by non-covalent bonds. Biotin bound by avidin (avidin is a biotin antagonist) is not available. Denatured protein does not react with biotin. Vitamin deficiency and avitaminosis manifests by hair loss (alopecia), conjunctivitis (also called red eyes), dermatitis (red rash around the eyes, nose, mouth and genital area) and in adults by neurological symptoms (depression, lethargy and hallucinations).

5.11.4 Use

The enrichment of foods with biotin occurs only rarely.

5.11.5 Occurrence

Biotin is found in a range of foods, but the concentration in most of them is usually low (Table 5.8). It is partly present as a free compound (milk, fruits and vegetables) and partly bound to proteins (animal tissues, plant seeds and yeast). Yeast autolysates, for example, contain free biotin and its precursors and analogues. These biotin vitamers, mainly dethiobiotin (**5-85**), biotin sulfone (**5-90**) and biocytin (**5-87**), are degradation products of enzymes containing biotin.

5.11.5.1 Foods of animal origin

Good sources of biotin are egg yolk and organ meats (especially liver and kidney). Milk has a lower vitamin content.

5.11.5.2 Foods of plant origin

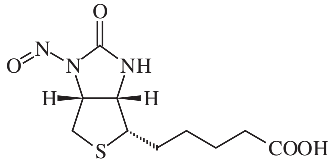
Rich sources are some vegetables, such as peas and cauliflower (about 0.1 mg/kg), cereals, cereal products and legumes. The biotin content in flour is strongly dependent (as is the content of all B group vitamins) on the flour extraction rate. In white flour a little over 10% of the original vitamin present remains in the grain. However, only a small proportion of biotin in wheat is available, better availability comes from maize and soybeans.

5.11.5.3 Other sources

A high level of biotin is found in yeast and mushrooms (about 0.2 mg/kg).

5.11.6 Reactions

Biotin is stable when heated, in the light, in neutral and strongly acidic solutions. It is unstable in alkaline media. It is easily oxidised by hydrogen peroxide and other oxidants to a mixture of isomeric (+)- and (−)-sulfoxides (**5-88** and **5-89**), eventually to biotin sulfone (**5-90**). Sulfoxides also form as metabolic products of microorganisms. They are fully available, whereas sulfone is unavailable as a vitamin. Nitrogen of a ureido ring may be nitrosated to nitrosobiotin (**5-91**) in the presence of nitrites or nitrogen oxides.



5-91, nitrosobiotin

5.11.7 Changes in foods

Biotin is very stable during food processing. Losses in hydrothermal processes are mainly caused by leaching into the water.

5.11.7.1 Meat and meat products

Biotin retention in cooked meat is relatively high, at about 80%.

5.11.7.2 Milk and dairy products

Pasteurisation of milk results in 10–15% losses of biotin. Milk drying losses are higher, but subsequent storage does not influence the vitamin level substantially. Biotin concentration in cheeses is lower by about 20–35% compared with milk. The biotin content of yoghurts is influenced by the microflora (*Lactobacillus* spp.) used, and is lower than in milk by about 45–60%. Some bacteria (e.g. bacteria of the genus *Micrococcus*) produce biotin, and its content in yoghurt may then increase by 5–25%.

5.11.7.3 Cereals and cereal products

Biotin losses during the baking of bread and other cereal products are small. Cooking legumes results in loss of vitamin, which reaches 5-15%, depending on the time of soaking.

5.11.7.4 Fruits and vegetables

During preservation of fruit and vegetables about 30% of biotin is lost. This large proportion is caused by leaching and can therefore be regarded as a loss only when the brew is not consumed.

5.12 Folacin

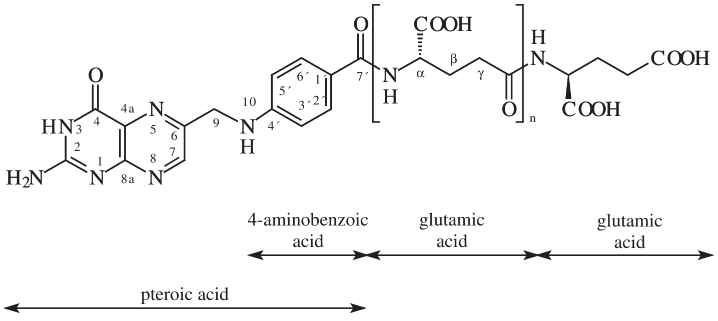
5.12.1 Structure and terminology

Folacin is the name for the biologically active derivatives of folic (pteroylglutamic) acid (**5-92**), formerly also known as vitamin B_9, vitamin B_c or vitamin M. The basis of its structure is pteroic acid, systematic name 4-[(pteridine-6-ylmethyl)amino]benzoic acid, which is hypothetically derived from 6-hydroxymethylpterin and 4-aminobenzoic acid. The carboxyl group of pteroic acid is conjugated, via an amide bond, with one or more L-glutamic acid units, typically with three to eight molecules ($n = 3–8$). These compounds are called glutamyl peptides or folate polyglutamates. The active form is (6*S*)-5,6,7,8-tetrahydrofolic or (6*S*)-5,6,7,8-tetrahydropteroylglutamic acid (**5-93**), for short H_4PteGlu or FH_4, with a reduced pteridine (more precisely pyrazine) ring. Heptaglutamate was previously known under the names of chick growth factor or vitamin B_{11}.

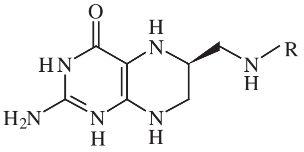
5.12.2 Biochemistry

Many microorganisms and plants are capable of *de novo* synthesis of 7,8-dihydrofolic (7,8-dihydropteroylglutamic) acid (7,8-H_2PteGlu, **5-94**). Animals can only reduce this form of vitamin to tetrahydrofolic acid. They are also able to reduce the folic acid to dihydrofolic acid and can hydrolyse or add additional glutamic acid residues. The starting compound for the biosynthesis of 7,8-dihydrofolic acid is guanosine 5′-triphosphate (GTP). Reactions with 4-aminobenzoic acid (which results from chorismic acid via 4-amino-4-deoxychorismic acid) and with glutamic acid proceed in the later stages of biosynthesis.

The activity of folacin is similar to the activity of cobalamins. It is linked with the transfer of one of the carbon functional groups, such as methyl (CH_3–), methylene (–CH_2–), formyl (–CH=O) and other groups whose donor is mainly choline, glyoxylic acid, serine and other compounds. These functional groups are bound



5-92, folic acid



5-93, tetrahydrofolic acid (H_4PteGlu, for R see **5-87**)

to N-5 or N-10 of tetrahydrofolic acid (**5-95** to **5-100**). Vitamin A is a cofactor for enzymes that act mainly in the metabolism of amino acids (e.g. transamination reactions and synthesis of creatine), purine and pyrimidine nucleotides. Folacin, along with corrinoids, has an important role in homocysteine metabolism, which is one of the risk factors for the origination and development of cardiovascular diseases.

5-100, 10-formyl-H_4PteGlu

5.12.3 Physiology and nutrition

The recommended daily intake of folic acid is 0.065–0.6 mg. Intake at the lower limit is recommended for infants (0.065 mg, 0–6 months; 0.08 mg, 7–12 months) and young children and teenagers (0.15 mg, 1–3 years; 0.2 mg, 4–8 years; 0.3 mg, 9–13 years), the upper income limit is recommended for teenagers, older men and women (0.4 mg; 14–19 years) and pregnant and lactating women (0.6 mg).

Daily intake of 0.6 mg or higher can no longer be obtained from food due to our eating habits, so intake through food supplements is therefore recommended. Because of the difference in bioavailability between folic acid in food supplements and the different forms of folacin found in food, the dietary folate equivalent (DFE) system was established. One DFE is defined as 1 μg of dietary folacin or 0.6 μg of supplemented folic acid. The tolerable Upper intake Level (UL) for folate is 1 mg for adult men and women and 800 μg for pregnant and lactating (breast-feeding) women under 18 years of age. Supplemental folic acid should not exceed the UL to prevent folic acid from masking symptoms of cobalamine deficiency.

Folacin deficiency may lead to glossitis, diarrhoea, depression and confusion. Deficiency anaemia may develop especially in pregnancy and in elderly people. Symptoms of deficiency are similar to symptoms of cobalamine deficiency (known as macrocytic anaemia). Megaloblastic anaemia, the most common cause of macrocytic anaemia, is due to a deficiency of either cobalamine or folic acid (or both). Deficiency in the early stages of pregnancy can lead to developmental defects of the foetus (spinal cord defects and incomplete development of the brain). Women who are at increased risk will need increased daily intake of folic acid.

5.12.4 Use

For enrichment of foods, relatively stable synthetic forms of the vitamin are used, such as 5-formyltetrahydrofolic (**5-99**), 5-methyltetrahydrofolic (**5-95**) and tetrahydrofolic (**5-93**) acids.

5.12.5 Occurrence

Folacin exists primarily in the form of reduced tetrahydrofolates (**5-93**) containing a variable number of glutamic acid units. For example, oranges contain predominantly pentaglutamate (about 40% of the total vitamin content) and tetraglutamate (about 10%), the main form in lettuce is pentaglutamate and monoglutamate (both forms represent about 30% of the vitamin content), the main form in most leafy vegetables is heptaglutamyl conjugate, and fresh meat vitamin consists mainly of penta-, hexa- and heptaglutamate, the major form in stored meat is triglutamate.[9] Fresh foods mostly contain 5-methyltetrahydrofolate (**5-95**) and 10-formyltetrahydrofolate (**5-100**). The total vitamin content in common foods is given in Table 5.8.

5.12.5.1 Foods of animal origin

Particularly important sources of folacin are eggs and offal. The main natural forms of folacin in animal materials are polyglutamylpeptides (the dominating form is the pentaglutamyl conjugate) derived from 5-methyltetrahydrofolic acid, abbreviated to 5-methyl-H_4PteGlu$_n$ (about 50%), which is followed by 10-formyltetrahydrofolic acid, abbreviated to 10-formyl-H_4PteGlu$_n$ (about 10%) and tetrahydrofolic acid or H_4PteGlu$_n$ (about 40%). In milk and dairy products, 25% of the total amount of vitamin is

[9] Plant and animal organisms contain a large number of pteridine derivatives. They act as germination stimulants, for example, in potatoes and soybeans or as pigments in the wings of butterflies (see Section 9.3.4). Animal organisms contain about 100 different forms of folacin.

5-methyl-H_4PteGlu$_n$, about 60% is 10-formyl-H_4PteGlu$_n$ and 15% is H_4PteGlu$_n$.

5.12.5.2 Foods of plant origin

In intact plant tissue, folates are derived from 5-methyl-H_4PteGlu$_n$ and 10-formyl-H_4PteGlu$_n$. These vitamers exist to a small extent as monoglutamates but are mainly conjugated to a chain of 2–8 glutamate moieties. Hydrolysis of folate poly-γ-glutamates to shorter poly-γ-glutamates and monoglutamates is catalysed by endogenous γ-glutamyl hydrolase. For example, 5-methyltetrahydrofolate is the predominant vitamer in sweet peppers (*Capsicum annuum*), but a significant amount of 5-formyltetrahydrolfolate and some 10-formylfolate are also present. Folate content in red and green peppers differs markedly (0.70–0.21 mg/kg, respectively). A significant amount of folic acid (PteGlu$_n$) and its derivatives also occurs in cereals and legumes. In wheat and rye (also in bread and other cereal products and legumes), for example, 38–55% of the vitamin is in the form of 10-formyl-H_4PteGlu$_n$, 5–20% as 5-methyl-H_4PteGlu$_n$ and 3–8% in the form of H_4PteGlu$_n$. In addition, 12–21% of folacin is present as 10-formyl-PteGlu$_n$ and 12–23% as PteGlu$_n$. A rich source of folate are rosehips. Their folate content is 4–6 mg/kg based on dry matter and 1.60–1.9 mg/kg based on the fresh weight (edible part). Fresh citrus juices contain relatively high amounts of mono- and polyglutamyl forms of 5-methyl-H_4PteGlu (0.01–0.13 mg/l) and folic acid (0.07–0.21 mg/l). The concentration of 5-methyl-H_4PteGlu is generally greater than that of folic acid in orange juice, grapefruit juice contains the least amount of 5-methyl-H_4PteGlu but relatively large quantities of folic acid. A relatively high amount (60%) of the 5-methyl-H_4PteGlu is present as the monoglutamyl form. Good folate sources are also strawberries. Their folate content in different strawberry cultivars varied from 0.30 to 0.69 mg/kg fresh weight.

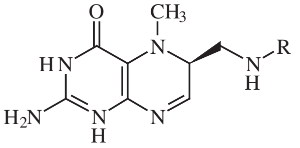
5.12.5.3 Other sources

Rich sources of dietary vitamin are yeast and higher fungi (Basidiomycetes). The dominating folate forms in commercial dry baker's yeast were found to be tetrahydrafolate and 5-methyltetrahydrofolate with a total folate content of 28.9 mg/kg.

5.12.6 Reactions

Folacin is unstable in acid, neutral and alkaline solutions, at higher temperatures and especially in the light in the presence of oxygen, in the presence of transition metals and riboflavin. Stability varies depending on the number of bound glutamate residues and groups at either N-5 or N-10, or a bridge that connects these two positions. Folic and 5-formyltetrahydrofolic acids are relatively stable against oxidation, and less stable is 5-methyltetrahydrofolic acid. Oxidation and other reactions commonly occur during processing and storage of food are shown in Figure 5.23.

In fresh vegetables 5-methyl-H_4PteGlu$_n$ is oxidised in acidic solutions creating unstable but bioavailable vitamin 5-methyl-5,6-dihydrofolic acid (5-methyl-5,6-H_2PteGlu$_n$, **5-101**). This compound isomerises in acidic solutions (during cooking or in the acidic environment of the stomach) to 5-methyl-5,8-dihydrofolic acid (5-methyl-5,8-H_2PteGlu$_n$, **5-102**), which is not bioavailable. Both these forms can be reduced to 5-methyl-H_4PteGlu$_n$ by ascorbic acid. 10-Formyl-H_4PteGlu$_n$ is easily oxidised to 10-formyl-PteGlu$_n$.



5-101, 5-methyl-5,6-dihydrofolic acid (for R see **5-87**)

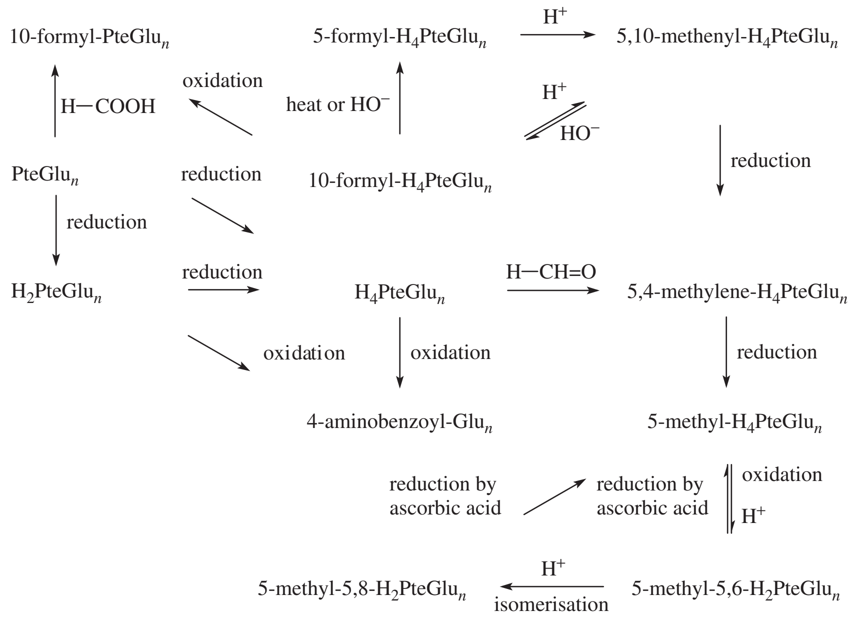


Figure 5.23 Non-enzymatic reactions of folylpolyglutamates.

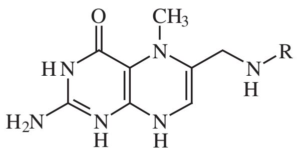

5-102, 5-methyl-5,8-dihydrofolic acid (for R see **5-87**)

During heating and in an alkaline environment, this compound spontaneously isomerises to 5-formyl-H_4PteGlu$_n$.

Folate degradation produces many different products, depending on pH and other factors. For example, tetrahydrofolic acid (H_4PteGlu) yields 4-aminobenzoyl-L-glutamic acid, 7,8-dihydrofolic acid and a number of simple pterins (Figure 5.24). In the presence of reducing sugars, folic acid may react with their degradation products, such as, the non-enzymatic glycation of folic acid by 1,3-dihydroxyacetone yields the corresponding N^2-[1-(carboxyethyl)]folic acid (Figure 5.25).

5.12.7 Changes in foods

5.12.7.1 Meat and meat products

Meat contains free folacin and folacin bound to polysaccharides. Losses during heat treatment can be as high as 95%. Most of the losses, as in other processed foods, are caused by leaching into water.

5.12.7.2 Milk and dairy products

The stability of folacin in milk depends on the presence of oxygen. Typical losses induced by pasteurisation reach 5%, losses during the production of UHT milk are 10–20%, and condensed milk contains about 75% of the vitamin of the original milk. Folacin content in yoghurt depends on the type of microorganisms used. It may be lower, but also higher than in the original milk. Hard cheeses contain 75–90% of folacin present in the raw material.

5.12.7.3 Cereals and cereal products

Folacin content in cereals is, just like the content of all B group vitamins, highest in the surface layers of the grain. The vitamin content of flour depends on the flour extraction rate. During the preparation of dough, this content does not change, but losses occur during bread baking (20% and more). Cooked pasta products lose about 20% of their folacin content.

5.12.7.4 Fruits and vegetables

When cooking and preserving vegetables, the vitamin loss is about 20–50%.

5.13 Corrinoids

5.13.1 Structure and terminology

Corrinoids are compounds with the activity of vitamin B_{12} that have the most complicated structure of all vitamins. The building block of corrinoids is the corrin ring (**5-103**), a partially hydrogenated, almost planar structure containing four reduced pyrrole rings joined into a macrocyclic ring by links between their α-positions,

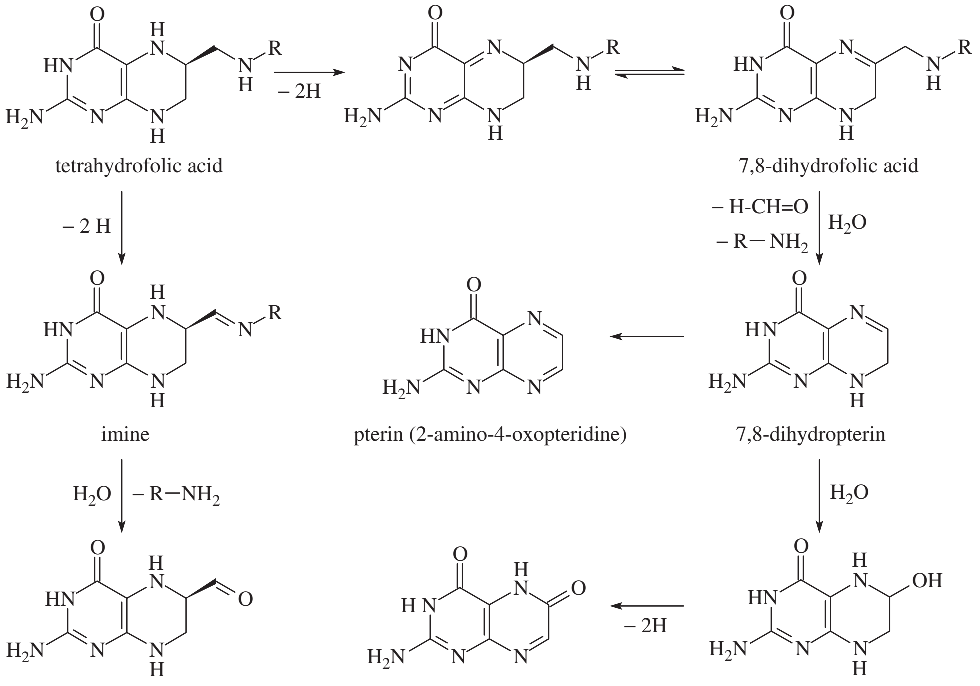

Figure 5.24 Degradation of tetrahydrofolic acid (for R see **5-87**).

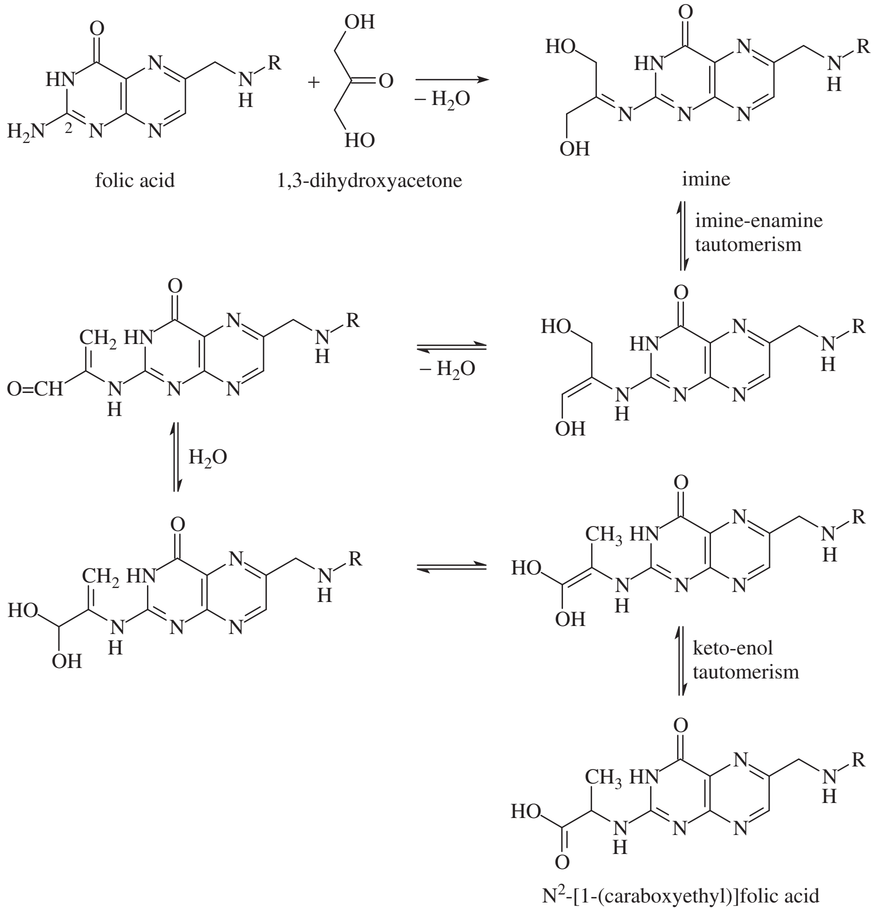

Figure 5.25 Reaction of folic acid with 1,3-dihydroxyacetone. Schneider *et al.* 2002, fig 5. Reproduced by permission of the American Chemical Society.

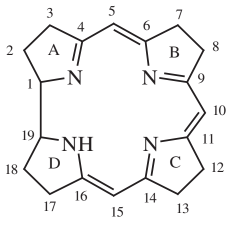
which resembles the porphyrine ring of haem and chlorophyll pigments. It differs from them, however, as three of these links are formed by one-carbon units (methylidene bridges) as in a porphyrine ring, but the other is by a direct Cα–Cα bond, therefore this structure does not contain the methylidene bridge between pyrrole rings A and D.



5-103, corrin

Substituents of the corrin ring are mostly methyl groups (six on pyrrole nuclei and two in positions 5 and 15) and amide residues, which include four propionamide residues R^2 (*bdef*) and three acetamide residues R^1 (*acg*) (**5-104**). The orientations of propionamide residues (R^2) are in the so-called α-orientation, while the acetamide residues have β-orientation. Six of the seven carboxamide groups are primary amides, the rest of the propionamide in cycle D, which is R^2 (*f*), has a complicated structure, because it is an amide of propionic acid with (*R*)-1-aminopropane-2-ol that is esterified by α-D-ribofuranosyl-5,6-dimethylbenzimidazole 3′-phosphate.

The central cobalt atom can generate up to six coordination bonds with ligands. It is coordinated to four nitrogen atoms of the pyrrole nuclei; the fifth coordination bond bounds the second nitrogen atom in 5,6-dimethylbenzimidazole in the so-called α-position. In some corrinoids, this position is not occupied. The forms of vitamin B_{12} containing 5,6-dimethylbenzimidazole are called cobalamins. Cobalamins are the only important natural substances that contain a covalent bond C–Co. Cobalt can have an oxidation degree, 3+, 2+, or 1+ according to substitution and biochemical function. For example, cyanocobalamin, hydroxycobalamine, aquacobalamin, methylcobalamin and some other compounds contain Co^{3+} and have a red colour. Enzymatic reduction (also the reaction with thiols) gives a brown product containing Co^{2+} and further reduction yields a grey–green product containing Co^{1+}. Substitution of cobalt by other metals leads to inactive products.

The sixth coordination bond in the β-position can occupy different groups or compounds, or this position may be not occupied at all. The molecule of naturally occurring cobalamine contains

cobinamide, R^1 =–CH_2–CO–NH_2, R^2 (*bde*)=–CH_2–CH_2–CO–NH_2, R^2(*f*)=–CH_2–CH_2–CO–NH–CH_2–CHOH–CH_3

adenosine, and correspondingly a 5′-deoxy-5′-adenosyl residue, bound through the carbon C-5′. This biologically active form of vitamin B_{12} is called adenosylcobalamine, adenosylvitamin B_{12} or coenzyme B_{12} (for short CoE-B_{12}). Another naturally occurring coenzyme is methylcobalamine that has a methyl group as a ligand (methylvitamin B_{12}). Other ligands are a hydroxyl group (hydroxycobalamine, vitamin B_{12a}), water (aquacobalamine, vitamin B_{12b}) or a nitro group (nitritocobalamine, vitamin B_{12c}). Synthetic vitamin B_{12} known as cyanocobalamine (metabolised to the active substance coenzyme B_{12}) is the form used in pharmaceutical preparations. It contains cyanide anion as a ligand. Cyanocobalamine can occur in the body in cases of cyanide poisoning. Depending on the reaction conditions, other ligands, such as sulfite anion in sulfitocobalamine, can also be bound to the carbon C-5′ as ligands. All these structural analogues based on the corrin skeleton are collectively known as corrinoids (**5-105**).

5.13.2 Biochemistry

Vitamin B_{12} is synthesised by many bacteria, some cyanobacteria and even some yeasts. The starting compound is 5-aminolaevulinic (5-amino-4-oxopentanoic) acid. The initial reaction sequences are the same as in the biosynthesis of porphyrins.

Vitamin produced by intestinal bacteria in the gastrointestinal tract of herbivores is absorbed in the tissues and becomes the main vitamin source for other animals in the food chain. Absorption of the vitamin produced by bacteria in the digestive tract of other animals is very small. Cobalamins found in the diet are mostly bound to proteins and released from their protein complexes through the action of acids or pepsin in the stomach. Then, in a unique process, R-protein (also referred to as cobalophilin, haptocorrin and transcobalamine I) secreted in saliva and in gastric juice, picks up the vitamin and transports it through the stomach into the small intestine, where the vitamin is liberated by the action of pancreatic proteases. The free vitamin then attaches to a glycoprotein produced by the parietal cells of the stomach, known as intrinsic factor (abbreviated IF) or gastric intrinsic factor (GIF), that carries the vitamin to the last section of the small intestine, the ileum, the cells of which contain receptors for the cobalamine-IF complex. In supplements, vitamin B_{12} is not bound to protein and therefore does not need digestive enzymes or stomach acid to be detached from protein. In addition to the IF mechanism, passive diffusion normally accounts for 1–3% of vitamin B_{12} absorbed when obtained through food. Another source of vitamin B_{12} can be food contaminated by bacteria producing vitamin B_{12}.

Coenzymes B_{12} as cofactors catalyse two completely different types of reactions. Methylcobalamine (as with folacin) acts in some transmethylation reactions (such as biosynthesis of methionine from homocysteine), collaborates with folic acid in the synthesis of DNA and red blood cells (biosynthesis of porphyrins) and in the fixation of carbon dioxide by some anaerobic acetogennic microorganisms. Enzymes using 5′-deoxy-5′-adenosylcobalamine catalyse a number of isomerisations that are otherwise only viable with difficulty (1,2-rearrangements, such as the formation of succinyl-CoA from methylmalonyl-CoA) and in some organisms they reduce ribonucleotides to deoxyribonucleotides.

5.13.3 Physiology and nutrition

Vitamin B_{12} is not absorbed very well, so relatively large amounts need to be supplied through the diet. The daily intake is estimated at 3–31 μg and about 20–70% is absorbed. The amount of vitamin B_{12} actually needed by the body of an adult is very small, probably only about 2–3 μg/day (the estimated average requirement is 2 μg/day; recommended dietary allowance is 2.4 μg/day), while pregnant and lactating women need 4 μg/day. The need is met mainly by meat, meat products and offal (about 70%; the richest dietary sources are the liver and kidney), followed by milk and dairy products (about 20%), eggs (about 9%) and cereal products (about 2%). Vegetables and fruits are very poor sources as they contain vitamin B_{12} only if contaminated by faecal bacteria.

In contrast to other water-soluble vitamins, vitamin B_{12} is not excreted quickly in the urine, but rather accumulates and is stored in the liver, kidney and other body tissues. As a result, vitamin B_{12} deficiency may not manifest itself until after 5 or 6 years of a diet supplying inadequate amounts. Since plants have no ability to synthesise vitamin B_{12}, strict vegetarians (vegans) have a greater risk of developing vitamin B_{12} deficiency and, hence, need to depend upon vitamin B_{12}-fortified foods or vitamin B_{12}-containing dietary supplements to meet their requirement. Cyanobacteria (blue–green bacteria) of the genus *Spirulina* (*Arthrospira* is in fact correct, nevertheless the older term *Spirulina* remains in use for historical reasons) is a minimal source of vitamin B_{12} and mostly contains the so-called pseudovitamin B_{12}, a derivative that is inactive in humans. Vitamin B_{12} production in higher mushrooms is controversial. It has been suggested that the source of vitamin B_{12} in mushrooms is the microorganisms living on the surface of the mushrooms or the compost containing horse manure–wheat straw that is used for cultivating mushrooms. For example, the highest vitamin B_{12} content in cultivated white button mushrooms (*Agaricus bisporus*) is found in the peel (0.7–3.5 μg/kg) than in the cap, stalk or flesh (0.07–0.8 μg/kg). Lacto-ovo vegetarians usually get enough vitamin B_{12} through consuming milk, dairy products and eggs. Many elderly people (or people after stomach resection or peptic ulcer disease operations) are also deficient because their production of the intrinsic factor needed to absorb the vitamin from the small intestine declines rapidly with age. People with intrinsic factor defects eventually develop a very serious pernicious (deadly) anaemia that manifests by a reduction of haem synthesis.

5.13.4 Use

Vitamin B_{12} is used for the enrichment of some foods (such as breakfast cereals, soy products, energy bars and yeast extract spread) and which may be the source of corrinoids for strict vegetarians and vegans. Along with other vitamins, vitamin B_{12} is added to many multivitamin preparations and to food supplements. Cyanocobalamin, which is used in most supplements, is readily converted into the coenzyme forms of cobalamin (methylcobalamin and 5′-deoxyadenosylcobalamin) in the human body.

5.13.5 Occurrence

5.13.5.1 Foods of animal origin

Corrinoids are present almost exclusively in foods of animal origin (Table 5.9). In milk, the main vitamins are adenosylcobalamine and methylcobalamine; cheeses and egg yolk contain mainly methylcobalamine.

5.13.5.2 Foods of plant origin

Cobalamine does not occur in plants, although its presence has been acknowledged in legumes. Occasional findings in vegetables or fermented foods (such as beer, miso and soy sauce) may originate from contamination by organic fertilisers or by wild types of

Table 5.9 Corrinoids content of selected foods.

Food	Edible portion (μg/kg or μg/l)	Food	Edible portion (μg/kg or μg/l)
Pork meat	6–10	Fish	13–28
Beef meat	112–20	Clams	11
Chicken meat	2–5	Milk	3–38
Pork liver	260–1220	Cheese	6–33
Beef liver	590–830	Eggs	7–9
Pork kidney	85–200	Yeast extract spread	5

microorganisms. The vitamin probably comes from the biomass of these microorganisms. It is synthesised by many bacteria and some yeasts, such as *Candida utilis*.

5.13.6 Reactions

Despite their complex structure, cobalamins are relatively stable in solution at pH 4–7. In acidic solutions, cyanocobalamine gives hydroxycobalamine, which in acidic and neutral solutions exists as aquacobalamine. Acid hydrolysis of corrinoids produces mono-, di- and tricarboxylic acids from the bound propionamides. Most susceptible to hydrolysis is the propionamide in position *e*. Hydrolysis of acetamide chains requires more drastic conditions, which simultaneously release the nucleotide and isopropylamine group in position *f*. Altogether, the acidic hydrolysis releases six molecules of ammonia. Hydrolysis in dilute solutions of alkali metal hydroxides yields biologically inactive dehydrovitamin B_{12} (the biologically inactive form with a lactam ring attached to ring B of the cobinamide ring). Alkaline hydrolysis further produces cyanocobinamide, 1-α-D-ribofuranosyl-5,6-dimethylbenzimidazole and phosphate. Under alkaline conditions a *c*-lactone ring in ring B also results.

Photodegradation of adenosylcobalamine in the absence of oxygen gives cobalamine and 5,8-cycloadenosine. In the presence of oxygen, aquacobalamine and adenosine-5′-carbaldehyde are produced. Photolysis of methylcobalamine in aqueous solutions and in the absence of oxygen produces, aquacobalamine and methane as major products, or aquacobalamine and formaldehyde if in the presence of oxygen. In aqueous solutions in the presence of ascorbic acid, aquacobalamine is reduced, hydroxylated at C-5, forms a lactone ring between the carboxyl *c* and C-6 of the corrin ring and yellow xanthocorrinoids are produced as the final products. The hydroxyl group in hydroxycobalamine can be easily substituted by another ligand, such as a cyanide anion and chlorine anion. The corrin ring can also be halogenated at C-10, for example, by chloramine-T (used as a disinfection and sanitation agent). The reaction of methylcobalamine with metal ions in aqueous solutions produces methyl derivatives of metals (transfer of methyl anion CH_3^-) and aquacobalamine.

5.13.7 Changes in foods

During food processing and culinary operations, vitamin B_{12} seems to be very stable. The main reason for the loss is leaching into water.

5.13.7.1 Meat and meat products

Vitamin losses during meat processing are dependent on the technology used. They can reach 55–70% of the original amount of the vitamin.

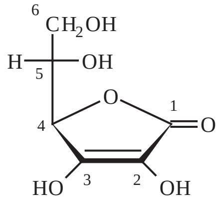
5.13.7.2 Milk and dairy products

Under normal processing conditions, the vitamin content in milk does not change too much. The loss caused by pasteurisation is up to 10% and about 10–20% in UHT milk. In the manufacture of hard cheeses, the vitamin retention is about 60–90% of the original content. Dairy products fermented using *Propionibacterium shermanii* (such as Swiss-type cheeses), have increased vitamin content in comparison with the original milk (up to 30 times).

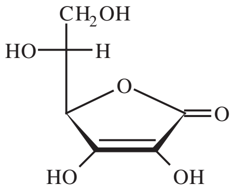
5.14 Vitamin C

5.14.1 Structure and terminology

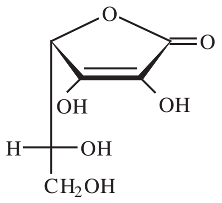
The basic biologically active compound is ascorbic acid. Of the four possible stereoisomers (asymmetric carbons C-4 and C-5), the activity of vitamin C is seen only in L-ascorbic acid (L-*threo*-hex-2-enonic acid 1,4-lactone; formerly called ceritaminic acid, 2-keto-L-gulonic acid, L-*xylo*-hex-2-ulosonic acid and later L-*xylo*-ascorbic acid). The D-isomer of ascorbic acid (D-*xylo*-ascorbic acid) and the second pair of enantiomers, known as L- and D-isoascorbic acids (**5-106** to **5-109**), do not show vitamin C activity. Previously, these acids, which are γ-lactones of L- and D-*erythro*-hex-2-enonic acids, were known as L- and D-erythorbic acids or L- and D-*arabino*-ascorbic acids.



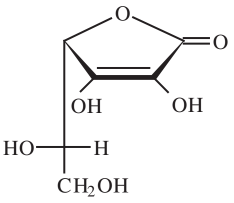
5-106, L-ascorbic acid



5-107, D-isoascorbic acid



5-108, D-ascorbic acid



5-109, L-isoascorbic acid

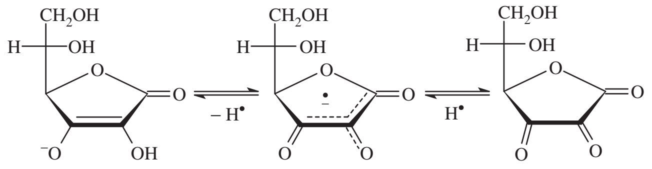


Figure 5.26 Biologically active forms of vitamin C.

The name vitamin C refers not only to L-ascorbic acid, but also to the whole reversible redox system that includes the one-electron oxidation product of L-ascorbic acid, known as L-ascorbyl radical (or L-monodehydroascorbic acid or semidehydroascorbic acid), and the two-electron oxidation product of L-ascorbic acid known as L-dehydroascorbic acid (Figure 5.26). Ascorbic acid and ascorbyl radical mainly occur as anions in solutions at physiological pH.

5.14.2 Biochemistry

Ascorbic acid is synthesised by all green plants that provide their energy needs through photosynthesis (photoautotrophic plants). Almost all living organisms, insects and invertebrates, most fish and many species of birds and mammals, have the ability to synthesise ascorbic acid. Notably, humans, but also gorillas, chimps, orangutans and some monkeys, frutivorous (fruit eating) bats, guinea pigs and capybaras lack this ability.

Plants synthesise ascorbic acid from the active form of D-mannose, which is GDP-D-mannose. In mammals, the starting compound is UDP-D-glucose. Microorganisms and higher fungi synthesise 6-deoxy-L-ascorbic acid from L-fucose and D-erythroascorbic acid from D-arabinose.

The functions of ascorbic acid are related primarily to its redox properties. In plants it has a role in photosynthesis; it regulates the amount of active oxygen species and also acts in the growth and differentiation of cells. Cleavage of the molecule of ascorbic acid also creates specific metabolites, such as L-threonic, L-tartaric, L-glyceric and oxalic acids.

In animals, ascorbic acid is involved primarily in hydroxylation reactions ongoing in the body. The most important oxidation reaction is hydroxylation of proline to 3-hydroxyproline and of lysine to 5-hydroxylysine in procollagen, which is related to protein biosynthesis of connective tissue. Another important reaction is hydroxylation of 3,4-dihydrophenylethylamine (dopamine) to norepinephrine (noradrenaline) and biosynthesis of betaine carnitine. Norepinephrine, along with other so-called catecholamines, acts as a carrier of chemical information (hormone and neurotransmitter); carnitine acts as a carrier of fatty acid residues through the membrane of the mitochondria. Vitamin C also participates in the biosynthesis of mucopolysaccharides, prostaglandins, homogentisic acid (the precursor of tocopherols and plastoquinones), participates in the absorption of ionic forms of iron, its transport, stimulating the transport of sodium, chloride and possibly also of calcium ions, allows the transfer of sulfate in the form of ascorbyl-2-sulfate and acts in the metabolism of cholesterol, drugs and in many other reactions.

Very important reactions related to the antioxidant properties of vitamin C are reactions with active oxygen forms, with free radicals and with oxidised forms of vitamin E, respectively, which protects vitamin E and lipid membranes from oxidation. Vitamin C has a protective function for labile forms of folic acid. It also inhibits formation of nitrosamines and acts in this way as a modulator of mutagenesis and carcinogenesis. Many other activities of vitamin C are still only partially understood or not even at all.

5.14.3 Physiology and nutrition

A daily dose of 10 mg of L-ascorbic acid is sufficient to prevent scurvy. In the past, the recommended daily intake was 30 mg (50 mg for adolescents and 60 mg for pregnant women). Today, recommendations for vitamin C intake have been set by various national agencies and range from 40 to 95 mg/day (e.g. 40 mg are recommended in Great Britain, 45 mg are recommended by the WHO, and 60–95 mg are recommended in the United States). The US-recommended daily dietary intake of vitamin C is 30 mg for infants, 45 mg for children, 60 mg for adult men and women, 80 mg for pregnant women (second and third trimesters) and 100 mg during lactation. For patients with respiratory diseases and during convalescence and in other cases (such as radiation therapy), the daily doses may reach 500–1000 mg or even more. The tolerable upper intake levels for adult men and women are 2000 mg/day. The possible adverse effects of high doses of vitamin C must also be considered. These include the so-called rebound scurvy (the vitamin C dependency state that occurs in the foetus of a woman taking megadoses of vitamin C during pregnancy), increased excretion of oxalic acid in the urine (which may lead to stones in the urinary tract), an increased absorption of iron in those susceptible to iron overload, increased absorption of toxic metals and interference with certain medications (e.g. warfarin, aspirin, antidepressants and contraceptive pills).

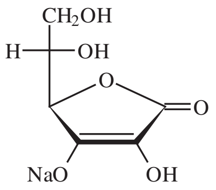
The total vitamin C requirement is met by foods, especially potatoes (that cover about 20–30%), vegetables (about 30–40%) and fruits (30–35%). Milk covers less than 10% of the vitamin need. Deficiency or hypovitaminosis manifests in a number of non-specific symptoms, most commonly known as spring fatigue. The best-known syndrome of acute avitaminosis is scurvy. According to some new findings, dehydroascorbic acid has somewhat lower activity than ascorbic acid.

Oxidoreductases (such as ascorbate oxidase, ascorbate peroxidase, monodehydroascorbate reductase, dehydroascorbate reductase, superoxide dismutase and ascorbate: cytochrome-*b* reductase) that act in the metabolism of vitamin C in animals and plants can be considered to be antivitamins C. Other oxidoreductases, such as enzymes known trivially as polyphenoloxidases and some others, may indirectly cause loss of ascorbic acid.

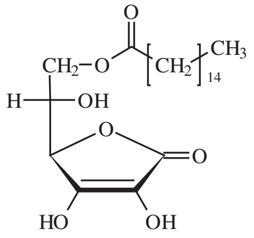
5.14.4 Use

Ascorbic acid is widely used as a food additive due to its properties (vitamin, antioxidant and chelating agent), especially in canning

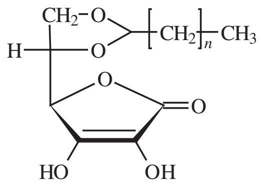
and fermentation processes, but also in meat, fat and cereal technologies. The water-soluble salt of L-ascorbic acid sodium L-ascorbate (**5-110**) and the lipophilic compound 6-palmitoyl-L-ascorbic acid (L-ascorbyl 6-palmitate, **5-111**), which inhibits the formation of nitrosamines in cured meat and meat products, are also used as antioxidants. Non-polar acetals of L-ascorbic acid derived from fatty aldehydes (dodecanal to octadecanal, **5-112**) were used as inhibitors of nitrosamine formation in the production of ham, as they are more stable than ascorbyl palmitate. D-Isoascorbic acid can in many cases (such as an antioxidant) replace L-ascorbic acid, but it cannot be used to improve the baking properties of flour (D- and L-isoascorbic acids are less active than L-ascorbic acid, D-ascorbic acid is completely inactive) because it is a stereospecific reaction.



5-110, sodium L-ascorbate

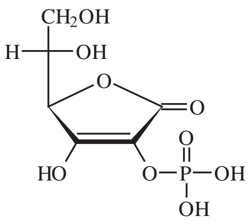


5-111, L-ascorbyl 6-palmitate

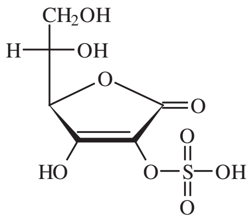


5-112, L-ascorbic acid acetals (n=10–16)

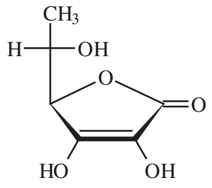
Sodium ascorbate and ascorbic acid esters, such as ascorbyl 6-palmitate (**5-111**) and ascorbyl 2-phosphate (**5-113**), are fully bioavailable, while ascorbyl 2-sulfate (**5-114**) is a completely inactive vitamin form. Phosphate and sulfate are about 20 times more stable to oxidation than the free acid. D-Isoascorbic acid (**5-107**) shows only 5–20% activity, 6-deoxy-L-ascorbic acid (**5-115**), found in fungi, has about 30% activity and the bound ascorbic acid form ascorbigen has 15–20% of the activity of ascorbic acid. Ascorbic acid 2-*O*-β-D-glucoside, systematic name 2-*O*-(β-D-glucopyranosyl)-L-ascorbic acid (**5-116**), has the same biological activity as ascorbic acid and is also stable against oxidation.



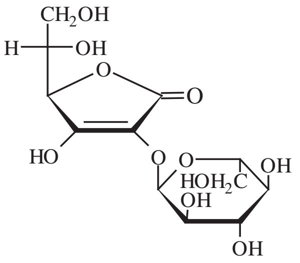
5-113, L-ascorbyl 2-phosphate



5-114, L-ascorbyl 2-sulfate



5-115, 6-deoxy-L-ascorbic acid



5-116, 2-*O*-(β-D-glucopyranosyl)-L-ascorbic acid

5.14.4.1 Fruits and vegetables

Ascorbic acid is added to fruit juices, stewed fruit and frozen fruit to prevent undesirable changes in flavour caused by oxidation during storage and processing. The removal of oxygen in airtight containers requires the addition of 3–7 mg of ascorbic acid per cm^3 of air present (depending on pH and temperature). Ascorbic acid at relatively low concentrations is often used as an inhibitor of the enzymatic browning reactions during peeling, slicing and drying of fruits, vegetables and potatoes. Ascorbic acid is often used in combination with citric acid as it is more stable in acid solutions, and the optimum pH of enzymes (phenolases) lies in the pH range of 6–7. A common practice is soaking the fruits or vegetables for 3 min in a solution containing 1–3% ascorbic acid, 0.1–0.3% calcium chloride and 0.015% hydrogen sulfites (they act as preservatives). In the absence of ascorbic acid, the amount of hydrogen sulfites in the bath has to be increased approximately tenfold.

5.14.4.2 Beer and wine

The addition of 20–30 mg/l ascorbic acid prevents the formation of colloidal turbidity (called chill haze) in beer, and also prevents adverse changes in flavour due to the oxidation that occurs during pasteurisation and storage. The use of ascorbic acid in winemaking can reduce the amount of sulfur dioxide used for fumigation.

5.14.4.3 Meat and meat products

The addition of ascorbic acid (or sodium ascorbate or ascorbyl palmitate) to meat and meat products together with nitrites (at a level of 60–180 mg/kg), for example, in the production of ham, is of functional and economic importance as it enhances and speeds up its production considerably. The characteristic pigment of raw meat treated with nitrites, nitroxymyoglobin, is formed approximately three times faster. The addition of ascorbic acid allows the time of smoking to be shortened and stabilises the colour of the finished

product. Ascorbic acid also enhances the inhibitory effects of nitrite on toxinogenic *Clostridium botulinum* bacteria. Additions of 300–1000 mg/kg of ascorbic acid (the optimal ratio of ascorbate and nitrite is 2 : 1; hydrophilic ascorbate is only partially effective and is often replaced by ascorbyl palmitate, which is soluble in fats) also inhibit the formation of nitrosamines. If nitrates used instead of nitrites, these are reduced to nitrites by ascorbic acid.

5.14.4.4 Bread

The baking properties of flour improve after a certain period of storage, when the products of lipid oxidation react with thiol groups of flour proteins that are oxidised and form disulfide bridges between the protein molecules. Simultaneous degradation of carotenoid pigments results in a lighter colour of the flour. The addition of ascorbic acid (10–100 mg/kg) improves the baking properties of flour, especially during the Chorleywood industrial bread making process, which reduces the time and labour input needed to make bread, thereby reducing manufacturing costs (see Section 5.14.6.1).

5.14.4.5 Fats and oils

Ascorbic acid does not occur in fats and oils, but is used, as ascorbyl palmitate, as an antioxidant in amounts ranging from 0.006 to 0.040%.

5.14.5 Occurrence

Plasma and tissues of animals, as well as of foods of plant origin, usually contain 90–95% of vitamin C as ascorbic acid, the remainder is dehydroascorbic acid.

5.14.5.1 Foods of animal origin

Vitamin C is found in significant amounts only in the liver (Table 5.10). Other foods of animal origin (meat, eggs and milk) have almost negligible importance as sources of vitamin C.

5.14.5.2 Foods of plant origin

More than 90% of vitamin C in the human diet is supplied by fruits and vegetables (including potatoes). Fresh fruits and vegetables are the richest sources of vitamin C, but its amount varies considerably between species and cultivars. The vitamin content in horticultural crops is also strongly dependent on a number of climatic environments, preharvest and postharvest factors, such as preharvest climatic conditions, maturity, harvesting methods and postharvest handling procedures. The absolute highest concentration of ascorbic acid, reaching 17–46 g/kg edible portion, accumulates in the fruit of acerola (*Malpighia emarginata, syn. A. glabra*, Malpighiaceae), also known as Barbados cherry or West Indian cherry. A comparable content of vitamin C, 23–32 g/kg edible portion is in the Australian fruit of *Terminalia ferdinandiana* (Combretaceae), commonly known as Kakadu plum or billygoat plum. Some other excellent sources of vitamin C (such as rosehips, blackcurrant and curly parsley) are usually not too important in meeting the needs of vitamin C, because they are consumed only occasionally and in small quantities. Of much greater importance are the sources with an average or lower level of the vitamin, such as potatoes that are known to be the most important source of vitamin C in the Western diet, because of the large quantities consumed (although the vitamin content in potatoes significantly decreases during storage for the winter months). In winter and spring months, subtropical fruits (especially oranges) fulfil a

Table 5.10 Vitamin C content of selected foods.

Food	Edible portion (mg/kg or mg/l)	Food	Edible portion (mg/kg or mg/l)
Meat	10–20	Carrot	50–100
Ham (pork, cured)[a]	300–500	Parsley (root)	230
Offal	50–340	Parsley (curly)	1500–2700
Milk	5–20	Chive	430
Apples	15–50	Leek	150–300
Pears	20–40	Onion	90–100
Plums	25–45	Garlic	150–160
Peaches	70–100	Horseradish	450–1200
Cherries, sweet cherries	60–300	Cabbage	170–700
Gooseberries	330–480	Cabbage (Savoy)	700–1400
Currant (red)	200–500	Brussel sprouts	1000–1030
Currant (black)	1100–3000	Broccoli	1100–1130
Grapes	20–50	Cauliflower	47–1610
Strawberries	400–700	Kohlrabi	280–700
Blackberries	90	Lettuce	60–300
Melons	130–590	Spinach	350–840
Oranges	300–600	Tomatoes	80–380
Lemons	300–640	Eggplant	80
Grapefruits	240–700	Pepper (various types)	620–3000
Pineapple	150–250	Cucumber	65–110
Bananas	90–320	Asparagus	150–400
Kiwi	700–1630	Peas	80–410
Mango	100–350	Beans	90–300
Papaya	620–980	Beetroot (red)	65
Rosehips	2500–10000	Potatoes	80–400

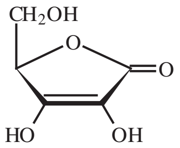
[a] Added ascorbic acid.

considerable portion of the vitamin C requirements. In the past, good sources of vitamin C were common vegetables that could be eaten year round, such as cabbage, but at present many other vegetable are regularly consumed (such as red and green peppers and tomatoes). Cereals contain only traces of vitamin C, somewhat higher levels are found only in germinating seeds.

A precursor of ascorbic acid, 2-*O*-(β-D-glucopyranosyl)ascorbic acid, was recently isolated from both the ripe fresh fruit and dried fruit of *Lycium barbarum* (Solanaceae) known as Chinese wolfberry or Chinese boxthorn, which is native to south eastern Europe and Asia. The dried fruit contains 2-*O*-(β-D-glucopyranosyl)ascorbic acid at a level of 5000 mg/kg, which is comparable to the ascorbic acid content of fresh lemons.

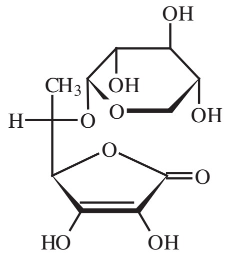
5.14.5.3 Other sources

Fungi, including the so-called higher fungi (commonly referred to as mushrooms), do not contain ascorbic acid; however, they contain a number of structurally related compounds. The main compounds are 6-desoxy-L-ascorbic acid (**5-116**), the five-carbon ascorbic acid analogue D-erythroascorbic acid, which is (4*R*)-2,3,4,5-tetrahydroxypent-2-enonic acid 1,4-lactone, also known as D-*glycero*-pent-2-enonic acid 1,4-lactone or D-*erythro*-pent-2-ulosonic acid 1,4-lactone (**5-117**). These acids occur as free compounds and as C-5 glycosides. 6-Deoxy-L-ascorbic acid, D-erythroascorbic acid, 6-deoxy-5-*O*-(α-D-xylopyranosyl)-L-ascorbic acid (**5-118**), 6-deoxy-5-*O*-(α-D-glucopyranosyl)-L-ascorbic acid (**5-119**), 5-*O*-(α-D-xylopyranosyl)-D-erythroascorbic acid (**5-120**) and 5-*O*-(α-D-glucopyranosyl)-D-erythroascorbic acid (**5-121**) were isolated from some edible fungi (of the phylum Basidiomycota), 5-*O*-(α-D-galactopyranosyl)-D-erythroascorbic acid (**5-122**) occurs in the pathogenic fungus *Sclerotinia sclerotiorum* (of the phylum Ascomycota) and 5-*O*-(α-D-glucopyranosyl)-D-erythroascorbic acid (**5-121**) were isolated from a filamentous fungus *Phycomyces blakesleeanus* (of the phylum Zygomycota). Yeast (*Saccharomyces cerevisiae*) and red bread mould (*Neurospora crassa*, Ascomycota) contain only D-erythroascorbic acid.[10] 6-Deoxyascorbic acid and its glycosides have lower activity than ascorbic acid and D-erythroascorbic acid does not show any vitamin C activity. All these compounds have similar functions in fungi to ascorbic acid in plants and animals, as they act as antioxidants.

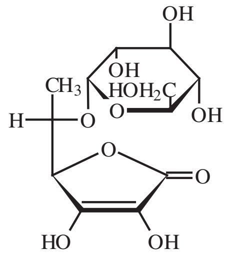


5-117, D-erythroascorbic acid

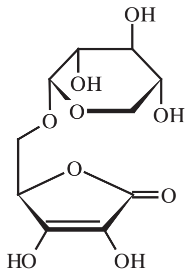
[10]The addition of non-physiological substrates (such as L-galactose) can in some microorganisms (also in the yeast *Saccharomyces cerevisiae*) induce the biosynthesis of L-ascorbic acid by enzymes that are otherwise employed in the biosynthesis of D-erythroascorbic acid.



5-118, 6-deoxy-5-*O*-(α-D-xylopyranosyl)-L-ascorbic acid



5-119, 6-deoxy-5-*O*-(α-D-glucopyranosyl)-L-ascorbic acid



5-120, 5-*O*-α-D-xylopyranosyl-D-erythroascorbic acid

5.14.6 Reactions

Both enolic hydroxyl groups of ascorbic acid can dissociate, and ascorbic acid can be considered as a diprotic acid (pK_1 = 4.25; pK_2 = 11.8). In solutions of physiological pH values, the prevailing ion is a monoanion. For example, in solutions of pH 7.4, 99.93% of ascorbic acid is present in the form of a monoanion, the rest are undissociated acid (0.06%) and dianions (0.01%). Only salts of the monovalent anion, such as sodium ascorbate, are known.

Ascorbyl radical is acid (pK = −0.96), which exists in solution as a resonance stabilised anion (as a bicyclic compound, apparently with a double bond between carbons C-2 and C-3) and with the unpaired electron located in the C-4 region. Dehydroascorbic acid occurs as the bicyclic hydrated monomer (3,6-anhydro-L-xylo-hexulono-l,4-lactone hydrate, Figure 5.27) in aqueous solutions.

5.14.6.1 Ascorbic acid

Oxidation of ascorbic acid to dehydroascorbic acid is catalysed by many enzymes (oxidoreductases), which belong to the category of ascorbic acid antivitamins. Ascorbic acid is also oxidised by atmospheric oxygen, hydrogen peroxide and various other oxidising agents. Oxidation to dehydroascorbic acid is a reversible reaction and can be carried out by various mechanisms. The loss of one electron yields a radical of ascorbic acid as an intermediate and the reaction is known as one-electron oxidation. Oxidation of ascorbic acid by the loss of two electrons yields dehydroascorbic acid, which is the first chemically stable product.

5.14.6.1.1 Enzymatic oxidation

Formation of dehydroascorbic acid

The oxidation of ascorbic acid in the enzymatically active and, especially, in the mechanically damaged plant tissues (e.g. by peeling and slicing) is mainly catalysed by ascorbate oxidase (L-ascorbate:O_2 oxidoreductase). The loss of vitamin activity in some plant tissues is associated with peroxidases and other enzymes. Ascorbate oxidase oxidises ascorbic acid in the presence of atmospheric oxygen. Generally, the reaction can be described by the following equation, where H_2A is ascorbic acid and A is dehydroascorbic acid:

$$2\,H_2A + O_2 \rightarrow 2\,A + 2\,H_2O$$

Ascorbate peroxidase employs hydrogen peroxide as a proton acceptor:

$$H_2A + H_2O_2 \rightarrow A + 2\,H_2O$$

Detailed reaction mechanisms are in fact more complex. In both cases, the primary product of oxidation of ascorbic acid is an ascorbyl radical ($HA^{\bullet}$) and its anion ($HA^{\bullet-}$) stabilised by resonance, respectively. It is relatively inert and does not react with oxygen, but comparatively quickly (the reaction half-life is about 0.2 s) provides an equimolar mixture of ascorbic acid and dehydroascorbic acid (or bicyclic dehydroascorbic acid hydrate, Figure 5.27) by disproportionation:

$$2\,H_2A \rightarrow 2\,HA^{\bullet} + 2\,H^{+} + 2\,e^{-}$$
$$2\,HA^{-} + 2\,e^{-} \rightarrow 2\,HA^{\bullet-}$$
$$2\,HA^{\bullet-} \rightarrow H_2A + A + 2\,e^{-}$$

The reaction is repeated until all the ascorbic acid is oxidised. The reaction is reversible and dehydroascorbic acid can be reduced back to ascorbic acid by reduced glutathione, cysteine and other thiols, hydroquinones and other compounds. Dehydroascorbic acid is already fairly unstable and spontaneously hydrolyses with lactone ring opening. This reaction is not reversible. Losses of vitamin caused by enzymatic oxidation in fruits and vegetables during processing can be effectively reduced by blanching using steam or boiling water, which inactivates the enzymes oxidising ascorbic acid.

Formation of oxalic, threonic and tartaric acids

The enzyme ascorbate 2,3-dioxygenase (L-ascorbate:O_2 2,3-oxidoreductase) splits the molecule of ascorbic acid between carbons C-2 and C-3 (this requires triplet oxygen, water and Fe^{2+} ions) to oxalic acid and L-threonic acid, also known as (2*R*,3*S*)-trihydroxybutanoic acid. The oxidative cleavage of ascorbic acid plays an important role in the metabolism in most plants, because, in addition to oxalic acid that plays a role in calcium metabolism, the final product is (+)-L-tartaric acid (Figure 5.28), which is formed by oxidation of threonic acid. Threonic and oxalic acids are the main decomposition products of ascorbic acid also in weakly alkaline solutions and during oxidation by singlet oxygen (Figure 5.29). D-Erythroascorbic acid in fungi decomposes in an anlogous way, yielding oxalic acid and D-glyceric acid.

5.14.6.1.2 Autoxidation and oxidation by singlet oxygen

The most important reaction is the oxidation of ascorbic acid by air oxygen (autoxidation), which mainly causes losses in foods during processing. It takes place in both the presence and absence

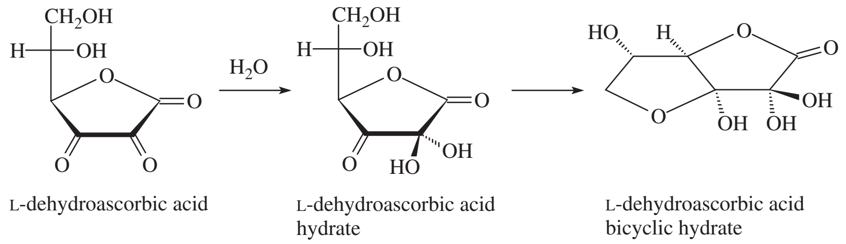

Figure 5.27 Formation of L-dehydroascorbic acid hydrate.

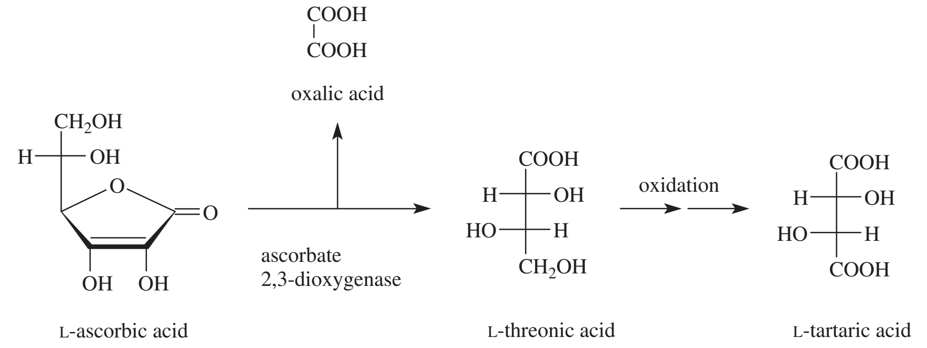

Figure 5.28 Formation of oxalic, threonic and tartaric acids.

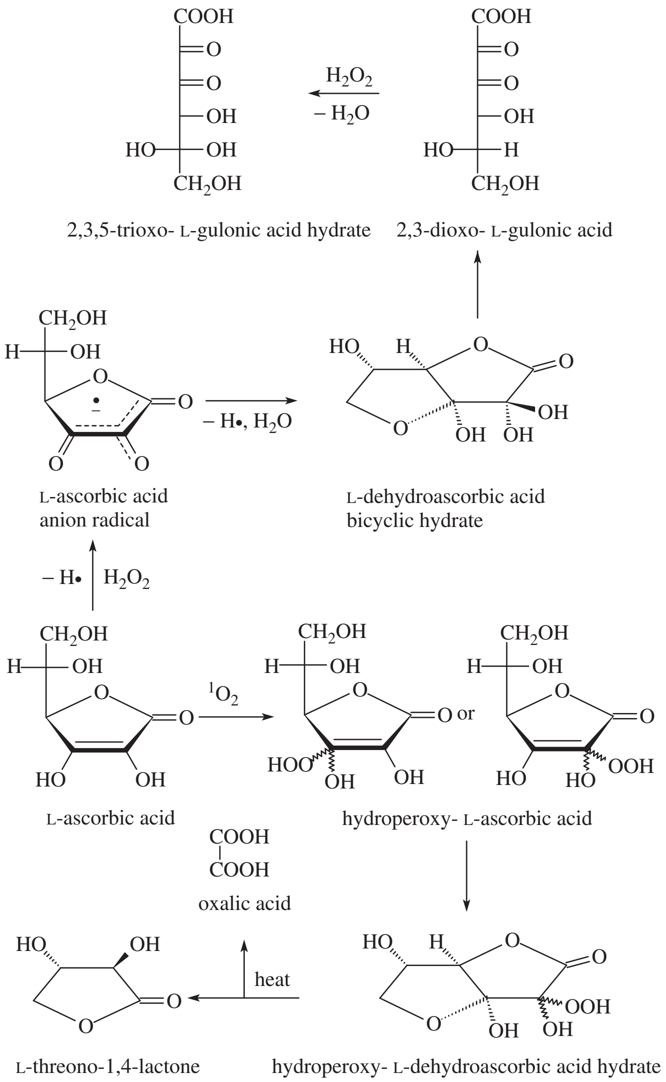

Figure 5.29 Oxidation of ascorbic acid by hydrogen peroxide and singlet oxygen.

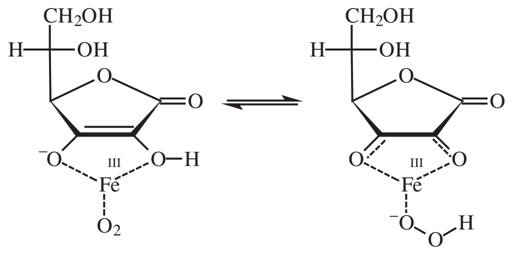
of transition metal ions. The most active ions are trivalent iron and divalent copper. The reaction depends on the pH; in an acidic solution it is slow, in a neutral solution it is faster and in an alkaline solution it is fastest. The catalytic efficiency of metal ions lies in the fact that ascorbic acid forms a very stable ternary complex (**5-123**) with a metal ion of higher valency and oxygen (in solutions of pH 2–8) in which it is present as an anion HA^-. Therefore, the reaction rate increases with pH. Other enediols react analogously.



5-123, complex of L-ascorbic acid with ferric ion sand oxygen

Within the complex, two electrons are transferred from ascorbic acid to oxygen through the metal ion. The complex dissociates by the action of hydrogen ions (H^+) forming dehydroascorbic acid, hydrogen peroxide and the metal ion. Reaction with Fe^{3+} (Fe^{2+} complex is less stable than the complex with Fe^{3+}) can be generally described by the following equations (similar reaction takes place with Cu^{2+}):

$$H_2A + O_2 \xrightarrow{Fe^{3+}} A + H_2O_2$$

The resulting hydrogen peroxide can oxidise another molecule of ascorbic acid to dehydroascorbic acid or other oxylabile compounds in foods (such as anthocyanin pigments), but can also react with Fe^{2+} ions to form hydroxyl ions and hydroxyl radicals:

$$H_2A + H_2O_2 \rightarrow A + 2\ H_2O$$

The resulting reaction, which is the sum of the previous two reactions, can be described as follows.

Oxidation of ascorbic acid by hydrogen peroxide proceeds via ascorbyl radical and dehydroascorbic acid (apparently its hydrate), which yields 2,3-dioxo-L-gulonic acid. Hydrogen peroxide further oxidises 2,3-dioxo-L-gulonic acid to give unstable 2,3,5-trioxo-L-gulonic acid (Figure 5.29), which decomposes and produces other

products. 2,3-Dioxo-L-gulonic acid and 2,3,5-trioxo-L-gulonic acid are probably hydrated in solutions.

Oxidation of ascorbic acid by singlet oxygen gives L-threonic acid 1,4-lactone and oxalic acid, analogously to the reaction catalysed by ascorbate 2,3-dioxygenase. Intermediates of this reaction are hydroperoxides of ascorbic acid and of dehydroascorbic acid hydrate (Figure 5.29).

5.14.6.1.3 Reduction of metal ions

Ascorbic acid reacts with metal ions to form complexes, but under certain conditions (especially at low pH values and if present in low concentrations) may also reduce metal ions. Reaction with Fe^{3+} ions (and by analogy with Cu^{2+} ions) is as follows:

$$H_2A + 2\,Fe^{3+} \rightarrow A + 2\,Fe^{2+} + 2\,H^+$$

The reducing effect of ascorbic acid in fact accelerates the oxidation reactions that lead to undesirable changes in flavour and colour of foods. These changes are the result of subsequent reaction of ions Fe^{2+} (and Cu^+) with oxygen that yields a radical of superoxide anion ($O_2^{\bullet-}$),[11] which further oxidises Fe^{2+} or Cu^+ and gives hydrogen peroxide. Further oxidation of Fe^{2+} or Cu^+ ions with hydrogen peroxide (Fenton reaction) generates hydroxyl radicals ($HO^\bullet$), which are the most important oxidants in biological systems (resulting in many pathological processes) and in foods:

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^{\bullet-}$$
$$Fe^{2+} + O_2^{\bullet-} + H_2O + H^+ \rightarrow Fe^{3+} + HO^- + H_2O_2$$
$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^- + HO^\bullet$$

Hydrogen peroxide can be replaced in these reactions by a fatty acid hydroperoxide (ROOH). Then, instead of hydroxyl radicals, alkoxyl radicals ($RO^\bullet$) are formed.

The prooxidant effects of ascorbic acid do not manifest when its concentration is sufficiently high, even though the increase of its concentration produces a higher amount of Fe^{2+} ions and hence $HO^\bullet$ radicals. In this case, a competitive reaction with free radicals takes place at the same time and ascorbic acid acts as an antioxidant.

5.14.6.1.4 Reaction with free radicals

Ascorbic acid, its isomers and derivatives can react with free radicals that cause oxidation of lipids and other oxylabile food components. It inhibits the radical chain autoxidation reaction and effectively acts as an antioxidant. The reaction of ascorbic acid with lipid (fatty acid) peroxyl radical ($ROO^\bullet$) or with alkoxyl radical ($RO^\bullet$) can be schematically represented by the following equation (ROOH is a fatty acid hydroperoxide):

$$H_2A + ROO^\bullet \rightarrow HA^\bullet + ROOH$$

The resulting ascorbyl radical ($HA^\bullet$) is no longer able to initiate a radical chain reaction and disproportionates into ascorbic acid and dehydroascorbic acid.

Ascorbic acid is generally a more effective antioxidant, when used in combination with tocopherols. They then preferentially react with lipid free radicals and the resulting tocopheryl radicals are, on the oil–water interface, reduced back to tocopherols by ascorbic acid. Ascorbyl palmitate yields, via the corresponding radical, dehydroascorbyl palmitate, which, unlike dehydroascorbic acid, cannot form a cyclic hydrate. Ascorbic acid also reacts similarly with toxic forms of oxygen, such as a hydroxyl radical ($HO^\bullet$), an anion of superoxide radical ($O_2^{\bullet-}$) and singlet oxygen ($^1O_2$). Simultaneously, all of these reactions slow down the oxidation of lipids:

$$H_2A + HO^\bullet \rightarrow HA^\bullet + H_2O$$
$$H_2A + O_2^{\bullet-} + H^+ \rightarrow HA^\bullet + H_2O_2$$

5.14.6.1.5 Acid catalysed degradation

In strongly acidic solutions, ascorbic acid can decarboxylate and, like other sugars, dehydrate. In model experiments almost quantitative amounts of carbon dioxide and furan-2-carbaldehyde are produced. The reaction mechanism is shown in Figure 5.30. An important product is 3-deoxy-L-*threo*-pentos-2-ulose, also known by its trivial name as 3-deoxy-L-xylosone, which plays an important role in the Maillard reaction of pentoses.

In the absence of atmospheric oxygen, acid-catalysed degradation of ascorbic acid is considered a major cause of the loss of vitamin C in dried fruits, canned fruit compotes and juices (pH value around 3.5), especially when stored at higher temperatures. For example, fruit juices lose 70–95% of ascorbic acid within 12 weeks of storage at 50 °C. The reaction rate is about ten times lower than that of autoxidation catalysed by metal ions.

5.14.6.1.6 Reaction with other food components

The loss of vitamin C may also occur during reactions of ascorbic acid with some of the reactive food components. In particular, reactions of ascorbic acid with quinones generated by enzymatic browning reactions, reactions with nitrites and haem pigments in meat and meat products are technologically significant.

Reactions with oxidised phenols

The enzymatic browning reactions of fruits and vegetables occur especially in materials that have a low content of ascorbic acid and active enzymes belonging to the group of *o*-diphenol:O_2 oxidoreductases. In damaged plant tissues and in the presence of atmospheric oxygen, these enzymes catalyse the oxidation of phenolic substrates (so-called monophenols or *o*-diphenols) to *o*-quinones, which then form brown polymeric pigments. As long

[11] Sometimes it is stated that instead of an anion of a superoxide radical, a hydrogen superoxide radical (it is actually a radical of hydrogen peroxide) forms and is in equilibrium with $O_2^{\bullet-}$ ($pK_a = 4.8$). The relevant equations then look as follows:

$$Fe^{2+} + O_2 + H_2O \rightarrow Fe^{3+} + HO_2^\bullet + HO^\bullet \quad \text{and}$$
$$Fe^{2+} + H_2O + HO_2^\bullet \rightarrow Fe^{3+} + HO^- + H_2O_2$$

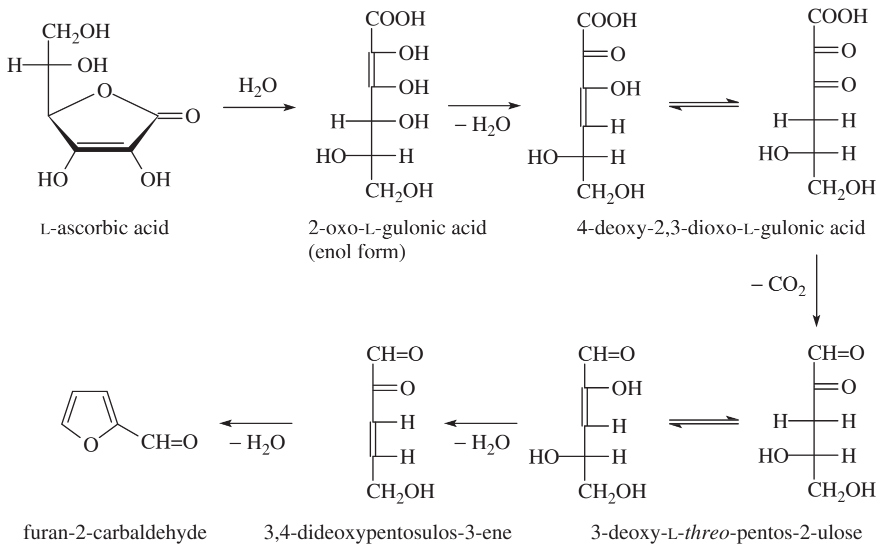


Figure 5.30 Degradation of L-ascorbic acid in acidic solutions.

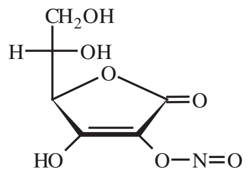
as ascorbic acid is present, quinones are reduced back to the parent diphenols and an equimolar amount of dehydroascorbic acid is formed (see Section 9.12).

Reaction with nitrites and haem pigments

The disadvantage of the use of nitrites in meat manufacturing processes is the formation of toxic nitroso compounds (mainly *N*-nitrosamines) by reaction of nitrous acid (nitrite) with naturally present secondary amines (see Section 12.2.7.3.1). Ascorbic acid added together with nitrites decomposes the excess of nitrous acid, which is a precursor of nitrosation agents (primarily dinitrogen trioxide, N_2O_3). It is assumed that the reaction of ascorbic acid with nitrous acid temporarily creates the corresponding 2-ester (**5-124**), which is decomposed to an ascorbyl radical and nitric oxide (nitrogen monoxide, NO) that reacts with haem pigments. Ascorbic acid 2,3-diester has also been proposed as an intermediate, which decomposes to dehydroascorbic acid and nitric oxide. Minor products generated from nitrite (with myoglobin acts as a reducing agent) are nitrous oxide (N_2O) and nitrogen.



5-124, L-ascorbic acid 2-ester with nitrous acid

Even under physiological conditions, about 1% of haemoglobin in erythrocytes is present in the form of methaemoglobin, which is reduced to haemoglobin by methaemoglobin reductase. Myoglobin (Mb) is present in meat in the form of oxymyoglobin (MbO_2) and metmyoglobin (MetMb). Added ascorbic acid reduces both of these pigments to myoglobin (see Section 9.2.1.5.3). In the presence of ascorbic acid, a higher amount of myoglobin is available for the reaction, which creates the desired dye nitroxymyoglobin:

$$H_2A + MbO_2 + H_2O + e^- \rightarrow HA^{\bullet -} + MetMb + H_2O_2$$
$$H_2A + MetMb + e^- \rightarrow HA^{\bullet -} + Mb$$

Reaction with proteins

The aim of the Chorleywood bread process (see Section 5.14.4.4) is to use cheaper, lower-protein wheat and to reduce processing time. Flour, water, yeast, salt, fat, ascorbic acid and minor ingredients (emulsifiers and enzymes) are mechanically mixed, which results in rapid oxidation of ascorbic acid to dehydroascorbic acid, caused mainly by ascorbase activity in the dough that is a co-substrate of glutathione dehydrogenase. Glutathione dehydrogenase oxidises reduced glutathione (G-SH) to the corresponding disulfide (oxidised glutathione, G-S-S-G), which does not affect the rheological properties of dough:

$$A + 2G\text{-}SH \rightarrow H_2A + G\text{-}S\text{-}S\text{-}G$$

The content of reduced glutathione in wheat flour is 10–15 mg/kg. In the absence of ascorbic acid (dehydroascorbic acid, respectively), G-SH reacts with components of gluten (P) that are linked by disulfide bridges (P-S-S-P) to form mixed disulfides, which show negative effects on the baking properties of flour:

$$P\text{-}S\text{-}S\text{-}P + G\text{-}SH \rightarrow P\text{-}S\text{-}S\text{-}G + P\text{-}SH$$

Free cysteine (Cys-SH) formed by hydrolysis of glutathione can also depolymerise gluten proteins or react with mixed disulfides that also have negative effects on the baking properties of flour:

$$P\text{-}S\text{-}S\text{-}Cys + G\text{-}SH \rightarrow P\text{-}S\text{-}S\text{-}G + Cys\text{-}SH$$
$$P\text{-}S\text{-}S\text{-}P + Cys\text{-}SH \rightarrow P\text{-}S\text{-}S\text{-}Cys + P\text{-}SH$$
$$P\text{-}S\text{-}S\text{-}G + Cys\text{-}SH \rightarrow P\text{-}S\text{-}S\text{-}Cys + G\text{-}SH$$

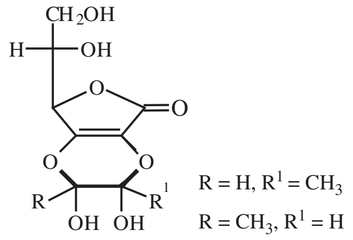
Reaction with glucosinolate degradation products

Ascorbic acid carbanion (C-2) reacts with electrofilic agents (carbonium cations). A typical example of this reaction is the formation of ascorbigen in the reaction of ascorbic acid with the degradation products of indole glucosinolates in Brassica vegetables. The glucosinolate glucobrassicin (and its analogues) is hydrolysed to glucose, hydrogensulfate anion and unstable isothiocyanate by the enzyme myrosinase (thioglucosid glucohydrolase) in the damaged plant tissue (such as shredded cabbage). The anion of the tautomeric form of ascorbate then replaces thiocyanate (rhodanide) anion in this intermediate, which yields ascorbigen (see Section 10.3.2.4.2). Ascorbigen is more stable to oxidation than ascorbic acid and exhibits anticarcinogenic effects.

Another ascorbic acid derivative is a water-soluble tannin called elaeocarpusin, which was isolated from the leaves of the evergreen tropical tree *Elaeocarpus sylvestris* (Elaeocarpaceae). Elaeocarpusin is derived by condensation of corilagin (see Section 8.3.5.1.2, Figure 8-294) with dehydroascorbic acid.

Reaction with carbonyl compounds

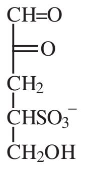
The reaction of ascorbic acid with aldehydes in aqueous solutions yields the corresponding hemiacetals. The reaction with methylglyoxal (a typical product of carbohydrate degradation) gives rise to two cyclic hemiacetals (**5-125**). Similar products are produced with acrolein, the degradation product of glycerol.



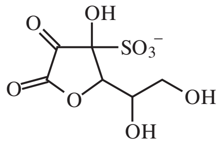
5-125, L-ascorbic acid acetals with methylglyoxal

Reaction with sulfur dioxide

Sulfur dioxide reduces dehydroascorbic acid to ascorbic acid and is therefore frequently used in combination with ascorbic acid, particularly in fruits and vegetables. It has been suggested that under anaerobic conditions, sulfite ion may catalyse degradation of ascorbic acid and readily adds across the double bond of the 3,4-dideoxypentosulos-3-ene (Figure 5.30) that is formed to yield 3,4-dideoxy-4-sulfopentos-2-ulose (**5-126**). Under aerobic conditions, the bisulfite ion forms hydroxysulfonate of dehydroascorbic acid (**5-127**).



5-126, 3,4-dideoxy-4-sulfopentos-2-ulose



5-127, hydroxysulfonate of dehydroascorbic acid

5.14.6.2 Dehydroascorbic acid

Like other vicinal dicarbonyl derivatives of sugars, dehydroascorbic acid is involved in the Maillard reaction. Dehydroascorbic acid (or its bicyclic hydrate, Figure 5.27) is a γ-lactone that is readily hydrolysed under a base catalysis to its parent unstable compound that undergoes a series of irreversible reactions. These reactions result in loss of vitamin C and the formation of coloured products, and the discoloration of fruit and vegetable products.

5.14.6.2.1 Hydrolysis

Dehydroascorbic acid hydrolysis yields biologically inactive 2,3-dioxogulonic (L-*threo*-hexo-2,3-diulosonic) acid. In aqueous solutions, this acid is present as a dihydrate (Figure 5.31). The reaction is generally acid-base catalysed. The activity of important ions and undissociated molecules decreases in the order: hydroxyl ions (HO^-) > hydronium ions (H_3O^+) > anions of carboxylic acids $R{-}COO^-$) > undissociated carboxylic acids (R–COOH) > water. The catalytic effect of hydroxyl ions is about 15×10^6 times higher than that of hydronium ions. This means that the reaction rate in the solution of pH 4 is 15×10^6 times lower than in solution of pH 10. Dehydroascorbic acid is most stable in solutions of pH 2.5–5.5, where the reaction is only catalysed by undissociated water molecules and is rapidly hydrolysed in neutral and alkaline solutions.

5.14.6.2.2 Subsequent reactions

2,3-Dioxogulonic acid is an unstable compound and undergoes a series of reactions that are analogous to reactions of sugars. Its decomposition produces many products depending on the pH and the presence of atmospheric oxygen. In acidic solutions, the main transformation products are furan derivatives, decomposition in alkaline solutions produces organic acids (their salts) and reductones. The key reaction that occurs in a wide range of pH values (in acidic and alkaline solutions) is decarboxylation to (3*R*,4*S*)-3,4,5-trihydroxy-2-oxopentanal (L-*threo*-pentosulose). In older literature this substance was called L-xylosone and its enolform was known as reductone C. It is assumed that this enolform reacts with another molecule of 2,3-dioxo-L-gulonic acid, which is reduced to L-ascorbic acid, while L-*threo*-pentosulose is simultaneously oxidised to L-erythroascorbic acid, also known as (*S*)-2,3,4,5-tetrahydroxypent-2-enonic acid (Figure 5.31). Some other reactions of L-*threo*-pentosulose are shown in Figure 5.32.

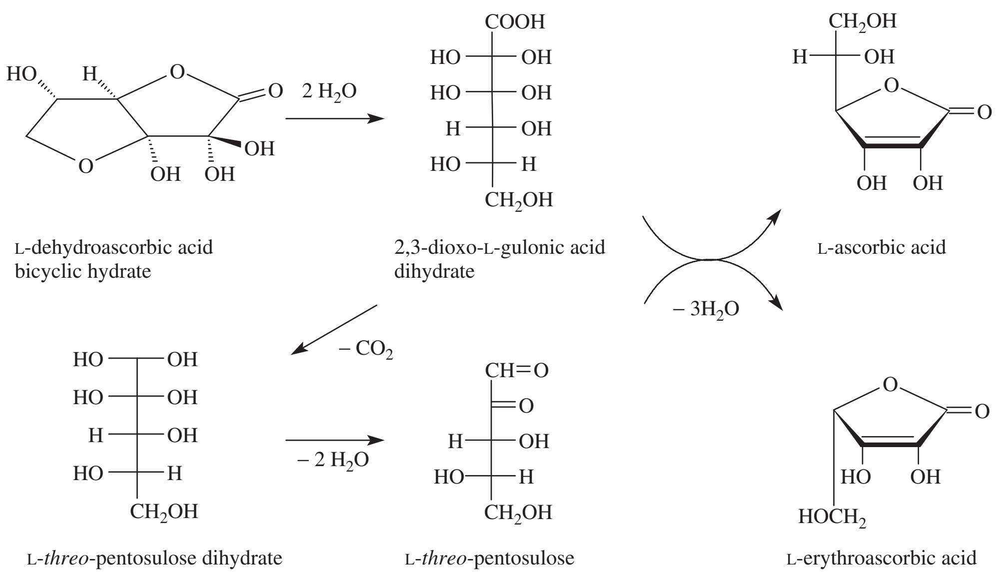


Figure 5.31 Degradation of L-dehydroascorbic acid.

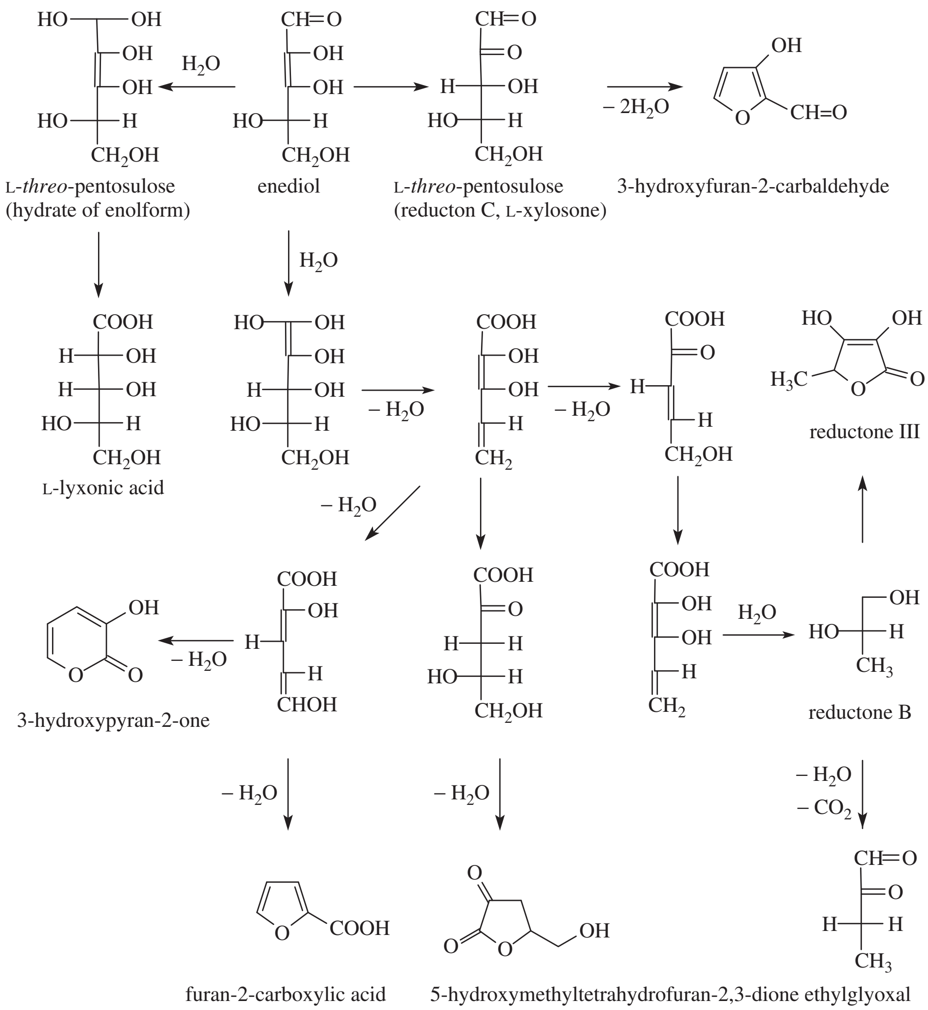

Figure 5.32 Degradation of L-*threo*-pentosulose.

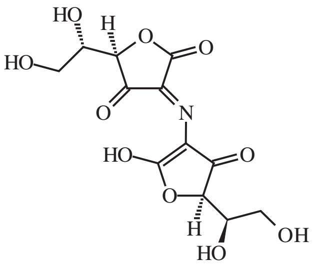
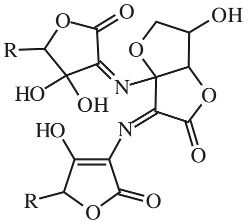
The main products formed by a sequence of isomerisation and (de)hydration reactions are 3-hydroxypyran-2-one and furan-2-carboxylic acid (also known as pyromucic or 2-furoic acid). The odour of 3-hydroxypyran-2-one is reminiscent of caramel (maltol and isomaltol have similar odours).

5.14.6.2.3 Reactions with amino compounds

Dehydroascorbic acid reacts with amines, amino acids and proteins and participates in the non-enzymatic browning reactions that occur mainly in foods with low water activity and relatively high content of vitamin C (e.g. in dehydrated fruit juices). The primary product of the reaction with amino compounds is imine. Reduction of imine gives the corresponding amine. Isomerisation of imine and elimination of carbon dioxide and aldehyde yields scorbamic acid (Figure 5.33). This reaction is known as Strecker degradation of amino acids. A detailed reaction mechanism is given in Section 2.5.2.3. This 2-amino derivative reacts with another molecule of dehydroascorbic acid and yields the so-called red pigment (**5-128**). Formation of this pigment, which sometimes occurs during the preservation of cauliflower, leads to unwanted discoloration of the preserved product. The subsequent reaction of scorbamic acid with the red pigment creates the yellow pigment (**5-129**), which is probably an intermediate in reactions leading

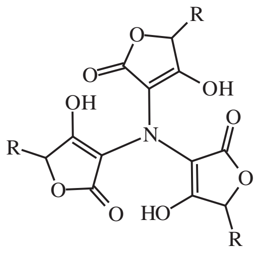


5-128, red pigment of ascorbic acid



5-129, yellow pigment of ascorbic acid

from dehydroascorbic acid to brown polymeric pigments called melanoidins. Other reaction products include cyclic nitrogenous products, and typically unstable free radicals and stable products, such as tris(2-deoxy-2-L-ascorbyl)amine (**5-130**).



5-130, tris(2-deoxy-2-L-ascorbyl)amine

5.14.7 Changes in foods

Ascorbic acid is one of the least stable vitamins. It is sensitive to heat, light and oxygen. Storage of foods, cooking procedures and industrial processing methods can result in significant loss of vitamin C. The most significant losses are caused by vitamin leaching and oxidation. In the absence of atmospheric oxygen, losses are mainly caused by acid catalysed degradation. Total losses generally range between 20 and 80%.

5.14.7.1 Fruits and vegetables

If fresh products are held at the appropriate temperature and consumed in a short period of time, they have more vitamin C than commercially canned products. Vitamin C degrades rapidly after harvest and its amount depends on the commodity, temperature, pH and other factors. During storage (and processing), the stability of ascorbic acid is higher in fruits that have lower pH than vegetables. For example, the effect of storage on the vitamin C content in

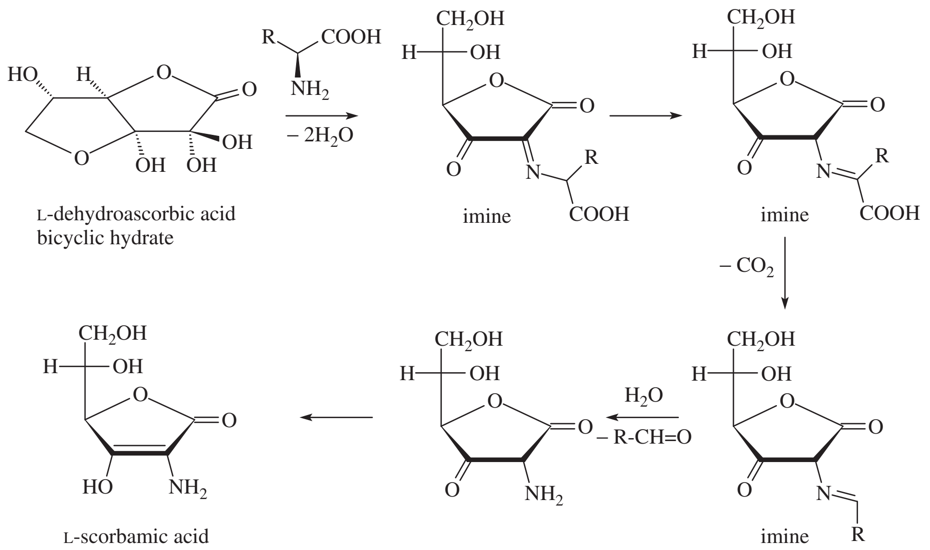


Figure 5.33 Formation of L-scorbamic acid from L-dehydroascorbic acid and amino acids.

apples depends upon the time of picking, storage temperature and composition of the storage atmosphere. Apples (Golden Delicious variety) stored at 25 °C lose 41% of vitamin C in 2 weeks after harvesting and almost 56% is lost after 6 weeks of storage. Only small changes in the vitamin C content occur at 4 °C. Green beans, however, lose up to 77% of vitamin C in 7 days of storage at 4 °C. The vitamin C level in fresh potatoes falls to 30–60% of the original level in the first 2 months after harvest, but then tends to stabilise at 25% of the original level.

Losses of ascorbic acid due to leaching occur during washing, blanching, cooking and preserving fruits and vegetables in cases where the extract is not further processed. Losses during washing are lower than losses during blanching and cooking. The nature and extent of losses depends on pH, temperature, water quantity, surface area that is in contact with water, maturity, extent of contamination by metals and presence of oxygen. A significant decrease in vitamin C content is also caused by peeling the fruit, when the surface layer rich in vitamin C is removed.

The average retention of fruit juices fortified with vitamin C is 60–80%. Between 10 and 90% of vitamin C is lost during canning of fruits, however the changes are little during storage of canned products and little is lost during re-heating, because the heating time is short. The lowest losses are achieved during short-term sterilisation at high temperature. In fruit treated with sulfur dioxide, the losses of ascorbic acid during technological processing are lower as sulfur dioxide reduces hydrogen peroxide produced by oxidation of ascorbic acid in the presence of heavy metals. Vitamin C is most stable during the freezing and refrigerated storage of fruits and vegetables. Storage at temperatures of −18 °C result in only minimal losses, while significant losses can occur during thawing (30–50%).

Losses are higher in green leafy vegetables with a large surface than in root vegetables. Degradation of vitamin C also occurs during processing of potatoes with absolute losses in the order of 30%, although the concentration of vitamin C in potato crisps can be higher than in fresh potato due to a reduction of water content during frying. Vitamin loss also occurs during fermentation of vegetables. Sauerkraut, for example, contains about 50% of the vitamin as compared with fresh cabbage (90–190 mg/kg).

The best methods for small-scale processing are drying, chemical preservation and heat processing; these and other methods may be applied in industrial processing. In order to retain the maximum amount of vitamin C in fruits and vegetables during storage and in processed products (based on reaction mechanisms described above), the following principles should be maintained:

- Fruits and vegetables should be used when freshly harvested.
- They must not be subjected to long soaking, washing or blanching.
- They must be processed immediately after preparation.
- The level of metal ions should be reduced by exclusion of any direct contact with copper, bronze, brass and iron parts of processing equipment or copper, iron or chipped pans; binding of metal ions to inactive complexes by chelating agents (such as ethylenediaminetetraacetic acid, or EDTA, citrates and phosphates); autoxidation of ascorbic acid is also slower in the presence of proteins, acidic polysaccharides and flavonoids; unfavourable conditions for the formation of complexes of metal ions with ascorbic acid may be created by lowering water activity, pH value, using appropriate *O*-2 substituted derivatives of ascorbic acid, such as 2-phosphate or 2-*O*-α-D-glucoside.
- Contact with air should be minimised by reducing the amount of oxygen (reduced pressure, inert atmosphere, addition of hydrogen bisulfites, fermentation, use of glucose oxidase and catalase; glucose oxidase catalyses the oxidation of D-glucose by oxygen to D-gluconic acid and hydrogen peroxide, which is then reduced by catalase to water:

$$2\,H_2O_2 \rightarrow 2\,H_2O + O_2$$

5.14.7.2 Milk and dairy products

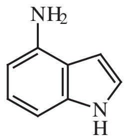
Losses of ascorbic acid during storage of raw milk are considerable. Cold storage causes about 50% loss of vitamin C, which increases with increased temperature. Heat treatment of milk decreases the content of vitamin C by 20–50%, depending on temperature and time of heating. The UHT treatment of milk causes about 10–30% loss. Ascorbic acid in dried, vitamin-enriched milk, packaged in an inert atmosphere, is relatively stable.

5.15 Other active substances

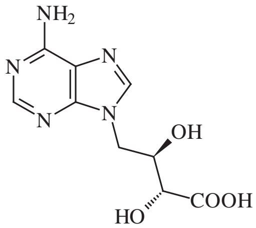
In the past, vitamins have included far more substances than today. The catalytic effect of some hydrophilic substances was subsequently not reliably proven in the metabolism of humans (such as 4-aminobenzoic acid, the building unit of folacin). The human body can synthesise some compounds in adequate amounts, such as adenine (vitamin B_4), 4-aminobenzoic acid (vitamin B_{10}), orotic acid (vitamin B_{13}), carnitine (vitamin B_{20}), *myo*-inositol (vitamin B_m), choline (vitamin B_p), 2-aminobenzoic (anthranilic) acid previously known as vitamin L_1, 9′-(5-thiomethylribofuranosyl)adenine, which is a metabolite of RNA previously known as vitamin L_2, and salicylic acid, previously known as vitamin S. Furthermore, no signs of their essentiality and avitaminosis have been demonstrated. The term vitamin never included other essential nutrients such as thioctic acid, taurine, coenzyme Q and other biologically active compounds. Some substances are vitamins only for microorganisms (4-aminobenzoic acid, thioctic acid and other growth factors of microorganisms). A range of biologically active compounds initially ranked among the vitamins are now categorised among other substances and are no longer considered true vitamins, such as essential fatty acids (previously known as vitamin or vitagen F) are classified as lipid constituents, bioflavonoids (previously vitamin P) are plant pigments called flavonoids, while vitamin J was a mixture of non-essential catechol and riboflavin. Coenzyme Q, carnitine, taurine, orotic acid, *myo*-inositol, choline and other compounds

are currently used as food supplements.[12] Some of the claimed benefits of food supplements have a more scientific basis than others, but all must be carefully evaluated and the supplemented compounds should not replace a varied and balanced diet.

The purine base adenine (6-aminopurine, previoulsy also known as vitamin B_4, **5-131**) is generally widespread as a building unit of the ribofuranoside adenosine and its phosphates, such as adenosine 5′-monophosphate (AMP, adenylic acid), adenosine 5′-diphosphate (ADP) and adenosine 5′-triphosphate (ATP), polynucleotides, such as ribonucleic acid (RNA) and deoxyribonucleic acid (DNA), vitamins (riboflavin, adenosylvitamin B_{12}) and cofactors $NAD(P)^+$ and FAD. Adenylic acid was once considered a member of the vitamin B complex (as vitamin B_8). The agent in shiitake (*Lentinula edodes*) mushrooms that can reduce the level of cholesterol in the blood is a purine derivative, (2*R*,3*R*)-dihydroxy-4-(9-adenyl)butyric acid (**5-132**) called eritadenine (lentinacin, lentysine).

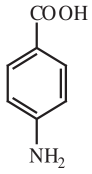


5-131, adenine

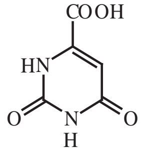


5-132, eritadenine

4-Aminobenzoic acid, also known as *p*-aminobenzoic acid (PABA), was previously ranked among the B group vitamins as vitamin B_{10}, vitamin B_x or vitamin H_1 (**5-133**). It arises from chorismic acid and commonly occurs in foods of animal and plant origin. Good sources include organ meats, such as liver and kidney, eggs, whole wheat flour, wheat germ and brewer's yeast. Aminobenzoic acid is also supplied by intestinal microorganisms. Aminobenzoic acid is probably most important as an intermediate in the biosynthesis of folacin; therefore it is a growth factor of some bacteria, but not for humans. Despite the lack of any recognised syndromes of aminobenzoic acid deficiency in humans, many claims of benefits are made by commercial suppliers of aminobenzoic acid as a nutritional supplement. Aminobenzoic acid supposedly participates in many metabolic processes in humans. It appears to function as a coenzyme in the conversion of certain chemical intermediates into purines. It has also been suggested that it has an antifibrosis activity and increases oxygen uptake at the tissues. These effects are, at present, still considered speculative. When it is in short supply, fatigue, irritability, nervousness and depression might manifest itself as well as constipation. Weeping eczema has also been noted in people with 4-aminobenzoic acid deficiency, as well as patchy areas on the skin. Aminobenzoic acid physically blocks ultraviolet rays when it is applied to the skin (it is a UVB absorber) and is sometimes suggested for treatment various skin diseases, such as weeping eczema (moist eczema), scleroderma (premature hardening of skin), depigmentation of skin (vitiligo) and premature grey hair, as well as for male infertility. The recommended daily allowance is 0.05 mg for infants, 0.2–0.3 mg for children, 0.4 mg for adults, 0.8 mg for pregnant women and 0.6 mg for lactating women.



5-133, 4-aminobenzoic acid



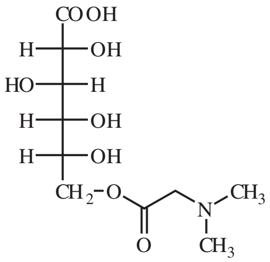
5-134, orotic acid

Orotic acid (originally known as vitamin B_{13}, **5-134**) is an intermediate in the biosynthesis of pyrimidines required for DNA and RNA synthesis, but essentiality has not been demonstrated. It is synthesised from carbamoyl phosphate and aspartic acid through dihydroorotic acid and then transformed into orotidin 5′-phosphate and further to uridine 5′-monophosphate. When there is insufficient capacity to detoxify the ammonia load for urea synthesis, carbamoyl phosphate leaves the mitochondria and enters the pyrimidine pathway, where orotic acid biosynthesis is stimulated; orotic acid excretion in urine then increases. Orotic acid synthesis is abnormally high in hereditary deficiencies of urea-cycle enzymes or uridine monophosphate synthase. This acid occurs mainly in milk from ruminants. In cows' milk, the level is 20–100 mg/l and in somewhat higher amounts are found in goats' and sheeps' milk (200–400 mg/l). In human milk, concentrations are in general low (under 2 mg/l). Good sources of orotic acid are also dairy products (at a level of about 150 mg/l in yoghurt), liver and baker's yeast. The benefit claims reportedly include the enhanced formation of albumen in the liver, especially in conditions of prolonged hypoxia that occurs in some diseases, such as heart failure and has a positive effect on foetal development during pregnancy. The effectiveness of orotic acid was shown in children from 6 months to 10 years, suffering from various skin diseases (eczema, atopic dermatitis, psoriasis and ichthyosis). The daily dose suggested by commercial suppliers is 0.125–0.5 g for children 1–3 years old, 0.25–1 g for children 3–8 years old and 0.5–1.5 g, or sometimes up to 3 g, for adults.

Pangamic acid (formerly known as vitamin B_{15}, **5-135**) occurs mainly in cereals, legumes, seeds (sunflower and pumpkin seeds) and yeast. Its nutritional value is debatable and no scientific evidence exists to substantiate any physiological function or biological effects. It probably acts (like choline) as a lipotropic factor, which stimulates

[12] Some EU member states (e.g. the Czech Republic in Decree No. 225/2008 Coll.) have set maximum permissible amount in daily intake for orotic acid (50 mg), acetylcarnitine (500 mg), and taurine (200 mg). The use of orotic acid salts as a source of minerals and choline is a safety concern.

the formation of very low density lipoproteins (VLDL) in the liver. Although no evidence supports its use, pangamic acid has been used to treat cancer, schizophrenia, *diabetes mellitus*, heart diseases, alcoholism, hepatitis and indigestion. It has also been asserted that pangamic acid detoxifies byproducts of human metabolism.



5-135, pangamic acid

N,*N*-Dimethylglycine (originally called vitamin B_{16}; see Section 2.2.1.2.1) is an amino acid found in almost all animal and plant cells and as a building unit of pangamic acid. It can be formed by demethylation of *N*,*N*,*N*-trimethylglycine (glycine betaine), a very efficient cytoplasmic osmolyte of some plants and bacteria or as an intermediate in the pathway leading from choline to glycine. Demethylation of dimethylglycine yields *N*-methylglycine (sarcosine). Dimethylglycine is contained in higher amounts in certain foods including liver, beans, cereal grains, many seeds and brewer's yeast. Deficiencies in dimethylglycine do not cause any adverse effects. Manufacturers of dimethylglycine supplements claim that as a supplement, vitamin B_{16} can improve athletic performance (it assists in oxygen utilisation within the body), enhances the immune system, stimulates neurological functions, helps to manage autism (noticeable improvements in cognitive functions are exhibited in combination with vitamin B_6 supplementation) and epilepsy and provides protection of cells against free radicals as an antioxidant.

The cyanogenic glycoside known as (*R*)-amygdalin, a β-gentiobioside of D-mandelic acid nitrile (see Section 10.3.2.3.1), is sometimes incorrectly referred to as vitamin B_{17}. Amygdalin is often confused with semi-synthetic laevomandelonitrile, also called laetrile for short, which is a β-glycoside of D-mandelic acid nitrile with D-glucuronic acid. Amygdalin occurs in plant seeds of the rose family (Rosaceae). Significant resources are bitter almonds and the pits of apricots, peaches, plums and cherries. Small amounts of amydalin are also present in the cores of apples, pears, quinces and other plant seeds. Amygdalin is capable of decomposing into a sugar molecule(s), benzaldehyde and toxic hydrogen cyanide through the action of the hydrolase amygdalase (also called emulsin). The enzyme rhodanase (in bacteria, plants and animals) acts in the catabolism of cyanides (R–C≡N) catalysing conversion of cyanides into thiocyanates (rhodanides, R–S–C≡N). Perhaps the most notable (yet controversial) benefit of amygdalin is its effectiveness in treating cancer, in particular prostate cancer, arthritic pain and high blood pressure. The claimed anticarcinogenic activity is based upon the fact that cancer tissues are rich in hydrolase that causes amygdalin to release cyanide, which destroys the cancer cells. According to this theory, non-cancerous tissues are protected from this fate by active rhodanase, which renders the cyanide harmless. However, no substantive benefit was observed in terms of cure, improvement or stabilisation of cancer, improvement of symptoms related to cancer or extension of life span. Furthermore, the hazards of amygdalin therapy were evidenced in several patients by symptoms of cyanide toxicity.

L-Carnitine, also known as (*R*)-carnitine or trimethylammonium-3-hydroxybutyrobetaine (formerly known as vitamin B_{20}, vitamin O or vitamin B_t; see Section 2.2.1.2.1) is synthesised from lysine and methionine in many organisms, ranging from bacteria to mammals. The lysine becomes available in the form of ε-(*N*,*N*,*N*-trimethyl)lysine after lysosomal hydrolysis of proteins that contain this amino acid as a result of the post-translational methylation of lysine residues. Carnitine, in the activated form as acylcarnitine, serves as a carrier of fatty acid residues across the inner membrane of the mitochondria, which helps in the consumption and disposal of fat in the body. Then, fatty acids can be degraded by β-oxidation to acetyl-CoA to obtain energy via the citric acid cycle. The highest amount of carnitine is present in the muscles of animals, in red meat levels range from 0.05 to 0.2% fresh weight. Good sources are also poultry and fish. Carnitine (free carnitine, acetylcarnitine or propionylcarnitine) is often sold as a nutritional supplement for stimulation of energy metabolism of fatty acids, which is used in weight reduction and also in sports nutrition. Although carnitine has been marketed as a weight loss supplement, there is no scientific evidence to show that it works. Some studies do show that oral carnitine reduces fat mass, increases muscle mass and reduces fatigue, which may contribute to weight loss in some people. Some research suggests that carnitine may help prevent or reduce symptoms of an overactive thyroid gland, slow down the progression of Alzheimer's disease, relieve depression related to senility and other forms of dementia and improve memory in the elderly, improve male sexual function and increase sperm count and mobility. Recommended doses of carnitine for adults vary depending on the health condition being treated. The usual dose is between 1 and 3 g/day.

The cyclic hexitol *myo*-inositol (incorrectly also known as *meso*-inositol; see Section 4.3.1.1.2) has previously been considered as one of the B group vitamins (called i-inositol, phaseomannitol, nucitol, vitamin B_m or bios I). Inositol is synthesised by conversion of D-glucose 6-phosphate and plays an important role as the structural basis for a number of secondary messengers in eukaryotic cells, including inositol phosphates and phosphatidylinositol in phospholipids. It is found in many foods, in particular, in legumes, cereals with high bran content, nuts and fruits. Concentrations of inositol in legumes range from about 200 to 3000 mg/kg dry weight. Phosphatidylinositol (and phosphatidylcholine) show lipotropic effects and prevent fatty liver disease, such as abnormal deposition of lipids within liver cells (steatosis). Inositol is a growth factor for various microorganisms. Deficiency in animals manifests by hair greying and falling out, but specific avitaminosis was not observed in humans. The manufactures of food supplements claim that inositol may be beneficial for treating certain psychiatric conditions, such as obsessive-compulsive disorder, panic attacks, trichotillomania (an impulse control disorder) and bipolar disorder. In addition, inositol may be useful for ameliorating some of the symptoms of polycystic

ovary syndrome (a female endocrine disorder). The daily intake of *myo*-inositol is estimated to be 1000 mg. The recommended daily dose from food supplements is 500 mg.

In plants (mainly in cereals and legumes), inositol occurs in a bound form known as phytic acid (*myo*-inositol-1,2,3,4,5,6-hexakisphosphoric acid). Salts of this acid are called phytates. Calcium-magnesium salt of phytic acid, which also contains a number of other mineral elements, is called phytin (see Section 6.2.2.3). Phytic acid plays a role as an antioxidant (due to strong binding of transition metals) and anticarcinogenic effects have also been demonstrated. Partial esters of phytic acid are used to regulate the amount of calcium in cells, exhibit anti-coagulant, anti-inflammatory and other effects. The other bound form of *myo*-inositol with sugar derivatives are pseudooligosaccharides (see Section 4.3.1.2.2) that occur in legumes.

Previous classification ranked choline, *N*,*N*,*N*-trimethylethanolammonium cation (with chloride or hydroxyl group as a counter ion), amongst the vitamins of the B group, and it was known as vitamin B_p (see Section 3.5.1.1.1). Plants and animals synthesise choline from glycine or serine, an intermediate of the biosynthesis is ethanolamine, which is methylated by folacin to yield choline. Choline is used for biosynthesis of phospholipids (phosphatidylcholine and sphingomyelin) occurring in cell membranes, in the biosynthesis of acetylcholine acting in the transmission of nerve impulses, participates in the transmethylation processes in the organism via its metabolite *N*,*N*,*N*-trimethylglycine (glycine betaine) and is a precursor of trimethylamine. Persons with the genetic disorder trimethylaminuria (the inability to metabolise trimethylamine) suffer from an unpleasant fishy body odour. Important food sources of choline include butter, egg yolk, pulses, oilseeds, nuts and cereals. The daily choline requirement is around 600 mg. Mild deficiency has been linked to fatigue, insomnia, poor ability of the kidneys to concentrate urine, problems with memory and nerve-muscle imbalances. Extreme dietary deficiency can result in liver dysfunction, cardiovascular disease, impaired growth, kidney failure, high blood pressure and other symptoms. Soybean lecithin is the most common form of supplemental choline, but choline itself is also available in food supplements. It is used therapeutically (perorally and parenterally) in various liver diseases (e.g. steatosis and cirrhosis), for maintenance of cell membrane integrity, support of nervous system activity and to lessen chronic inflammation. Adequate intake levels established by the U.S. National Academy of Sciences are: 125 mg (0–6 months), 150 mg (6–12 months), 200 mg (1–3 years), 250 mg (4–8 years), 375 mg (males and females 9–13 years), 400 mg (females 14–18 years), 425 mg (females 19 years and older), 450 mg (pregnant females), 550 mg (males 14 years and older and lactating females). Prevention of liver damage was the main criterion used in establishment of these recommended levels.

Acetylcholine is found in foods of animal origin. In some plants, such as rape seed, choline is found in the form of various phenolic acid esters, especially in sinapic (4-hydroxy-3,5-dimethoxycinnamic) acid esters, which are trivially called sinapine (see Section 8.2.7.1.1).

Bioflavonoids, also known as vitamin P (the permeability vitamin) are a group of biologically active flavonoids (flavonol and flavanone glycosides) that affect the permeability and elasticity of blood capillaries. These effects were first observed in a compound known as citrine obtained from citrus fruits. Later it was found that citrine is a mixture of hesperidin and eriocitrin (also known as eriodyctin). Significant biological effects have been demonstrated mainly in quercetin-3-β-rutinoside known as rutin (see Section 9.4.2.4). Bioflavonoids are found mainly in fruits and vegetables at a level of about 100–7000 mg/kg.

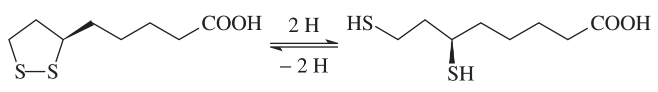
Vitamin U, also known as *S*-methyl-L-methionine, methylmethionine sulfonium chloride, cabigen or antiulcer vitamin, was originally called vitamin U, because of its usefulness against ulceration of the digestive system. It is produced from methionine in an enzymatically catalysed methylation by *S*-adenosyl-L-methionine (SAM), but can also arise in non-enzymatic reactions, for example by methylation of methionine with pectin. *S*-Methylmethionine serves as the storage form of labile methyl groups in plants and plays a role in preventing accumulation of the methylation agent SAM. It occurs mainly in *Brassica* vegetables where it is a precursor of dimethyl sulfide during thermal processing. Its cabbage-like odour plays an important role in cooked vegetables. The content of *S*-methionine is about 90 mg/kg in kohlrabi, 75–81 mg/kg in cabbage, 124 mg/kg in turnip, cabbage and 60 mg/kg in Savoy cabbage and Brussel sprouts. High concentrations of *S*-methylmethionine are also found in celery (60–176 mg/kg), leeks (60–94 mg/kg) and beetroot (89 mg/kg), but its concentration in tomatoes is only 2.8 mg/kg. In other vegetables the levels are lower and those found in fruits are about 1 mg/kg. *S*-Methylmethionine was recommended for the therapy of peptic ulcers, particularly of duodenal ulcers and also in hyperlipidaemia. The traditional use of raw cabbage juice for the treatment of peptic ulcers would seem to support the use of vitamin U supplements as a healing aid for damaged and eroded intestinal mucous. There is currently no recommended daily allowance of vitamin U. The recommended daily dose from food supplement manufacturers is 500–1000 mg.

Taurine (1-aminoethane-2-sulfonic acid, **5-136**) is the only known naturally occurring sulfonic acid that is essential for many biological processes. The major pathway of taurine metabolism is the synthesis of bile acids, which emulsify dietary fat and promote its processing in the intestines. Taurine is further involved in calcium metabolism modulation, neuroinhibition in the central nervous system, reproduction, osmoregulation, as well as the anti-inflammatory activity of leukocytes and platelet aggregation. It also plays a significant role as an antioxidant preventing the oxidative damage that occurs during the aging process. Recent studies have provided evidence that taurine also becomes a constituent of some biological macromolecules. For example, taurine-containing modified uridines have been found in the human mitochondria. Taurine combined with higher fatty acids, such as 2-(octadecanoylamino)ethanesulfonic acid, occur in cells of some protozoa (such as *Tetrahymena thermophila*). Taurine is biosynthesised from cysteine by two main distinct pathways, via cysteine

5-136, taurine

sulfinic acid and hypotaurine and via cysteic acid. Hypotaurine can likewise be produced from L-cysteamine. In mammalian tissues, taurine is a ubiquitous semi-essential amino acid occurring as a free compound, although its concentrations in different tissues and fluids vary widely. It also occurs in insect tissues and it is particularly abundant in flight muscle and in eyes. On the other hand, taurine is completely absent in plants. The estimated mean daily intake of taurine in food is around 58 mg. Good sources of taurine include meat (0.02–0.1% fresh weight) and some types of seafood, the latter being particularly rich sources. In mammalian tissues, taurine is the most abundant amino acid in the skeletal muscle, heart, retina, brain and leukocytes. Taurine is used as an ingredient in many energy drinks and energy products, usually containing 4000 mg/l taurine. They are marketed worldwide for the treatment of various physiological conditions, for improvement of athletic performance and for general wellbeing. Taurine is also available in food supplements and is claimed to treat a wide range of conditions, from alcoholism and hepatitis to congestive heart failure. There is no recommended dietary allowance for this compound. The daily dose recommended by producers of dietary supplements varies between 2000 and 4000 mg.

The lipophilic sulfur-containing coenzyme (*R*)-lipoic (α-lipoic) acid has the systematic name (*R*)-5-(1,2-dithiolan-3-yl)pentanoic acid. Lipoic acid is synthesised as an off-shoot of the fatty acid biosynthesis pathway in a wide number of organisms, including bacteria, fungi, plants and animals. Lipoic acid is essential for the activity of a variety of enzyme complexes that catalyse oxidative decarboxylation. In the cell, very little lipoic acid exists as the free acid; almost all is bound to the ε-amino group of the lysine residue of target complexes. In plants, lipoic acid as the prosthetic group of pyruvate oxidase is a key substance in photosynthesis and acts as a growth factor of many bacteria. Besides its activity as a coenzyme, lipoic acid is considered as an efficient antioxidant since, in its reduced form, (*R*)-dihydrolipoic acid (6,8-disulfanyloctanoic acid or 6,8-dimercaptooctanoic acid), it constitutes a redox couple via modulation of the NADH/NAD^+ ratio (Figure 5.34). Dihydrolipoic acid can scavenge hydroxyl and peroxyl radicals, but can also chelate transition metals (such as Fe and Cu). Lipoic acid occurs in almost all foods. Good sources are offal, yeast and some vegetables (such as spinach and broccoli), but lipoic acid is not readily available as it occurs in bound forms. Lipoic acid is also available in food supplements, primarily as an antioxidant and weight loss agent. It has also been suggested for treatment of cataracts, glaucoma, multiple sclerosis, burning mouth syndrome, Alzheimer's disease and strokes. The daily dose suggested by commercial suppliers is 200–300 mg, but no recommended daily allowance has been established.

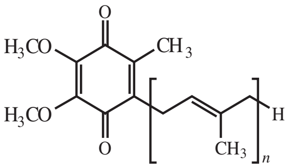


(*R*)-lipoic acid (*R*)-dihydrolipoic acid

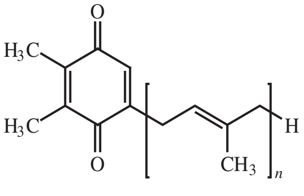
Figure 5.34 Reactions of lipoic acid.

A similar compound, 1,2-dithiacyclopentane-3-carboxylic acid (also known as tetranorlipoic or tetranorthioctic acid), was recently isolated from garlic.

Coenzymes Q_n (in short CoQ_n or ubiquinones-*n*) are 2,3-dimethoxy-5-methyl-1,4-benzoquinones with a long side-chain attached to C-2, which is composed of varying number of isoprene units ($n = 1–12$), which is dependent on the species (**5-137**). Most organisms synthesise a range of compounds, of which those where $n = 7–10$ usually predominate. Coenzyme Q_n functions as a mobile electron carrier within the mitochondrial inner membrane in all aerobic eukaryotic cells and many bacteria. Apart from this vital function, coenzymes Q_n act as effective antioxidants protecting cells from damage by free radicals, such as structurally similar vitamin E. In mammals, the most common form is coenzyme Q_{10} (also known as ubiquinone-10 or ubidecarenone), which contains ten isoprene units. Coenzyme Q_{10} co-exists with its reduced form $CoQ_{10}H_2$, known as ubiquinol-10. Coenzyme Q_{10} is derived from 4-hydroxybenzoic acid (*p*-hydroxybenzoic acid), though the origin of this compound varies according to the organisms. Thus, bacteria are known to produce coenzyme Q_{10} from chorismic acid, whereas plants and animals utilise a route from L-phenylalanine or L-tyrosine via 4-hydroxycinnamic acid (4-coumaric acid). The adult human body pool of coenzyme Q_{10} has been found to be approximately 2 g and requires replacement of about 500 mg per day. This must be supplied either by endogenous synthesis or from exogenous sources. Reduced biosynthesis and increased utilisation by the body (increasingly with age) are the major factors that lead to deficiency of coenzyme Q_{10} in humans. Coenzyme Q_{10} is found in almost all foods of animal and vegetable origin. The average daily content of the western diet is 3–5 mg. It is met mostly by meat, poultry and fish and to some extent by food of vegetable origin. Higher amounts of coenzyme Q_{10} are found in meat (14–54 mg/kg), liver (26–50 mg/kg), fish (4–67 mg/kg), vegetable oils (4–280 mg/kg) and nuts (2–27 mg/kg). Supplementation appears to be the way for older people, and certainly the ill, to provide the major proportion of the 500 mg/day needed, however the optimal intake is not yet known, as the available clinical trials have provided conflicting results.



5-137, coenzymes Q (ubiquinones), $n = 1–12$



5-138, plastoquinones, $n = 3–10$

In plants, coenzymes Q_n are accompanied by other lipophilic compounds of similar structure, plastoquinones (**5-138**), vitamin E and vitamin K_1. Similarly to tocopherols and tocotrienols, plastoquinones are produced from homogentisic acid by *C*-alkylation (*ortho* to the OH group) using polyisoprenyl diphosphate with $n = 3–10$, but most commonly with $n = 9$, which is called solanesyl diphosphate. Plastoquinones are involved in the photosynthetic electron transport chain in plants.

6

Minerals

6.1 Introduction

The chemical composition of food can be viewed either in terms of material composition, which is the representation of individual compounds, or in terms of elemental composition (content of individual elements). If we leave aside water, the bulk of the materials are organic food substances. The main constitutional elements of the organic compounds are non-metals: carbon (C), oxygen (O), hydrogen (H), nitrogen (N), phosphorus (P) and sulfur (S). These elements are called **organogenic elements**. Other chemical elements contained in food are **minerals**. The elements phosphorus and sulfur belong to both groups.

Minerals in food (dietary minerals, also known as mineral nutrients) are the chemical elements required by living organisms (other than carbon, hydrogen, nitrogen and oxygen present in common organic molecules) that are usually defined as the elements contained in the ash of a food, or more accurately as the elements that remain after the complete oxidation of the organic fraction of food to carbon dioxide, water and other oxidation products. The mineral fraction for most foods accounts for 0.5–3% by weight.

Minerals can be classified according to various criteria, for example with regard to concentration, biological and nutritional importance, dietetic effects and origin. According to the amount present, minerals are divided into the following four groups:

- **Majority mineral elements** Or quantity elements, formerly referred to as **macroelements**, which occur in food in larger amounts, usually in hundredths to units of weight per cent (hundreds to ten thousands mg/kg) and include alkali metals sodium (Na) and potassium (K), alkaline earth metals magnesium (Mg) and calcium (Ca), halogen chlorine (Cl) and non-metals phosphorus (P) and sulfur (S).

- **Minority mineral elements** These are found in foods in smaller amounts, representing the tens to hundreds mg/kg; a transition between the majority elements and trace elements; this category usually includes transition metals iron (Fe) and zinc (Zn).

- **Trace elements** or **microelements** Occurring in even lower concentrations (tens of mg/kg or less); important trace elements are transition metals cobalt (Co), chromium (Cr), copper (Cu), Fe (sometimes), manganese (Mn), molybdenum (Mo), nickel (Ni) and sometimes zinc (Zn), post-transition metal aluminium (Al), the halogen iodine (I) and non-metal selenium (Se).

- **Ultra trace elements** Normally comprising less than 1 μg/g (less than 0.0001% by weight); possible ultra trace elements in humans include the metalloids boron (B) and silicon (Si), the halogen fluorine (F), metalloid arsenic (As) and the transition metal vanadium (V); other possible ultra trace elements in other organisms include the alkali metal lithium (Li), halogens fluorine (F) and bromine (Br), transition metals cadmium (Cd) and tungsten, also known as wolfram, (W) and post-transition metals lead (Pb) and tin (Sn). Despite demonstrations of their roles in experimental animals, the exact function of these elements in human tissues and their importance for human health are uncertain.

The classification of minerals in foods to majority, minority, trace and ultra trace elements roughly corresponds to the occurrence of these elements in the human organism (Table 6.1).

The mineral contents in food are very different and extremely variable within the individual commodities and even within one commodity. This is due to differences in the metabolism of elements of diverse organisms, genetic factors and, in particular, conditions of production of the raw materials. Minerals originate in the soil and cannot be created by living organisms. Plants absorb minerals from the soil and animals obtain their minerals from the plants or other animals that they eat. Most of the minerals in the human diet come directly from foods of plant origin or indirectly from animal sources. Minerals from plant sources may vary from place to place, because the mineral content of the soil varies according to the location in which the plant was grown, and it further depends on soil characteristics, mode and degree of fertilisation, climatic conditions, level of maturity of crops and other factors. The mineral

Table 6.1 Minerals content in the body of an adult (body weight 70 kg).

Element	Total amount	Unit	Element	Total amount	Unit
Ca	1000–1500	g	Si	1.4	g
Mg	25–40	g	Cu	100–180	mg
K	140–180	g	Mn	10–20	mg
Na	70–100	g	Mo	5–10	mg
P	420–840	g	Co	1–1.5	mg
S	cca 140	g	Ni	10	mg
Cl	70–110	g	Cr	5	mg
Fe	3–5	g	V	<1–20	mg
Zn	1.4–3	g	I	10–30	mg
F	0.8–2.5	g	Se	10–20	mg

content of foods of animal origin depends on nutrition, age and state of health.

The general classification of elements as majority, minority, trace or ultra trace elements is therefore only approximate. For example, Al is present in various spices and tea in hundreds of milligrams per kilogram, so from this perspective it is one of the minor elements, while in milk it may be classified as a trace element or ultra trace element (because it is usually found in concentrations of less than 0.1 mg/kg). Another example of the difficulty in classification of elements is Mn. In animal products, such as beef or pork flesh, Mn is found only in traces (0.1–0.2 mg/kg), but about a 100-fold to 300-fold higher amount is found in cereals (wheat 35–49, rye 31–44, barley 16–25 and oats 45–72 mg/kg) and approximately 1000-fold higher level (300–1000 mg/kg) is present in tea leaves. In some food materials that are highly purified (refined sugar, refined oils), the total content of minerals is very low (up to hundredths to tenths of a per cent), so within these foods the common majority elements (Ca, P, K) are trace elements.

According to their physiological significance, minerals in foods are divided into three groups, namely:

- **Essential elements** Also known as **necessary** (**obligatory**) elements that the body must receive from food in certain amounts to ensure important biological functions (e.g. construction of biological structures, catalytic, regulatory and protective functions); the essential elements are all the majority elements (Na, K, Mg, Ca, Cl, P and S) and many trace elements (such as Fe, Zn, Mn, Cu, Ni, Co, Mo, Cr, Se, I, F, B and Si).

- **Non-essential elements** Physiologically indifferent elements or elements with as yet unknown biological functions that are not significantly toxic; this group includes all other chemical elements in food that usually occur in trace amounts (e.g. Li, Rb, Cs, Ti, Au, Sn, Bi, Te and Br); these elements sometimes regularly accompany essential elements (e.g. Li accompanies Na, and Rb accompanies K).

- **Toxic elements** Elements that have no biological role and are poisonous in the elemental form or produce poisonous soluble compounds exhibiting toxic effects; mechanisms of these effects often lie in the inhibition of metabolically significant enzymes as a consequence of interaction of the toxic element with the enzyme molecule; the most important toxic elements in food are particular metals (Pb, Cd and Hg) and metalloids (As).

Classification of an element into these groups is not definitive and depends on the specific biological species for which the element is essential. Furthermore, the toxic effects of certain metals are different for different organisms. It should be noted that even the essential elements (e.g. Se and Ni) can be toxic at higher doses. On the other hand, As, whose toxic effects have been known for a long time, is a physiological stimulating factor for some animals.

A certain element may be included among the essential elements of a larger group of animals if it satisfies the following conditions:

- the element is present in all healthy tissues of the body;
- its concentrations in the same body tissues of different species are similar;
- its exclusion from the diet leads to repeated physiological abnormalities;
- re-introduction to the deficient diet results in normal physiological state;
- complete and long-term elimination of the element from the diet results in the death of the organism.

Elements that do not meet all these criteria, even if there is evidence of positive effects of their presence in a nutritionally balanced diet, are not essential. They are referred to as **functionally beneficial**. Some elements can be found in characteristic quantities in the bodies of all organisms (such as alkali elements, P, S, Cl, Fe, Zn, Cu and Mn) and these are termed **invariable elements**. Other elements, known as **variable elements**, occur in higher concentrations only in some organisms. For example, V is present in blood cells of some tunicates, also known as urochordates or in fruiting bodies of some fungi (see Section 6.3.14.2), while in most other organisms it belongs to the trace or ultra trace elements.

Most of the elements discussed so far are natural food components. This means that they are present in a given food commodity in a characteristic amount, which is a consequence of a cycle of elements in nature and their natural distribution in different parts of the biosphere.

The presence in food of a higher amount of an element may be the result of contamination during the manufacturing process, or of the raw material during the agricultural production. This element is then considered a contaminant (e.g. toxic elements Pb, Hg, Cd, As, Tl and Sb). Any essential element (e.g. Cu, Co, Cr, Fe, Mn, Ni, Se and Zn) may also become a contaminant if its content

in food is significantly higher than the typical concentrations. Some anions also have toxic effects (see Section 6.6), as do some radionuclides (see Section 6.7).

For selected elements, the Recommended Daily Allowance (RDA) are set in the EU (first number) and United States (second number) as follows: K (2000/4700 mg), Cl (800/2300 mg), Ca (800/1000 mg), P (700/700 mg), Fe (14/8 mg), mg (375/400 mg), Zn (10/11 mg), Cu (1/0.9 mg), Mn (2/2.3 mg), F (3.5/4 mg), Se (55/55 μg), Cr (40/35 μg), Mo (50/45 μg) and I (150/150 μg). Insufficient intake of some essential elements through food can be solved by enrichment. For example, Ca can be added to dairy milk at a level of 30%, and I at 20% of the recommended daily allowances. Generally, food enrichment with calcium is through different calcium salts (carbonate, chloride, citrate, gluconate, lactate and phosphate), calcium oxide and hydroxide; iodine is added in the form of sodium or potassium iodide. If the element enrichment only compensates for the losses that occur during technological processing of raw materials, we talk about **restitution**. If the level of the element is increased above its natural concentration in the food by enrichment, it is called **fortification**. In both cases, the element is considered a food additive. Dietary supplements (also known as food supplements or nutritional supplements) may contain a single element, a mixture of different dietary minerals or combination of minerals together with vitamins and/or other beneficial compounds.

This chapter is devoted to mineral substances in foods, and deals first with their chemistry, binding options and interactions with food ingredients. All of the majority, minority, trace, ultra trace and non-essential mineral elements are described, and their presence in food, biochemical and physiological functions, metabolism, nutritional significance and health consequences are discussed. The next part of the chapter deals with toxic elements and toxic anionts, their occurrence in foods and the environment, dietary intake, metabolism, toxic effects and toxicological evaluation. The final part, dealing with radionuclides and radioactivity, concentrates on radioactive nuclides occurring in the environment and foods and their health implications.

6.2 Chemistry of minerals

Mineral substances found in food interact with water, with the organic matter present and with one another. These interactions affect the bioavailability of elements in the diet. The chemical state of the element in the food is determined by food composition, pH, the possibility of hydration of the metal ions, redox potential of the system and the related possibility of changing the degree of oxidation of the element and other factors. The solubility of the individual substances is closely associated with the resorption properties of the minerals. Food contains a number of components, such as amino acids, peptides, proteins, carbohydrates, lignin, phytic acid, organic acids and other compounds, which can bind minerals and thereby influence their biological availability. Interactions of various elements with organic molecules are studied in bioinorganic chemistry.

6.2.1 Bonding possibilities of elements

The chemical properties of the given element (depending on the form of the products) are crucial in the interactions of the element in the organic food matrix. These properties are determined by the position of the element in the Periodic Table and are a result of the electron configuration in the atom of the element.

Non-metals and metalloids with medium electronegativity values[1] (P, As, S and Se) form **covalent compounds** in biological systems, such as esters of phosphoric, pyrophosphoric and tripolyphosphoric acids, sulfur amino acids and their selenium analogues, arsenic analogues of amino compounds and sulfur heterocycles.

Elements with very low electronegativity (alkali metals, alkaline earth metals, such as Na, Ca and Mg) and elements with high electronegativity (halogens such as Cl and I) occur mainly as free ions in biological materials, and are preferably involved in electrostatic interactions. However, even these elements can form less soluble compounds (calcium oxalate), covalent compounds (hormones thyroxine and triiodothyronine are iodinated aromatic amino acids, see Section 2.2.1.2.5) or complex compounds (chlorides as ligands and some metal ions as central atoms). A ligand is an entity (atom, ion or molecule), which can act as an electron pair acceptor to create a coordinate covalent bond with the central ion. Cd and Hg also tend to form covalent compounds.

Transition metals and some post-transition metals (Al, Pb and Zn) have a strong tendency to form complex compounds. This is due, among other things, to the smaller radius and larger electric charge of their ions. These elements have a large number of potential reaction partners (ligands) in biological materials. The stability of complexes depends on the type of ligand donor atoms, the metal and its oxidation state together with steric factors. Divalent cations of the first transitional series, for example biologically important Cu^{2+} ions, form the most stable complexes. The preferred ligands of Cu^{2+} ions are ligands containing sulfur and nitrogen or several nitrogen atoms as donors. Conversely, Mn^{2+} ions form complexes fairly reluctantly, and in addition to ligands with sulfur and nitrogen entities with oxygen donor atoms can also act as ligands (Figure 6.1). Metal ions in oxidation

[1] Electronegativity is the ability of the covalently bound atom of an element to attract electrons. The light halogens and oxygen have the highest electronegativity and the heavier alkali metals have the lowest electronegativity. In general, the metals have lower electonegativities than the non-metals. Hydrogen has a medium electronegativity (2.1 according to the Pauling scale) and represents the transition between the two groups (of the metals, only Au and Pt have a higher electronegativity than hydrogen). For selected elements, the order of decreasing electronegativity is as follows: $F \gg O \gg Cl > N > Br > S = I > C = Se > P = H > As = B > Hg = Cu = Ag = Sb > Si = Sn = Pb = Tl = Fe = Co = Ni = Mo > Cd > Zn = Cr = V > Al = Mn = Ti = Be > Sc > Y > La = Ac > Mg > Ca = Sr = Li > Na = Ba > K = Rb > Cs = Fr$.

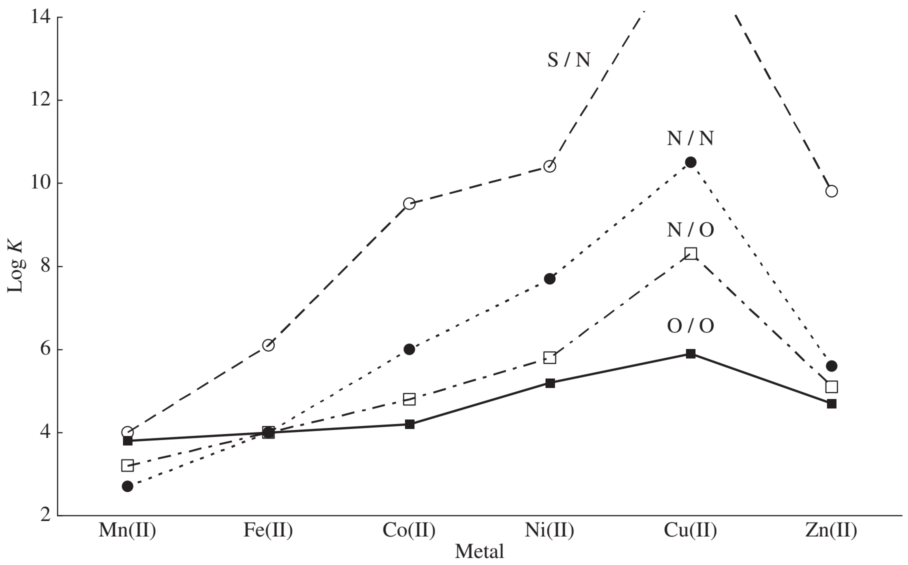

Figure 6.1 Dependence of the logarithm of stability constants (log *K*) of divalent metal cations complexes of the first transitional series on the type of ligand according to the type of donor atoms: (── oxalic acid-oxygen/oxygen; ·-·-·-· glycine-nitrogen/oxygen; ······· ethylenediamine-nitrogen/nitrogen; ------cysteine-sulfur/nitrogen). da Silva and Williams, 2001, fig 2.8. Reproduced by permission of Oxford University Press.

states III and IV are generally more stable than the corresponding cationic complexes in oxidation state II. Metal cations with higher charge may, however, in the neutral or weakly acidic environments typical of foods, form insoluble hydroxides, for example $Fe(OH)_3$, oxides (MnO_2) or oxocations (TiO^{2+}, VO^{2+} and BiO^{+}). Some metal ions in a middle oxidation state, unless they are bound in complexes, are susceptible to disproportionation (e.g. $2\ Mn^{3+} + 2\ H_2O \rightarrow Mn^{2+} + MnO_2 + 4\ H^{+}$). With the exception of Mo, which is commonly in the very stable oxidation state VI, transition metals do not occur in high oxidation states in biological materials (e.g. oxoanions MnO_4^{-}, MnO_4^{2-} and CrO_4^{2-}). Various forms of minerals in foods are summarised in Table 6.2.

6.2.2 Interaction with organic food components

6.2.2.1 Aminocarboxylic acids

Aminocarboxylic acids can bind metal ions as coordination compounds via dissociated carboxyl groups and amino groups. The donor atoms are the oxygen atom in the carboxyl group and

Table 6.2 Overview of forms of minerals in foods.

Form	Example
Elemental form	Fe in some fortified foods
Free and hydrated ions of metals and non-metals in different oxidation states	Cu^{2+}, $Cu(H_2O)_4^{2+}$, $Fe(H_2O)_6^{2+}$, $Fe(H_2O)_6^{3+}$, AsO_3^{3-}, AsO_4^{3-}
Complex compounds of metals with inorganic ligands	$CuCl_4^{2-}$, $Cu(NH_3)_4^{2+}$
Complex compounds of metals with organic ligands	Compounds with amino acids, peptides, proteins, carbohydrates, phytic acid, hydroxycarboxylic acids, plant phenols (flavonoids) and porphyrins
Minerals bound to insoluble biopolymers	Binding to various components of fiber
Slightly soluble compounds	Sulfides, sulfates, phosphates, oxalates, hydroxides, phytates
Covalent compounds of non-metallic and semimetallic elements	Phytic acid, sulfur amino acids and their selenium analogues, arsenic analogues of amino compounds
Organometallic compounds	Methylmercury, dimethylmercury, tetraethyllead

the nitrogen atom in amino group, which are able to provide an electron pair to the coordinate covalent bonds with the central metal ion. The stability of complexes of bivalent metal cations with amino acids decreases according to the bound metal in the order:

$$Cu^{2+} > Ni^{2+} > Zn^{2+} > Co^{2+} > Cd^{2+} > Fe^{2+} > Mn^{2+}$$

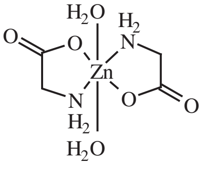
For a given metal, however, the stability constants of complexes with different amino acids can differ by more than two orders of magnitude. Amino acids and derived compounds (peptides and proteins) have amphoteric character and occur in an aqueous medium, depending on the pH, in various forms, which differ in their dissociations of the functional groups. The presences of these groups in the ligand molecule and the pH value have a decisive influence on the formation of complexes with metal ions. The participation of various functional groups in metal binding depends on two conditions:

- how the relevant functional group competes with other groups in the vicinity of the metal ions;
- how metal ions compete with hydrogen ions for the binding sites in the ligand functional groups.

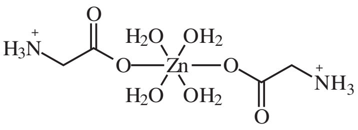
Dissociation constant values of various functional groups of amino acids thus affect the complex formation. The lower the pK value, the greater the ability of the ligand donor atom to bind the metal. In a certain pH range, more functional groups can act as electron acceptors, which lead to the formation of cyclic complexes, **chelates**, which are thermodynamically more stable than complexes with monofunctional ligands. The ability to form a chelate of suitable coordination geometry depends on whether the ligand molecule configuration allows the creation of five- to seven-membered rings. Amino groups of amino acids are, despite of high pK values, often involved in coordination bonds with metals together with the amino acid anion. The nucleophilic character of the nitrogen atom facilitates coordination.

The effect of the acid–base equilibrium on the structure of amino acid–metal complexes can be demonstrated by glycine complexes with zinc. In neutral media, both functional groups of glycine (Gly) are involved in the binding of zinc, yielding the chelate $Zn(Gly)_2{\cdot}2H_2O$ (**6-1**). In acidic media, amino groups are protonised, so the metal is bound only by the carboxyl groups and the tetrahydrate of the zinc salt of glycine, $Zn(Gly)_2.4H_2O$ (**6-2**), forms. The nucleophilic character of nitrogen facilitates the coordination.

Other functional groups of amino acids may also contribute to the formation of complexes with metals and stabilise them through

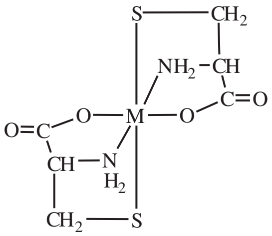


6-1, diaqua-bis(glycinato)zinc complex



6-2, glycine zinc salt tetrahydrate

additional bonds. Metals and metalloids with a distinctive affinity for sulfur (such as Hg, Cd, Ag, Cu, Bi, Sb and As) yield very stable compounds with thiols. The participation of the sulfhydryl group in cysteine in bonds with metal ions leads to a complex of higher stability (**6-3**). Stability constants of cysteine complexes with Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+} a Pb^{2+} are significantly higher than the corresponding glycine and histidine complexes. Unlike sulfhydryl groups, hydroxyl groups in serine, threonine and tyrosine do not contribute significantly in the metal binding.

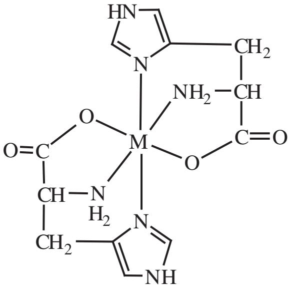


6-3, complex of metal (M) with cysteine (M = Cu, Zn, Cd, Mn, Ni, Fe, Pb)

Often, however, the imidazole nucleus of histidine (free and bound histidine in peptides and proteins) is involved in metal binding. The order of dissociation of functional groups in the molecule of histidine is evident from the following pK values: pK_1 (COOH) = 1.80, pK_2 (imidazolium) = 6.04, pK_3 (NH_3^+) = 9.33, pK_4 (imidazole) = 14. This results in the following stages during the formation of histidine complexes with metals:

- coordination at the oxygen atom of the carboxyl, even at low pH value
- metal binding to the nitrogen atom of the imidazole nucleus
- metal binding to the amino group nitrogen.

All three types of bonds occur in complexes such as bis-L-histidinatonickel or bis-L-histidinatocobalt (**6-4**). Stable



6-4, complex of metal (M) with histidine (M = Co, Ni)

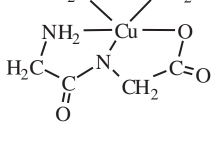
complexes also form amines and diamines (products of decarboxylation of amino acids) such as histamine, cysteamine, putrescine and cadaverine (see Section 10.3.2.10).

As well as the common basic amino acids and their homologues, such as ornithine and homocysteine, some less common amino acids may also act as metal ligands. Examples are heterocyclic amino acids with an azetidine ring (see Section 2.2.1.2.10), especially nicotianamine (2-71) and its hydroxylated derivative mugineic acid (2-72). Amino acids of this type are, among other substances, excreted by plants in the vicinity of the roots, and the complexing action solubilises iron and some other elements in the soil. The metals are then more accessible to the root system of the plants. In relation to this function, these compounds are referred to as **phytosiderophores**. Nicotianamine was found in some plants (called heavy metal hyperacumulators) to have an extraordinary ability to accumulate particular metals from the soil, especially nickel and zinc. However, other than nicotianamine, further ligands, especially hydroxycarboxylic acids, are similarly involved in the binding of metals accumulated in excessive amounts in plant tissues. Another important natural ligand, ethylenediaminetetraacetic acid (EDTA), was recently found in some hyperaccumulating herbs. This compound has been widely used in analytical chemistry (where it is known as Chelatone 3), in chemical technology and as a food additive (see Section 11.3.3).

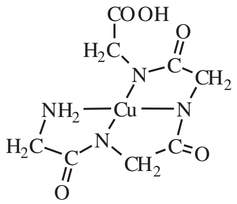
6.2.2.2 Peptides and proteins

Peptides and proteins can bind metals through the *N*-terminal amino group, *C*-terminal carboxyl and functional groups in the side chain of amino acid residues. This is particularly true of amino acids such as lysine (Lys), ornithine (Orn), aspartic acid (Asp), glutamic acid (Glu), cysteine (Cys) and histidine (His). Another option is to bind the metal to the oxygen or nitrogen atom of the peptide bond. The oxygen atom of the carbonyl group of the peptide bond has only a slight nucleophilic character, so that metal binding is weak. The neighbouring amino group can provide chelate stabilisation. Binding of metal ions on the nitrogen atom of the peptide bond assumes that dissociation of the NH group as an electron pair on the nitrogen is not available.

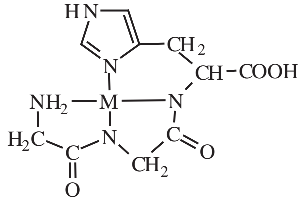
In metal complexes of some oligopeptides, such as Gly-Gly, Gly-Gly-Gly-Gly or Gly-Gly-His, a peptide chain surrounds the central metal ion and creates bonds with the participation of all sterically accessible donor groups. Alternatively, free coordination sites are occupied by water molecules (**6-5** to **6-7**). In some simple peptides, such as Gly-Gly, the structure of their complexes with metals may be rather complex and multinucleated complexes may arise, such as $Zn_2(Gly\text{-}Gly)_4.2H_2O$.



6-5, complex of copper with dipeptide Gly-Gly



6-6, complex of copper with tetrapeptide Gly-Gly-Gly-Gly



6-7, complex of metal (M) with tripeptide Gly-Gly-His

Metallothioneins, a family of cysteine-rich metal-binding peptides and low molecular weight proteins (molecular weight of 3.5–14 kDa), occupy a special role among naturally occurring compounds that act as metal ligands. Metallothioneins are found in the bodies of many microorganisms, plants, fungi, invertebrates and vertebrates, including humans. They were originally found in the internal organs of mammals, such as the kidneys, liver, intestines, spleen and pancreas of horses, cattle and other livestock. Metallothioneins ensure detoxification of toxic metals (such as Cd) by formation of stable complexes. Stable complexes with essential metals (e.g. Zn and Cu) are employed for temporary storage of metals in tissues until they are required for the synthesis of metalloproteins or other substances. They also provide protection against oxidative stress. The first categorisation of metallothioneins (MTs) established three classes: class I, includes the metallothioneins that are homologous with horse metallothionein; class II, includes the rest of the metallothioneins with no homology with horse metallothionein; and class III, which includes phytochelatins.[2] All mammals express at least the main isoforms of class I metallothioneins, designated as MT1, MT2, MT3 and MT4. MT1 and MT2 are expressed in almost all tissues, whereas MT3 and MT4 are tissue-specific.

Metallothioneins of class I are thermostable and acid resistant peptides characterised by a molecular weight of 6–7 kDa, containing 60–68 amino acid residues, including 20 cysteine residues (cysteine residues represent about 30% of the amino acid content of metallothioneins) and binding a total of seven equivalents of bivalent metal ions. Aromatic amino acids are usually absent. The positions of the cysteine and lysine units in peptide chains are almost identical in various types of mammalian metallothioneins. The *N*-terminal amino acid is *N*-acetylmethionine (Figure 6.2).

[2]The current classification divides metallothioneins into 15 groups and is based on taxonomic parameters and the pattern of distribution of cysteine residues along the metallothionein sequence. Family 15 contains the plant metallothioneins later classified into four different types depending on the distribution of their cysteine residues and cysteine-devoid regions.

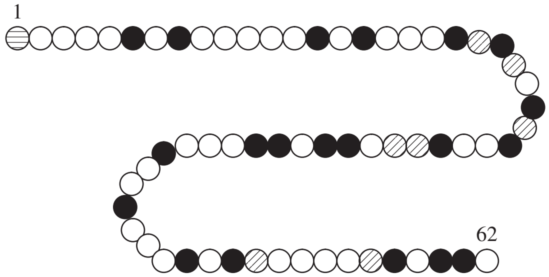


Figure 6.2 Cysteine (full circles), lysine (obliquely shaded circles) and *N*-acetylmethionine (horizontally hatched circle) positions in the sequence of amino acids in mammalian metallothioneine.

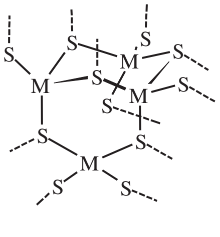
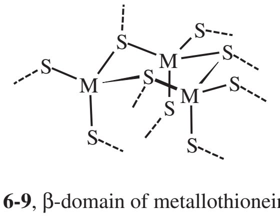
All cysteine residues occur in the reduced form and are coordinated to the metal ions through mercaptide bonds. Despite these common structural features, metallothioneins are organ-specific species. Their increased synthesis in the body is induced by higher dietary intake of metals (Cd, Cu, Zn, Ni, Pb, Co, Bi, Hg, Au and Ag) or exposure in the environment in which an organism lives. The synthesis of metallothioneins is most strongly induced by Cd. One peptide molecule can bind up to seven atoms of divalent metals. Complexes isolated from animal tissues almost always contain Zn and Cd. These substances, however, still have binding capacity, which allows the fixing of the other metal ions. Detailed studies of the metallothionein structure have found that the metal atoms are bound in two domains, α and β. Domain α (**6-8**) is located near the *C*-terminus of the peptide chain and the participation of 11 sulfur atoms fixes the four metal atoms. Domain β (**6-9**) is located near the *N*-terminus of the peptide chain and the participation of nine sulfur atoms fixes three metal atoms (M). Cu in the monovalent form may be bound in complexes with metallothionein in even larger quantities (12 Cu^{I} atoms in one molecule). Cu–thioneins are characterised by a distinctive orange to red fluorescence when excited by UV radiation.

Another type of class I metallothionein, known as MT3, contains bound Cu and Zn and occurs in brain tissue. A typical representative is composed of 68 amino acids and is similar to metallothioneins of crustaceans, which contain 18 cysteine residues. Similar binding peptides were also found in other animals exposed to toxic elements, for example in fish and invertebrates.



6-8, α-domain of metallothioneine (M = metal)



6-9, β-domain of metallothioneine (M = metal)

Metallothioneins of class II also contain a high proportion of cysteine units and their positions in various polypeptides of this group are quite different. A molecule of these peptides contains the characteristic repeating units Cys-Cys and Cys-X-Cys or Cys-X-X-Cys, where X is an amino acid other than cysteine. These polypeptides were found in several economically important crops such as wheat, maize, rice, buckwheat and cotton, but often only in certain parts of the plant and at specific stages of its growth.

Class III metallothioneins represent plant and microbial peptides called **phytochelatins** (previously known as cadystins or EC-peptides). These peptides are oligomers of glutathione, produced by the enzyme phytochelatin synthase, and have a primary structure $(\gamma\text{Glu-Cys})_n$-Gly, where $n = 2$–11. Phytochelatins also includes homophytochelatins, $(\gamma\text{Glu-Cys})_n$-β-Ala, homoglutathione oligomers, (glycine is replaced by β-alanine), hydroxymethylphytochelatins (hydroxyglutathione oligomers), $(\gamma\text{Glu-Cys})_n$-Ser, with serine as the *C*-terminal amino acid and isophytochelatins that have their amino acid sequence terminated by glutamic acid (glutamylcysteinylglutamate derivatives) or glutamine, $(\gamma\text{Glu-Cys})_n$-Glx. Other groups include deglycylphytochelatins, $(\gamma\text{Glu-Cys})_n$ and deglutamylphytochelatins with the structure Cys-$(\gamma\text{Glu-Cys})_n$-Gly. Phytochelatins and related substances in the cells are able to bind heavy metal ions into stable complexes, which are then stored in the vacuoles. Phytochelatins can be found in yeasts, algae, mosses and even higher plants. Their formation in plant tissues is probably to protect the plant against the toxic effects of heavy metals. They also occur in some agriculturally important plants, such as potatoes, beans, wheat, barley or maize. Legume plants (family Fabaceae) primarily contain homophytochelatins, while grasses such as cereals (members of the monocot family Poaceae), with the exception of maize, synthesise hydroxymethylphytochelatins.

Binding of metals in biological materials is largely mediated by proteins. This binding of the metal ions by the protein molecule proceeds by a similar mechanisms to that for the amino acids and peptides. The functional groups of proteins that are involved in metal binding are not necessarily the amino acid residues that are adjacent in the polypeptide chains. The close contact with the metal ion due to the tertiary structure of the proteins can also extend to those parts of the macromolecule that are fairly distant from one another in the amino acid sequence. Another possibility is the binding of metals by interaction with phosphate groups of phosphoproteins (e.g. glycophosphoprotein of egg yolk, called phosvitin, forms complexes through the serine residues with Fe^{3+}, Ca^{2+} or Mg^{2+}). The possibility of interactions of proteins with metal ions and the stability of the resulting complexes depends on temperature, pH, the type of metal ion, the presence of other components in the primary structure and protein conformation.

Metal complexes of proteins that occur in foods can be of two types. The first group of complexes, arising randomly, is relatively labile. Owing to the large number of reactive functional groups, practically every protein interacts with metal ions under appropriate

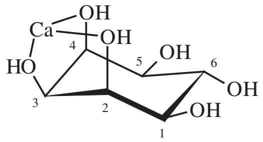
conditions (pH value). The constitution of such a complex is not uniform and demonstrates the statistical distribution of the individual particles, which reflects the degree of dissociation of the functional groups of the protein. The stability and properties of such complexes can only be partially estimated on the basis of theory, so in each particular case it is necessary to examine them experimentally. Higher concentrations of some metal ions can lead to protein denaturation.

The second group of metal complexes with proteins are **metalloproteins**, which have a regular structure, metal binding sites for the metal ion and a characteristic way of binding. The metal can also be bound by substances other than amino acids in the protein macromolecule, for example prosthetic groups (Fe bound in the porphyrin structure of haem in haemoglobin, myoglobin and haem enzymes). Some metalloproteins have very important biological functions; metalloproteins act as catalysts (metalloenzymes), transport and storage compounds (Table 6.3). A number of important metalloenzymes are mentioned in the relevant sections dealing with the individual elements.

6.2.2.3 Saccharides and their derivatives

In principle, polyhydroxy compounds such as saccharides and sugar alcohols also have chelating effects (due to the affinity of the chelating ligands for a metal ion). These compounds, however, (with the exception of the special steric arrangement) occur only under exceptional chemical conditions, which foods do not usually encounter. The oxygen atom of the hydroxyl group is for most metals a much weaker donor of an electron pair than atoms of nitrogen or sulfur. Monosaccharides, disaccharides and sugar alcohols form complexes with metal ions in an alkaline medium. Complexes with ferric ions are coloured yellow to dark brown, and the stoichiometric ratio of Fe and sugar is 1 : 1. The study of these compounds was initiated because of the finding that the addition of some sugars in the diet (especially D-fructose and D-glucitol) increases the bioavailability of iron. Aldoses and ketoses may form complexes with metals in acyclic (hydrates) or cyclic forms (furanoses and pyranoses). For example, in acidic media, D-altrose (also D-arabinose and D-idose) predominantly form complexes in their acyclic forms with hexavalent Mo ions. In the binding of ions, the hydroxyl group of the hydrated carbonyl group and the secondary hydroxyl group at C-2, C-3 and C-4 act as donors. The aldopyranoses D-allose and D-gulose form complexes under the participation of hydroxyls at C-2, C-3, C-4 and C-6. Similar complexes are formed from pentose D-ribose. Derivatives of carbohydrates, such as aldonic and alduronic acids, 2-amino-2-deoxysugars and sugar phosphates, have an even stronger tendency to form complexes.

Spontaneous formation of complexes of carbohydrates and related compounds with metal ions in food can be expected for those substances where configuration of the hydroxyl groups on the three adjacent carbon atoms in the six-membered rings of the chair conformations are alternately axial, equatorial and axial. This is the case for the *epi*-inositol–Ca^{2+} complex (**6-10**).



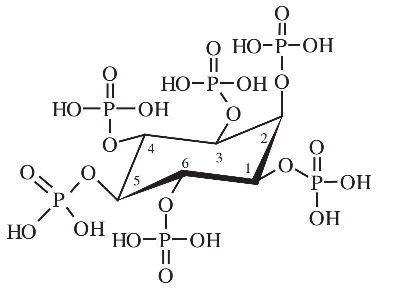
6-10, complex of calcium with *epi*-inositol

Phosphorylated organic substrates (e.g. sugar phosphates) are weak acids and can form salts with various metals. An important binding agent for metallic elements is **phytic acid** (*myo*-inositol hexakisdihydrogen phosphate). Conformation of phytic acid in solutions of pH 0.5–9 (one phosphate group in the axial position and five phosphate groups in equatorial positions) is represented by the formula shown in **6-11**. In solutions of pH > 9.5, five phosphate groups are bound in the axial positions and one in

Table 6.3 Some important metalloproteins.

Element	Metalloprotein	Occurrence	Element	Metalloprotein	Occurrence
Ca	Calmodulin	Muscle	Cu	Plantacyanin	Spinach
	Parvalbumin	Muscle		Ceruloplasmin	Blood plasma
	Troponin C	Muscle		Cerebrocuprein	Brain
Fe	Myoglobin	Muscle		Haemocuprein	Blood
	Haemoglobin	Erythrocytes	Mo	Xanthinoxidase	Liver
	Cytochromes, catalases, peroxidases	Widespread	Fe (Cu, Zn, Mn)	Conalbumin	Egg white
	Transferrin	Blood, liver	Ni	Nickelplasmin	Krevní plasma
	Ferritin	Spleen		Urease	Soy, rice
	Lactoferrin	Milk	Mn	Pyruvate decarboxylase	Widespread
	Ferredoxins	Spinach		Arginase	Liver

the equatorial position. At pH 9.5, both chair conformations are present in equimolar concentrations.



6-11, phytic acid

Phytic acid forms stable complexes with calcium, magnesium, iron, zinc and other metal ions, so-called **phytates**, in ratios of 1 : 1 to 1 : 6. The calcium–magnesium complex of phytic acid is known as **phytin** (or calcium–magnesium phytate). Binding of various metals on phytic acid at pH = 7.4 drops in the order: Cu > Zn > Ni > Co > Mn > Fe > Ca. The strong binding of the elements in these compounds and low solubility (iron phytate) results in decreased bioavailability of the bound elements in diets that contain higher amounts of phytic acid and phytin, which may, however, prevent colon cancer by reducing oxidative stress in the lumen of the intestinal tract. Phytic acid and its salts with metals are found in foods of plant origin, especially cereals, legumes, oil seeds and nut hulls (see Section 6.3.4.2.1).

Owing to the negative charges of the dissociated phosphate groups, phytic acid (even with bound metal) can react with ionised proteins or with some phospholipids (Figure 6.3), and the complexes phytic acid–protein, metal–phytic acid–protein or phytic acid–metal–phospholipid are formed. In an acid medium, the proteins are bound to phytic acid by positively charged amino groups of the basic amino acids (Lys, Arg and His) and by the terminal amino groups. At a pH value equal to the pH of the protein isoelectric point, only weak interactions proceed. In neutral and alkaline media, phytate complexes with metals bind to proteins through ionised carboxyl groups. Crude soybean oil, for example, contains approximately 50–340 mg/kg phytate, which is largely removed during oil degumming and passes, together with the phospholipid fraction, into the lecithin fraction. Degummed oil contains phytates at a level of about 4–50 mg/kg.

During the sugar juice clarification (known as carbonation; see Section 4.4.2.1.2) using calcium hydroxide, saccharose dissociates in an alkaline medium in several steps (at 25 °C: $pK_1 = 12.60$; $pK_2 = 13.52$; $pK_3 = 13.72$; $pK_4 = 13.77$). The most reactive atoms are hydrogens of the primary hydroxyl at C-6 of the glucose moiety, and C-1 and C-6 of fructose moiety. It is reported that in solutions of pH 11, about 10% of sucrose is present in the form of

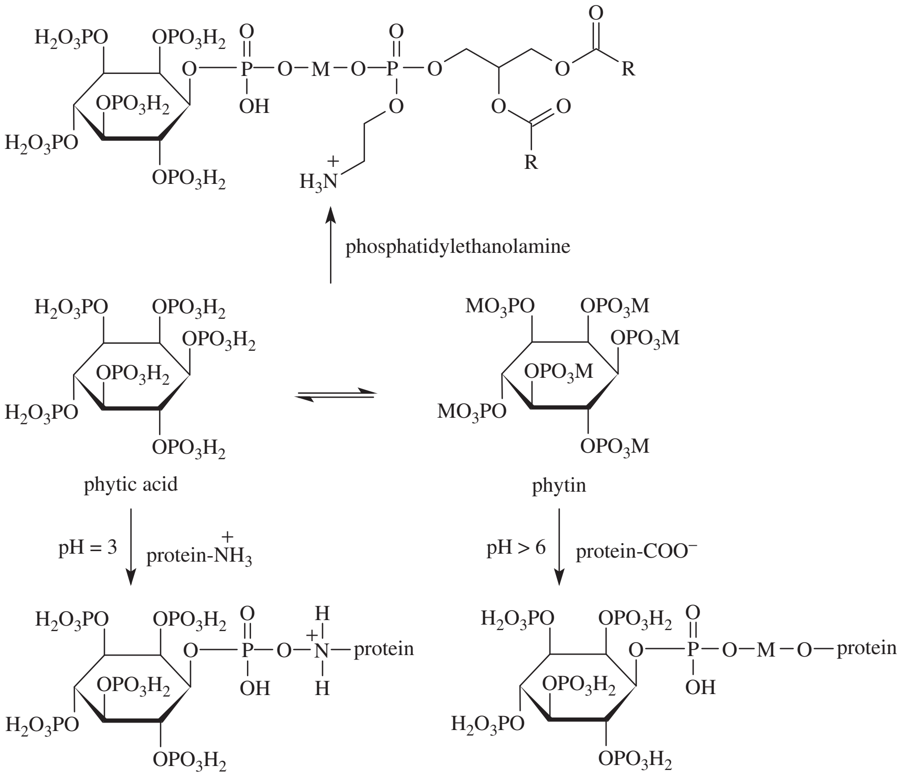


Figure 6.3 Reactions of phytic acid and phytin with metal ions (M = Ca, Mg, Zn, Fe, Cu, Mn), proteins and phospholipids (R = fatty acid residue).

monovalent anions, at pH 12.2 about 50% of the molecules, and at pH 12.5 bivalent anions[3] are also present. Depending on the amount of added lime milk (pH of the juice) and the temperature, initially soluble monocalcium saccharate (with the molecular formula $C_{12}H_{22}O_{11}{\cdot}CaO$) and slightly soluble dicalcium saccharate ($C_{12}H_{22}O_{11}{\cdot}2CaO$) form, followed at higher pH and higher temperatures by insoluble tricalcium saccharate ($C_{12}H_{22}O_{11}{\cdot}3CaO$). In solutions, the ions $(C_{12}H_{21}O_{11}Ca)^+$ or $(C_{12}H_{21}O_{11}Ca_2)^{3+}$ are apparently present. After saturation of juice by carbon dioxide, which decreases the pH to 8.9–9.2, saccharates decompose. Formation of insoluble tricalcium saccharate is used to obtain saccharose from molasses. Similar complexes, as with calcium ions, are similarly formed with Sr^{2+} and Ba^{2+}ions.

Disaccharide lactose has a unique position in terms of its ability to form complexes. It was found that it forms complexes with metals (Ca, Ba, Sr, Mg, Mn, Zn, Na and Li) in the ratio of 1 : 1 and in the range of pH 2–6.5. Binding of calcium by lactose is considered to result in increased resorption of calcium from milk.

Polysaccharides derived from glycuronic acids (such as pectins and alginates) form strong complexes with Ca^{2+} ions, which result in the formation of gels. Non-utilisable insoluble polysaccharides (e.g. cellulose and some hemicelluloses) and lignin that are classified as the insoluble fibre can also bind various minerals. These interactions can have a significant effect on the resorption of bound elements in the gastrointestinal tract. When studying metal binding to cellulose and hemicelluloses (such as arabinoxylans) it was found that the strength of interaction decreases in the order: Cu > Zn > Ca. In slightly acidic media, cupric ions show a high affinity for cellulose, but in the presence of glycine the binding of copper to the surface of cellulose molecules is substantially reduced. Lignin has two types of binding sites for binding metals. For binding sites with high affinity, the interaction strength decreases in the order: Fe > Cu > Zn, while for binding sites with low affinity the order of decreasing interaction strength is: Cu > Fe > Zn.

Various components of dietary fibre also have considerably different ion-exchange capacity. A long-term excessive intake of dietary fibre may bring about symptoms of calcium, iron and zinc deficiency. This reduced resorption of minerals is especially pronounced for high doses of fibre and likewise of phytic acid.

6.2.2.4 Lipids

Food lipids usually contain only trace amounts of minerals. Non-polar triglycerols and waxes have virtually no possibility of bindig mineral components. The exception is the opportunity for π-interaction of unsaturated fatty acids and unsaturated lipids that are able to complex with transition metals, such as silver. The complexes are of the charge-transfer type where the unsaturated compound acts as an electron donor and the Ag^+ cation as an electron acceptor. Free fatty acids yield salts with metals.

The situation is different in the polar lipids as their molecules contain both hydrophobic chains of fatty acids and the hydrophilic residue. Phospholipids, especially phosphatidic and lysophosphatidic acids, form salts with various metal ions. The stability of salts of phosphatidic acid decreases as: $UO_2^{2+} > Th^{4+} > Ce^{3+} > La^{3+} > Cd^{2+} > Pb^{2+} > Mn^{2+} > Cu^{2+} > Zn^{2+} > Co^{2+} > Ca^{2+} > Mg^{2+} > Ni^{2+} > Sr^{2+} > Ba^{2+} > Ag^{+} > Li^{+} > Na^{+} > K^{+}$. Ampholytic phospholipids (e.g. phosphatidylserine and phosphatidylethanolamine) form complexes with metal ions. The phosphate group and probably the amino group are also involved in the metal binding.

[3]Carbonation is usually carried out in two stages, first at pH 10.8–11.9 and temperature of 60–70 °C for about 20 min and then, after another addition of lime milk (CaO content in the juice is 2–2.5%) at 80–85 °C for 30 min.

6.2.2.5 Carboxylic acids

Aliphatic mono- and dicarboxylic acids (such as acetic acid and oxalic acid, respectively), oxocarboxylic acids (such as pyruvic acid), hydroxycarboxylic acids (citric, tartaric, malic and lactic acids) and numerous aromatic acids (such as benzoic acid) are normal constituents of plant and animal foods. They form salts with metal ions and their anions also have the properties of ligands. Carboxylic acids are the major binding partners of metals in fruits and some vegetables. They also contribute significantly to the binding of minerals (metal ions) by humic substances in soils and sediments.

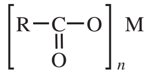
Calcium forms stable insoluble salt with oxalic acid (see Section 10.2.3.2). In plant cells with higher concentrations of oxalic acid, calcium oxalate can be actually present in the form of crystals. Some plants have been shown to bind metals in mixed complexes. For example, chromium can be bound in an oxalate–malate complex, and nickel and zinc can form a citrate–malate complex. Citric acid has been proven to be a low molecular weight zinc ligand in human milk, and in casein micelles it binds calcium. It is also used as a food additive (acidulant, synergist to antioxidants and sequestrant), so great attention has been paid to the formation of its complexes with metal ions. The addition to cereal products leads to increased solubility of naturally present iron, due to its release from phytic acid salts (phytates).

Other acidic substances, such as ascorbic acid, also form metals complexes. Of particular interest is the ternary complex of ascorbic acid with oxygen and Fe^{3+} or Cu^{2+} ions, formed during autoxidation of vitamin C (see Section 5.14.6.1.2). Ascorbic acid can also reduce metal ions. During the reduction of Fe^{3+} ions to Fe^{2+} ions, hydroxyl radicals are generated as byproducts (see Section 5.14.6.1.3). In this reaction, ascorbic acid acts as a prooxidant. The stability of ferric complexes of aliphatic organic acids decrease in the series: citrate $\gg$ succinate $\approx$ ascorbate $\approx$ malate > lactate.

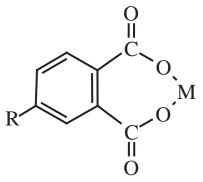
Examples of some complexes of aliphatic and aromatic carboxylic acids with metal ions are represented by formulae (**6-12**) to (**6-16**), and in Figure 6.4. Aromatic 1,2-dicarboxylic acids form metal complexes with M^{2+} ions in a molar ratio of 1 : 1 (**6-13**), but the metals may also be coordinated with a ligand belonging to two or more acid molecules (**6-14**).

6.2.2.6 Flavonoids and other plant phenols

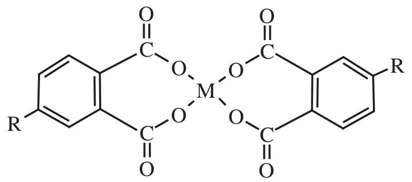
The transition element ions form complexes with a number of aromatic compounds in which two adjacent carbon atoms of the



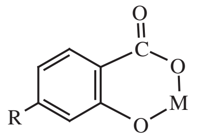
6-12, complex of metal (M) ion with aliphatic carboxylic acid



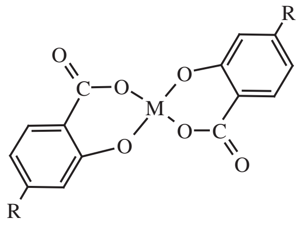
6-13, complex of metal (M) ion with aromatic dicarboxylic acid



6-14, complex of metal (M) ion with two molecules of aromatic dicarboxylic acid



6-15, complex of metal (M) ion with an aromatic 2-hydroxycarboxylic acid (salicylic acid derivative)



6-16, complex of metal (M) ion with two molecules of an aromatic 2-hydroxycarboxylic acid (salicylic acid derivative)

aromatic ring bear hydroxyl groups or hydroxyl and carbonyl groups. This structural motif is common to a large number of plant phenolic compounds.

Reaction with metal ions is related to the antioxidant activity of phenols. For example, flavonoids with two hydroxyl groups in positions C-3′ and C-4′, a carbonyl group in position C-4 and free hydroxyl at position C-3 or two hydroxyls in positions C-3 and C-5 have the highest antioxidant activity. The reaction of metal ions with flavonols is given in Figure 6.5 as an illustration, as flavonols belong to prominent yellow pigments of plants and act as very efficient antioxidants. Glycosides of flavonols, for example, have been identified as the main ligands of zinc in tea infusions. Aluminium in tealeaves is bound preferentially by catechins, and to a lesser extent by chlorogenic acid and other phenolics.

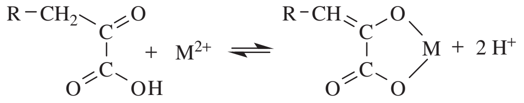


Figure 6.4 Formation of metal (M) ion complex of 2-oxocarboxylic acid.

6.2.2.7 Porphyrins and corrinoids

The macrocyclic tetrapyrrole skeletons of a range of natural substances can act as ligands that bind metals to form complexes. In foods, the main important types of macrocyclic tetrapyrroles are porphin (see Section 9.2) and corrin (see Section 5.13.1) derivatives.

Biologically important porphyrins (compounds with modified pyrrole subunits) are **haems** that contain iron as the central atom and act as a prosthetic group of important proteins, such as haemoglobin (the respiratory pigment in red blood cells of vertebrates), myoglobin (the pigment in muscle fibres) and other porphyrins. Metalloproteins that have haem as their prosthetic group are known as haemoproteins. Of the various Fe-porphyrins, haem *b* (an iron chelate derived from protoporphyrin IX) is the most important compound contained in the molecules of globins, catalase, peroxidase, as well as proteins involved in the synthesis and transport of nitric oxide and proteins involved in electron transport (P450 enzymes). Haems are also the prosthetic groups of a small number of enzymes, such as cytochrome *c* oxidase (haem a_3), cytochrome *c* 554 (haem *c*), nitrite reductase, sulfite reductase (sirohaem), cytochrome cd_1 sulfite reductase (hem d_1), quinol oxidase cytochrome *bo* (haem *o*) or hydroxylamine oxidoreductase (haem P460). With the exceptions of haem c and P450 that are covalently bound to the protein via the cysteine unit sulfur atom, other haems are bound to the corresponding proteins by non-covalent interactions, especially by hydrophobic interactions. This allows the substitution of hydrophobic porphyrin vinyl

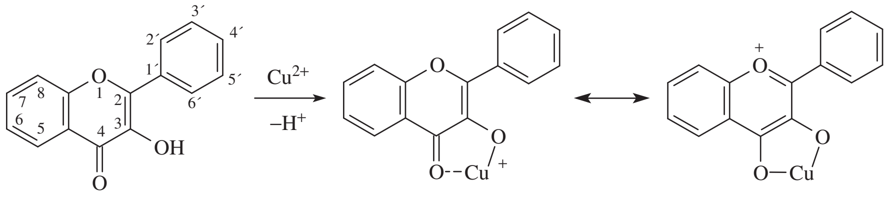

Figure 6.5 Complex of flavonols with Cu ions.

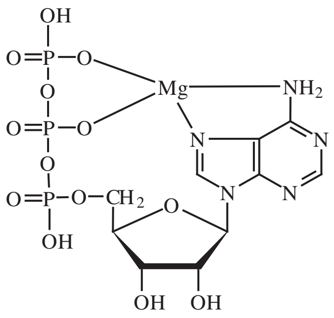
(majority of haems) and farnesyl groups (haem *a* and haem *o*). Iron bound to haemoproteins has the coordination number five or six. In addition to the four nitrogen atoms of the pyrrole subunits, iron is coordinated in a direction perpendicular to the plane of the porphyrin cycle with the imidazole nitrogen atom of the histidine residue, or with the sulfur atom of the cysteine residue, or with the phenolic oxygen atom of the tyrosine residue in the protein. The sixth coordination site of iron is usually occupied by a diatomic molecule, such as O_2 (e.g. in oxymyoglobin and haem oxidase), NO (e.g. in nitroxymyoglobin) or CO (e.g. in carbonylmyoglobin).

Porphyrin structures known as **chlorophylls** (green pigments of many plants, algae and cyanobacteria) contain magnesium as the central atom. Magnesium is not very tightly bound and in acidic media can be replaced by hydrogen ions. This substitution yields compounds called phaeophytins that can similarly re-bind other metal ions, such as Cu^{2+}, Zn^{2+} or Sn^{2+}. Some of these complexes are more stable than chlorophylls. Their spontaneous formation, however, proceeds only in contaminated foods. The intentional addition of salts of these elements to foods, in order to stabilise their colour, is not allowed. The most common form used as a food additive and in alternative medicine (including cancer prevention) is chlorophyllin (natural green 3, E140), a semi-synthetic mixture of water soluble sodium–copper salts derived from chlorophylls.

A group of cobalt-containing organometallic compounds derived from corrin that are known as cobalamins, have the activity of vitamin B_{12}. In addition to the four coordination bonds with nitrogens of the tetrapyrrole cycle, the central Co^{3+} atom is bound by two other coordination bonds. The fifth bond connects cobalt with the cyano group (in cyanocobalamin, the principal vitamin B_{12} form used in foods and nutritional supplements), water (in aquacobalamin also known as vitamin B_{12a}), methyl group (in methylcobalamin, methylvitamin B_{12}) or 5′-adenosyl group (5′-deoxy-5′-adenosylcobalamin, often called 5′-deoxyadenosylcobalamin or adenosylvitamin B_{12}). The sixth ligand can contain different groups or compounds, or this position may be not occupied at all (see Section 5.13.1).

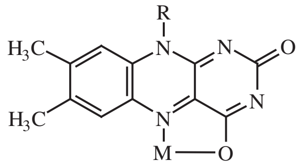
6.2.2.8 Other complexing agents

Phosphorylated organic substrates (such as phosphoric acid esters of sugars) have acidic properties and can form salts with various metals. Compounds containing heterocyclic nitrogen (such as nucleotides) have even greater binding abilities than sugar phosphates. For example, adenosine 5′-triphosphate (ATP) forms complexes with magnesium ions (**6-17**).

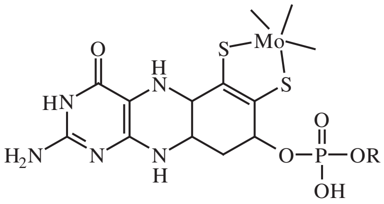


6-17, complex of magnesium with ATP

Similarly, some vitamins (riboflavin, folic acid) and derived compounds (riboflavin 5′-phosphate and flavoprotein FAD) have donor heteroatoms in suitable positions and thus have chelating properties. Isoalloxazine derived compounds, such as riboflavin, yield chelates shown in formula **6-18**. Comparable pyranopterins, containing two thiol groups, were identified as ligands of molybdenum and tungsten in cofactors of some bacterial metalloenzymes and metalloenzymes of mammals, such as cows' milk xanthinoxidase. Molybdopterin is a phosphorylated pyranopterin with an ene-dithiol group coordinating molybdenum. The structure of the molybdopterin complex can be seen in formula **6-19** (free valences of Mo are available for binding other pyranopterin molecules or other ligands, R represents hydrogen or adenosine).

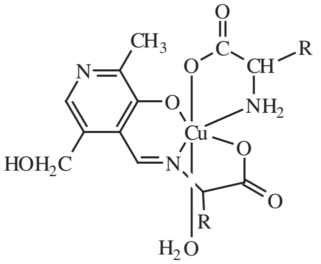


6-18, metal (M) complex of riboflavin and of other isoalloxazine derivatives



6-19, complex of molybdopterin with molybdene (R = H or adenosine)

Chelates can also be formed with amino acids and nicotinic acid or with amino acids and imines (such as reaction products of pyridoxal with amino acids) (**6-20**). Furthermore, metal ions form very stable chelates with β-dicarbonyl compounds (Figure 6.6). This property has been widely used in analytical chemistry.



6-20, copper complex of pyridoxal imine with an amino acid (R = amino acid residue)

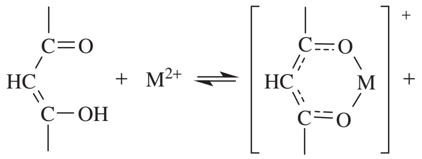


Figure 6.6 Complex of metal ions (M) with β-diketones (enolised).

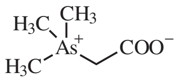
6.2.3 Bonding in covalent compounds

6.2.3.1 Compounds of non-metals and semimetals

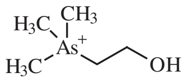
Covalent phosphorus compounds (sugar phosphates, phytic acid and nucleotides) have already been mentioned several times. Foods also contain many organic sulfur compounds, such as sulfur-containing amino acids, thiols, (oligo)sulfides, glucosinolates, heterocyclic compounds (derivatives of thiophene and thiazole). Their occurrence, properties, reactions and importance are covered elsewhere in this book.

Selenium is present in biological materials in a number of compounds that correspond in their structure to sulfur compounds. The amino acid L-selenocysteine (see Section 2.2.1.1.1) bound in proteins arises from selane and *O*-acetyl-L-serine, methylation yields Se-methyl-L-selenocysteine, reaction with *O*-succinyl-L-homoserine leads to L,L-selenocystathionine, hydrolysis of the last compound provides L-selenohomocysteine and methylation gives rise to L-selenomethionine (Figure 6.7). In plants growing in areas with a high level of selenium in the soil, the main compounds containing selenium are Se-methylselenocysteine, γ-L-glutamyl-Se-methylselenocysteine, selenocystathionine and selenomethionine. In many foods of plant and animal origin, the main compound of selenium is selenocysteine bound in proteins.

In biological materials arsenic can be found in a number of organic compounds. Methylarsonic acid, $CH_3AsO(OH)_2$ and dimethylarsinic (cacodylic) acid, $(CH_3)_2AsO(OH)$, are formed from inorganic arsenic compounds in aquatic organisms by biomethylation. These substances are also products of metabolic transformation of inorganic arsenic compounds that proceeds in mammals, so they occur in the urine of individuals intoxicated with arsenic. Seafood and some other marine organisms accumulate arsenic in their bodies in the form of quaternary arsonium compounds, such as arsenobetaine (**6-21**) and arsenocholine (**6-22**).



6-21, arsenobetaine



6-22, arsenocholine

In tissues of chondrichthyans (fish with a cartilaginous skeleton, such as sharks and rays), many species of marine fish (cod, flatfish, mackerel, herring, salmon and others), crustaceans (e.g. lobsters, shrimps and crabs) and molluscs (e.g. mussels and scallops), arsenobetaine is the main arsenic organic compound.

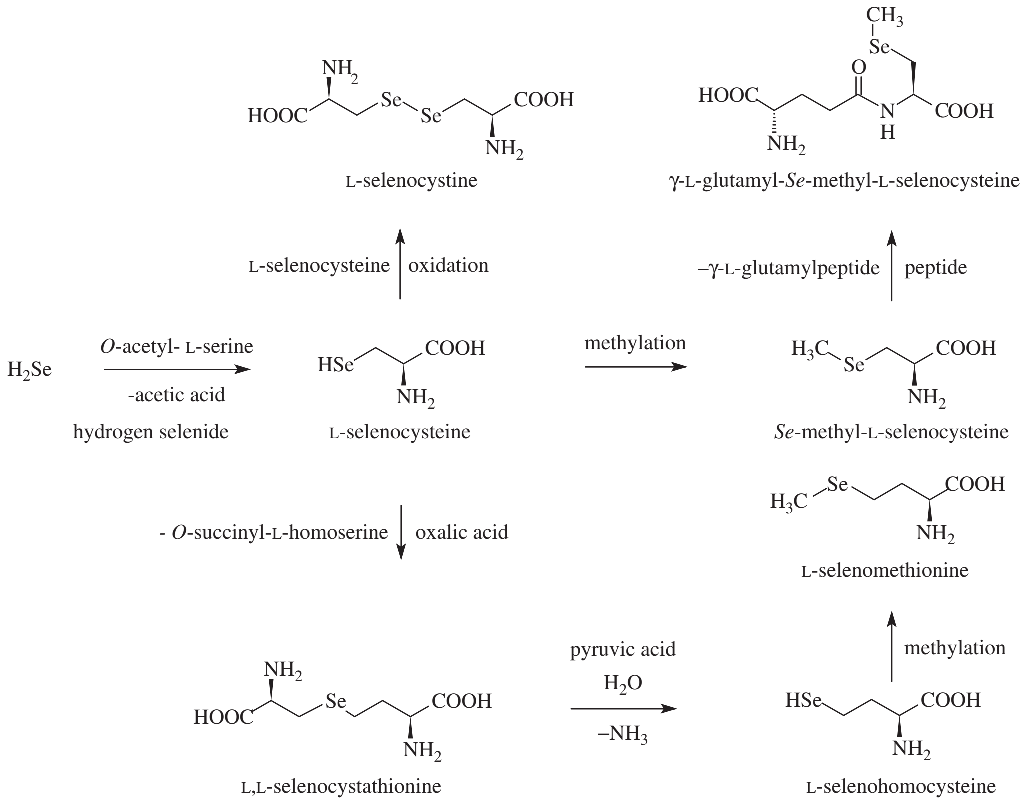


Figure 6.7 Biosynthesis of selenium amino acids.

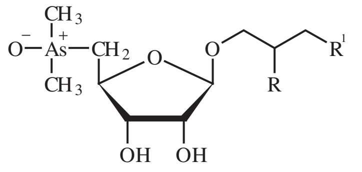
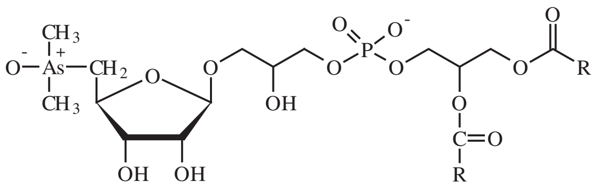
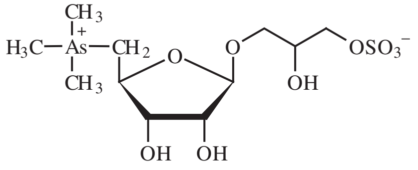
In shrimps, the dominant form is arsenocholine and arsenobetaine is present in lower amounts. In freshwater fish, arsenic is mostly found in further compounds that have not yet been satisfactorily described. Certain marine algae (such as *Ecklonia radiata*) contain **arsenosugars** derived from D-ribose, namely dimethylarsinoylriboside (**6-23**), the corresponding phosphatidylglycerol (**6-24**), a glycolipid usually esterified by palmitic acid, and trimethylarsinoylriboside glycerol sulfate (**6-25**).



6-23, dimethylarsinoylribosides: R = OH, R^1 = OH or R = OH, $R^1 = SO_3^-$ or R = OH, $R^1 = OSO_3^-$ or R= NH_2, $R^1 = OSO_3^-$ or R = OH, $R^1 = OPO_3^- OCH_2 CH(OH)CH_2OH$



6-24, dimethylarsinoylriboside phosphatidylglycerol: R = $[CH_2]_{14} CH_3$



6-25, trimethylarsinoylriboside glycerol sulfate

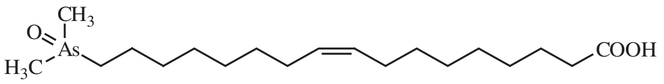
It has long been known that arsenic in seafood is contained in the lipid fraction. More recently, in cod liver oil containing 5 mg/kg arsenic, the following fatty acids containing arsenic were found: ω-(dimethylarsinoyl)alkanoic acids $(CH_3)_2As(O)(CH_2)_nCOOH$ ($n = 12$, 14, 16 and 18), ω-(dimethylarsinoyl)alkenoic acid with chain length of 17 carbon atoms and ω-(dimethylarsinoyl)alkapentaenoic acid with chain length of 21 carbons. The probable structures of these fatty acids are presented in formulae (**6-26**) and (**6-27**).

In marine fish oil (capelin, *Mallotus villosus*), some other lipophilic compounds containing arsenic have been found: two dimethylarsinoylalkanes, 1-(dimethylarsinoyl)pentadecane (**6-28**), 1-(dimethylarsinoyl)heptadecane and a polyene compound $(CH_3)_2As(O)C_{21}H_{30}$ with six double bonds. The position and geometry of double bonds is not yet known, but by analogy with the structure of docosahexaenoic acid, which commonly occurs in fish oil, it is assumed that this compound is all-*cis*-1-(dimethylarsinoyl)-heneicosa-2,5,8,11,14,17-hexaene (**6-29**).

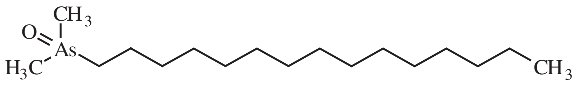
6.2.3.2 Organometallic compounds

The bonds of a metallic element to a carbon atom in organometallic compounds are relatively polar. Depending on the binding capacity of the metal, several bonds can be present, such as in tetramethyllead, $(CH_3)_4Pb$ (the main use of this was in antiknock additives for gasoline). Combustion of such fuel in car engines in the past was an important source of environmental contamination. Some alkyl groups may be replaced by other groups, as is the case of dimethyllead dichloride $(CH_3)_2PbCl_2$. Organometallic compounds with the full number of alkyl substituents are non-polar substances with relatively low boiling point temperatures. Apart from tetramethyllead, traces of some other synthetic organometallic compounds may be found in food as contaminants. These compounds, for example, include tetraethyl lead, $(CH_3CH_2)_4Pb$ (also used as an additive to gasoline), tributyl tin, a group of compounds containing the $(CH_3CH_2\ CH_2CH_2)_3Sn$ moiety as in tributyltin hydride or tributyltin oxide (used as pesticides) and in their decomposition products.

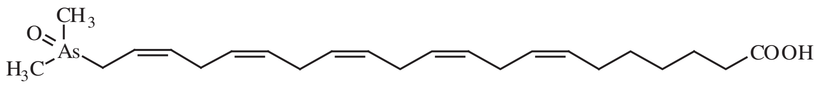
In bacteria, fungi, aquatic animals and plants, organometallic and organometalloid compounds are produced by **biomethylation** of some elements. This applies especially to mercury and arsenic, but to a lesser extent also to antimony, bismuth, selenium, tellurium, lead, tin and cadmium. Products of methylation of inorganic arsenic compounds are listed in the previous Section 6.2.3.1. Biological methylation of mercury can be carried out under aerobic or anaerobic conditions. A donor of methyl groups (CH_3 anion) is methylcobalamin that, in addition to mercury methylation, also participates in other methylation reactions (e.g. in the conversion of L-homocysteine into L-methionine). Other biomethylation agents are N^5-methyltetrahydrofolate and *S*-adenosyl-L-methionine that operate mainly in the methylation of arsenic compounds and other elements that form anions. The microorganisms methylating mercury include bacterial species of



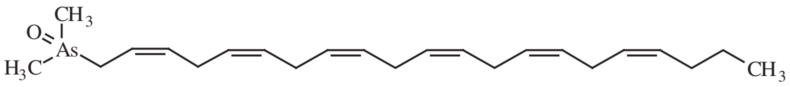
6-26, (Z)-17-(dimethylarsinoyl)heptadeca-9-enoic acid



6-28, 1-(dimethylarsinoyl)pentadecane



6-27, (7Z,10Z,13Z,16Z,19Z)-21-(dimethylarsinoyl)heneikosa-7,10,13,15,18-pentaenoic acid



6-29, all-*cis*-1-(dimethylarsinoyl)heneicosa-2,5,8,11,14,17-hexaene

the genera *Bifidobacterium*, *Chromobacterium*, *Clostridium*, *Enterobacter*, *Escherichia*, *Methanobacterium* and *Pseudomonas* and the microscopic fungi *Aspergillus niger*, *Neurospora crassa* and some other bacteria.

The product of biomethylation of the inorganic forms of mercury in fish and other aquatic organisms is called methyl mercury. This is the name given to a compound CH_3HgX, where X can be, for example, halogen, hydroxyl anion, a sulfhydryl group or a sulfide group. A minor product of mercury biomethylation and also a breakdown product of methylmercury sulfide, $(CH_3Hg)_2S$, is dimethylmercury, $(CH_3)_2Hg$. Methylmercury is the predominant form of mercury in fish, crustaceans and molluscs. Owing to the high affinity of mercury compounds for sulfur compounds, methylmercury CH_3Hg^+ cation bound through sulfhydryl groups of cysteine residues in proteins and peptides can thus be expected in fish tissue. It is also probable that this cation reacts with selenium compounds. In addition to fish, it is possible to find methylmercury in the bodies of animals that feed on fish, such as aquatic birds, cetaceans, pinnipeds and others, and in the gastrointestinal tract of various other animals. In this case, enteric bacteria cause the biomethylation of dietary mercury.

6.3 Essential elements

6.3.1 Sodium and potassium

6.3.1.1 Biochemistry and physiology

6.3.1.1.1 Occurrence in human body

The total sodium and potassium contents in the human body are about 70–100 g and 140–180 g, respectively. Sodium is found predominantly in the extracellular space, while potassium is located mainly inside the cells. Large amounts of sodium and potassium ions are found in the gastric juices.

6.3.1.1.2 Biochemical functions

The main function of sodium and potassium in the body, with chloride as the counter ion, is to maintain the osmotic pressure of fluids outside and inside cells and acid–base equilibrium. In addition, these elements are required for the activation of some enzymes, such as sodium for activatation of α-amylase and potassium for activation of glycolytic enzymes and respiratory chain enzymes. Potassium significantly affects muscle activity, especially the activity of cardiac muscle.

6.3.1.1.3 Metabolism

Resorption of sodium and potassium in the gastrointestinal tract is rapid and its effectiveness in a typical diet amounts to about 90%. The daily level of alkali metals obtained from food varies, with sodium ranging from 1.7 to 6.9 g and for potassium from 2 to 5.9 g. Both elements are excreted from the body in urine, but a significant amount of sodium is lost in sweat as well. Excessive sweating in extreme physical exertion may lead to loss of 8 g of sodium per day (which corresponds to 20 g NaCl). Unless sodium is supplied in the diet at an increased level, in such cases muscle cramps, headaches and diarrhoea develop. Although sodium is essential for the body functions, too much sodium can be harmful for people with kidney diseases and long-term excessive sodium intake can cause hypertension. Other sodium-related complications include oedema (noticeable swelling in legs, hands and face), heart failure and shortness of breath. Lack of potassium (caused, for example, by excessive loss of fluids in some diseases) can cause kidney failure, muscle weakness and an irregular heartbeat.

6.3.1.2 Occurrence in foods

In foods, sodium and potassium are found mainly as free ions. The natural sodium content in foods is highly variable. In many foods of plant origin, sodium is a minority element. In contrast, the potassium content in some plant materials is extremely high and can reach up to 2% (e.g. in tea and roasted coffee). The sodium content can increase by several orders in salted foods, to which it is added in the form of table salt for preservation and to increase flavour. The contents of sodium and potassium and other majority elements in selected foods are summarised in Table 6.4.

6.3.1.3 Nutrition

For an adult, the minimum required daily dose is 500 mg sodium and 2000 mg potassium; for children under 1 year old, 120–200 mg Na and 500–700 mg K; and for children 1–9 years old, 225–400 mg Na and 1000–1600 mg K. The actual amounts of sodium intake are often considerably higher. Approximately 75% of dietary sodium comes from sodium chloride or sodium hydrogen glutamate (monosodium glutamate) used in food technology and culinary processing. With the exception of manual workers, the amount of dietary sodium should not be greater than 2.4 g per day (6 g NaCl).

6.3.2 Chlorine

6.3.2.1 Biochemistry and physiology

The amount of chlorine in the human body is about 80 g. In living organisms, chlorine mostly occurs in the form of anions, which are, together with sodium counter ions, located in the cytoplasm of cells and extracellular fluids (blood, gastric juice and urine). Their main role is, similarly to sodium ions, to maintain osmotic pressure. In the gastric juices, chlorides act as counter ions of hydrogen

Table 6.4 Majority mineral element content in some crops and foods.

Food	Content (mg/kg)						
	Na	K	Cl	Mg	Ca	P	S
Pork meat	450-600	2600-4000	480-490	80-220	50-90	1300-2200	1400-2600

[a] Breast milk content of majority elements is: Na 160, K 530, Cl 860, Mg 20, Ca 250-310, P 130-160, S 100-160 mg/kg.

in hydrochloric acid, which is excreted by the gastric wall. The concentration of hydrochloric acid in the gastric juices is around 0.5% (pH 1–2). Chlorine is supplied in food mainly as sodium chloride at a level of 3–12 g per day. Chlorides are rapidly absorbed from the diet and excreted in the urine.

6.3.2.2 Occurrence in foods

Chlorine is a majority element in a range of foods. Chloride content in foods, however, depends mainly on whether table salt has been added to the raw material during food preparation and production. The concentrations of sodium and chlorides then correlate significantly. The chloride content of some foods are summarised in Table 6.4.

Perchlorates (ClO_4^-) are important oxidisers for fireworks, airbags and of solid rocket propellants. Low levels of perchlorates can then contaminate groundwater, drinking water and even milk. For example, levels of perchlorates up to 1.3 μg/l were found in California, USA (in 2004) in the milk of cows grazing on contaminated pastures. Perchlorates may interfere with the ability of the thyroid gland to utilise iodine in hormone production. Organic chlorine-containing compounds are generally classified as contaminants.

6.3.2.3 Nutrition

The minimum dose of chlorine required daily for an adult is 75 mg, for children under 1 year 180–300 mg, and for children from 1 to 9 years old 350–600 mg.

6.3.3 Magnesium and calcium

6.3.3.1 Biochemistry and physiology

6.3.3.1.1 Occurrence in human body

The content of magnesium in the body of an adult is about 25–40 g. This accounts for about 60% of the content of the skeleton. The highest concentrations of magnesium in soft tissues are found in the pancreas, liver and skeletal muscles. Blood and extracellular fluids contain only 1% of the total amount of magnesium in the body. Calcium is quantitatively the major mineral component in the human body. The total amount is about 1500 g, with 99% of this being in bones and teeth as calcium phosphate.

6.3.3.1.2 Biochemical functions

Both of these elements (magnesium and calcium) have many important biochemical functions in organisms. Magnesium is essential for all metabolic processes in which ATP arises or is hydrolysed, it participates in the stabilisation of the macromolecules of DNA and is required to activate certain enzymes, such as phosphotransferases (kinases) and phosphatases. In this function, magnesium ions can sometimes be replaced by manganous ions (Mn^{2+}). Owing to the binding of magnesium in chlorophylls, this metal is essential for photosynthesising organisms. Together with calcium, magnesium affects the permeability of biological membranes and cell excitability. The concentration of magnesium ions in the extracellular fluids affects the function of nerve cells. Magnesium deficiency, especially with an excess of calcium, leads to increased irritation and *vice versa*. A very high excess of magnesium causes suppression of nerve activity. In addition to structural functions together with proteins **osteocalcin** and **osteonectin**, the main biological function of calcium is participation in nerve and muscle activities. Calcium is also essential for blood clotting. A series of metabolic processes are regulated by calcium ions through the calcium-binding serum protein **calmodulin**, which affects the activity of certain enzymes (such as adenylate cyclase and along with magnesium the activity of ATPase).

6.3.3.1.3 Metabolism

Resorption of magnesium and calcium from food takes place in the small intestine. The effectiveness of resorption of magnesium from the diet at the normal dose of magnesium in a healthy man is 40–50%. A higher proportion of magnesium is resorbed in diets that contain low amounts of this element. Excessive amounts are excreted from the body in urine. The degree of resorption of calcium from food is low (about 5–15%), and is highly dependent on the chemical form of the calcium and the composition of the diet. The degree of resorption of calcium from spinach (the predominant form is calcium oxalate), for example, is only 2–5%. However, the degree of resorption of calcium from wheat bread (which contains calcium mainly in phytin) is about 40%, and from cabbage (where the main forms are calcium salts of organic acids, especially in lemons) it is between 40 and 70%.

Phytic acid and some components of dietary fibre also reduce the resorption of magnesium and some other elements from the diet (especially iron and zinc). A higher protein content in the diet increases the resorption of calcium.

6.3.3.2 Occurrence in foods

The contents of magnesium and calcium in certain foods are summarised in Table 6.4.

6.3.3.3 Nutrition

The recommended daily dietary intake of magnesium is 50–70 mg for children under 1 year, 150–200 mg for children under 6 years, 350 mg for adult men and 300 mg for adult women. During pregnancy and lactation, the daily dose of magnesium should be increased to 450 mg. The recommended daily intake is 400–500 mg of calcium for children under 1 year, 800–1200 mg for older children and adolescents, 800 mg for adults and 1200 mg for pregnant and lactating women.

6.3.4 Phosphorus

6.3.4.1 Biochemistry and physiology

6.3.4.1.1 Occurrence in human body

The adult human body contains about 420–840 g of phosphorus, and 80–85% of this is found in bones and teeth. The main minerals

of bones are calcium, phosphorus and fluorine. The weight ratio of Ca/P in bones is probably equal to 2. The phosphorus content in various tissues is as follows: in blood about 400 mg/l, in muscles 1700–2500 mg/kg, in nervous tissue 600 mg/kg, in bones and teeth 22% by weight.

6.3.4.1.2 Biochemical functions

Phosphorus acts as an essential element in living matter in a number of functions associated with the structure of compounds containing this element. They are mainly structural functions, functions in energy metabolism and activation, regulatory and catalytic functions.

The phosphorus compounds can be found in a number of important biological structures (inorganic phosphates in bones and teeth, phospholipids in biomembranes). Hydrolysis of macroergic phosphates, such as ATP, GTP, phosphoenolpyruvate and creatine phosphate, allows the realisation of energy-demanding biosynthetic reactions. Conversely, in catabolic processes (oxidative phosphorylation, reactions of the citric acid cycle and glycolysis), the chemical energy gained from the substrate is stored in ATP. Reaction of the transfer of the phosphate group (phosphorylation) activates common substrates (such as glucose). Participation of phosphate in the regulation of metabolism depends on the conversion of inactive forms of some enzymes (such as glycogen phosphorylase or protein kinase) by phosphorylation. The allosteric activator of some enzymes (including protein kinase) is another phosphorus compound known as cyclic AMP. Some enzyme co-factors are also phosphates (thiamine diphosphate, FAD, FMN, NADH and pyridoxal phosphate). Phosphorus is also present in nucleic acids, which provide storage and expression of genetic information. Phosphorus compounds are therefore involved in virtually all major metabolic processes.

6.3.4.1.3 Metabolism

Phosphorus is resorbed in the small intestine, mainly in the form of the HPO_4^{2-} anion. Resorption and excretion of phosphorus partly depends on the calcium content in the diet and vice versa. If one of these elements is present in large excess, this increases the excretion of the second element. This indicates that the optimum weight ratio of calcium to phosphorus in the diet is between 1 : 1 and 1 : 1.5.

The degree of resorption of phosphorus is dependent on the composition of the diet (in particular the levels of phosphorus and calcium and the forms of phosphorus received) and the age and health of the consumer. Newborns resorb 85–90% of phosphorus from breast milk and about 65–70% of phosphorus from cows' milk. In older children and adults, the degree of resorption of phosphorus from the normal diet is about 50–70%, but may increase to 90% in the case of low doses of phosphorus.

As regards the resorption of various phosphorus compounds, it is known that the best utilisable compounds are salts and esters of *ortho*-phosphoric (*o*-phosphoric) acid, and somewhat less utilisable are salts of *meta*-phosphoric (*m*-phosphoric) acid and polyphosphates. Phosphorus in the form of phytic acid is resorbed at a level of from 20 to 50%, and the efficiency of absorption decreases significantly at higher doses of dietary calcium. Partial resorption of phytate phosphorus appears to be related to the fact that intestinal alkaline phosphatase of some animals also has phytase activity.

6.3.4.2 Occurrence in foods

6.3.4.2.1 Total phosphorus content

Phosphorus is found in most foods in concentrations above 100 mg/kg. The exceptions are refined fats and refined sugar, which contain only traces of phosphorus. Nuts, cheeses and other dairy products are rich sources of dietary phosphorus. For cows' milk, the ratio of Ca to P is about 1.2 : 1, while for breast milk the ratio is about 2 : 1. The absolute amounts of both elements in breast milk compared with cows' milk are lower. Many foods of plant origin with high concentrations of phosphorus contain considerable amounts of phytic acid and its salts, phytates, which are not very utilisable. The phosphorus contents in foods are summarised in Table 6.4.

6.3.4.2.2 Phytic acid

Phytic acid (*myo*-inositol-1,2,3,4,5,6-hexakisdihydrogen phosphate) occurs in a number of important crops, especially cereals, legumes and oilseeds. The main form is a mixed calcium and magnesium salt, which is called phytin. Phytate phosphorus has reduced biological utilisation and lower utilisation than other minerals (Ca, Mg and Zn and Fe in particular). The contents of phytic acid in some food materials and foods, and the ratio of phytate phosphorus to total phosphorus, are shown in Table 6.5.

In addition to cereals, legumes and oilseeds, which are characterised by a high content of phytic acid, there are plant products with a low amount of phytic acid (potatoes, artichokes, carrots, broccoli, strawberries, blackberries and figs) and crops that do not contain phytic acid (lettuce, spinach, onion, celery, mushrooms, apples, bananas, pineapple and citrus fruits).

Phytic acid is accompanied by a smaller amount of the partial esters of *myo*-inositol with phosphoric acid. Theoretically there are 63 ($=2^6-1$) acyclic and cyclic esters. In animal tissues, for example, more than 20 different esters have been shown. In lenses containing 0.49% of phytic acid, 0.07% of a mixture of pentakisphosphates and 0.01% of the mixture of tetrakisphosphates are present.

It is assumed that phytic acid and phytates in seeds of plants are used as a storage form of phosphorus and other minerals. Phytic acid has, however, numerous other biological functions in plant and animal organisms; for example, it acts as an antioxidant and anticarcinogen. Partial phosphoric acid esters, such as *myo*-inositol-1,4,5-trisdihydrogenphosphate and *myo*-inositol-1,3,4,5-tetrakisdihydrogenphosphate, for example, act in the regulation of the intracellular calcium level; *myo*-inositol-1,3,4,5,6-pentakisdihydrogenphosphate modulates the affinity of haemoglobin for oxygen; *myo*-inositol-1,2,6-trisdihydrogenphosphate inhibits blood coagulation (platelet aggregation) and has anti-inflammatory effects. *Myo*-inositol itself was once considered a member of the B group vitamins.

Table 6.5 Phytic acid and phytate phosphorus contents in some crops and foods.

Material	Phytic acid (g/kg)	Phytate phosphorus (%)	Material	Phytic acid (g/kg)	Phytate phosphorus (%)
Bread (whole wheat)	4.3–8.2	38–66	Soy flour (defatted)	15.2–25.2	87
Wheat	3.9–13.5	60–80	Lentil	2.7–10.5	27–87
Rye	5.4–14.6	38–46	Peas	2.2–12.2	37
Barley	7.5–11.6	66–70	Almonds	12.9–14.6	82
Oat	7.0–11.6	49–71	Peanuts	17.6	57
Maize	8.3–22.2	71–88	Walnuts	6.5–7.7	42
Rice unpealed	8.4–8.9	–	Cocoa	0.9	15
Rice peeled	3.4–5.0	61	Carrot	0.2–0.3	16
Soybeans	10.0–22.2	50–70	Potatoes	0.2–0.5	19–23

Under normal conditions (acidic or alkaline medium), phytic acid is not hydrolysed chemically, but may be hydrolysed enzymatically. The enzymatic hydrolysis proceeds in fermented cereal products such as bread and yields pentakis-, tetrakis-, tris-, bis- and monodihydrogenphosphates and possibly also free *myo*-inositol. In wheat and rye flour, the phytase of the grain is still partly active, and hydrolysis of phytic acid in dough is made by the action of this endogenous phytase (6-phytase) that hydrolyses the ester bond, predominantly in position C-6. Subsequent hydrolysis is achieved by the action of phytase of baker's yeasts and phytases of colon microorganisms. Microbial phytases preferentially hydrolyse the ester bond in position C-3. Partial hydrolytic cleavage of ester bonds of phytic acid occurs during baking. It was found that the production of bread from wheat flour can result in a loss of up to 70–85% of the phytic acid originally present. Table 6.6 illustrates the overall extent of hydrolysis of phytic acid during the fermentation and baking of cereal products. Activity of phytase also increases during germination of seeds. Particularly high activity is seen in phytase of germinating grains of wheat and rye and phytase of pea seeds. Losses of phytic acid during the cooking of legumes are caused mainly by leaching.

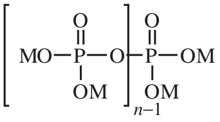
Phytic acid is also used as an agent (food additive) for the clarification of wines, which ensures the removal of ferric ions by precipitation of ferric phytate.

Table 6.6 *Myo*-inositol phosphates content in rice cakes.

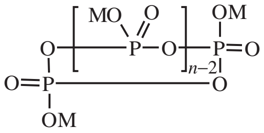
Phosphates of *myo*-inositol	Content (mg/kg)	Phosphates of *myo*-inositol	Content (mg/kg)
Hexakisphosphate	110	Trisphosphates	340
Pentakisphosphates	130	Bisphosphates	160
Tetrakisphosphates	460	Monophosphates	160

6.3.4.2.3 Phosphates and phosphoric acid

The phosphorus content in some foods can be raised above the natural level using food additives based on polyphosphoric acid salts or salts of phosphoric acid. Polyphosphates are either sodium or potassium salts of polyphosphoric acids with straight chains and different degrees of polymerisation, $M^{I}_{n+2}P_nO_{3n+1}$ (**6-30**) or salts of cyclic polyphosphoric acids, $(M^{I}PO_3)_n$ (**6-31**), which are actually oligomers of hydrogenphosphoric acid (*m*-phosphoric acid), HPO_3. The most commonly used materials are sodium and potassium phosphates, especially disodium dihydrogendiphosphate, tetrasodium diphosphate, sodium triphosphate and the so-called sodium hexametaphosphate.



6-30, linear polyphosphate (M = Na or K)



6-31, cyclic polyphosphate (M = Na or K)

The addition of phosphates (polyphosphates) to food affects the hydration of proteins and polysaccharides and their colloidal properties. It is used to increase the water-holding capacity (WHC) capacity, sometimes referred to as water-binding capacity (WBC) when water is added to cured meat and certain meat products. Phosphates also provide the appropriate texture to processed cheeses made from traditional cheese and emulsifying salts, often with the

addition of milk, salt, preservatives and food colouring. Polyphosphates are used as agents for clarification and stabilisation of wine and beer, and also have an antimicrobial effect. Phosphoric acid is often used as an acidifying agent (acidulant) for soft drinks (e.g. in Coca-Cola). In drinks in cans, phosphates retard the corrosion of the packaging.

6.3.4.3 Nutrition

The recommended daily dietary intake of phosphorus is 300–500 mg for children under 1 year, 800 mg for children under 10 years and 1200 mg for adults. These amounts are easily achieved in a normal diet. It is more important to maintain an appropriate ratio of calcium to phosphorus in the diet than the actual realised amount of phosphorus. Meat, poultry and fish (without bones) contain about 15–20 times more phosphorus than calcium; eggs, cereals and legumes contain about 2–4 times more phosphorus than calcium. Only milk, cheese, leafy vegetables and bones contain more calcium than phosphorus.

6.3.5 Sulfur

6.3.5.1 Biochemistry and physiology

The sulfur content in the human body is about 140 g. Foods contain a large number of covalent sulfur compounds. Many sulfur compounds perform important biochemical functions as biocatalysts (e.g. thiamine, pantothenic acid bound in coenzyme A and biotin), and sulfur-containing amino acids, cysteine and methionine, are protein constituents. Many sulfur compounds are important precursors of flavour-active compounds.

6.3.5.2 Occurrence in foods

The sulfur contents in selected foods are presented in Table 6.4.

6.3.5.3 Nutrition

The main sulfur compounds in foods are known and can be determined individually. Therefore, the total sulfur content in foods is not usually considered, and the recommended daily intake (approximately 0.1–0.6 g) is not officially established.

6.3.6 Iron

6.3.6.1 Biochemistry and physiology

6.3.6.1.1 Occurrence in human body

The total amount of iron in the body of an adult is about 3–5 g. The highest concentrations are found in the blood (haemoglobin), liver and spleen (ferritin and homosiderin); lower concentrations are in the kidney, heart and skeletal muscle (myoglobin). The concentration of iron in the pancreas and brain is about 2–10 times lower than the content of the liver or spleen. A list of the organic compounds of iron is given in Table 6.7.

Enzymes contain only minute quantities of the total iron in the body. They can be divided into two groups:

- haem enzymes: cytochromes, oxygenases and peroxidases
- non-haem enzymes: succinate dehydrogenase, also liver xanthine oxidase, NADH-cytochrome c reductase (flavin enzymes, oxidoreductases) and aconitase (lyase).

6.3.6.1.2 Biochemical functions

The function of iron in the body depends on the compound in which iron occurs. Iron mostly participates in oxygen transport through the bloodstream and oxygen storage in muscle tissue (the iron is in the haemoglobin and myoglobin) and participates in catalytic and oxidation–reduction reactions (iron in haem and flavin enzymes).

The blood plasma contains non-haem glycometalloprotein **transferrin**, which serves as a transport form of iron. Transferrin is pink coloured and contains Fe^{3+} bound to the apoprotein with a molecular weight of 86 kDa, which belongs to the group of β_1-globulins. A transferrin molecule consists of two identical subunits, each of which contains one binding site for iron.

Ferritin, together with **haemosiderin**, is the principal iron storage protein in bacteria, plants and animals. In animals, ferritins occur mainly in the spleen, liver and bone marrow. Ferritins are metalloproteins that can contain up to 23% iron. The protein constituent of apoferritin has a molecular weight of 445 kDa and consists of 24 cubically arranged subunits. Apoferritin forms the core package, which contains hydrated ferric hydroxide. One ferritin molecule can bind from 2000 up to 4500 iron atoms and

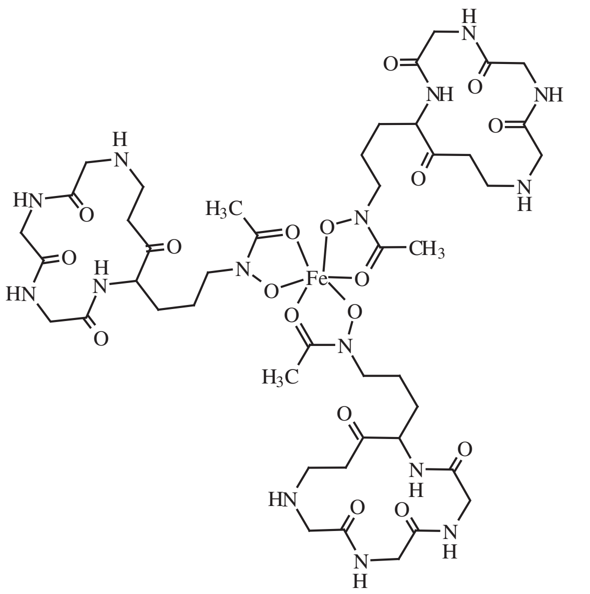
Table 6.7 Important iron compounds found in the human body.

Compound	Amount (g)	Amount in Fe (g)	Of total Fe (%)	Compound	Amount (g)	Amount in Fe (g)	Of total Fe (%)
Haemoglobin	900	3.0	60–70	Transferrin	10	0.004	0.1
Myoglobin	40	0.13	3–5	Catalase	5	0.004	0.1
Ferritin	2–4	0.4–0.8	7–15	Cytochrom c	0.8	0.004	0.1

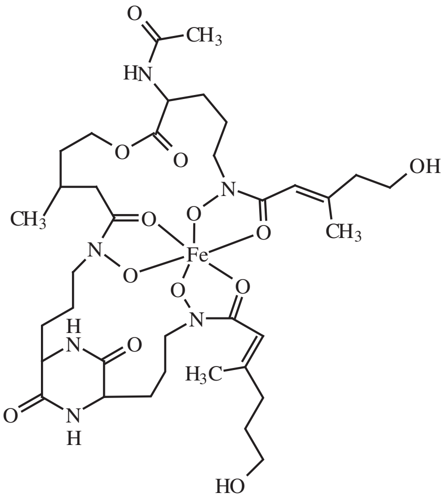
store them as Fe^{3+} ions. The binding of ferritin to iron reduces the risk of formation of insoluble iron compounds. In animals, ferritin is found not only inside cells, but is circulating in plasma if the body does not suffer from iron deficiency. Therefore, plasma levels of ferritin have sometimes been used as an index of iron storage deficiency. In some plants, a structurally similar metalloprotein called **phytoferritin** is present. The amino acid composition of the phytoferritins shows some similarities to those of mammalian apoferritins. Although the quaternary structure of 24 polypeptide chains is preserved, the phytoferritins can potentially store 1.2–1.4 times as much iron. Haemosiderin is an amorphous material, a complex of ferritin, denatured ferritin and other material, containing 35% iron in the form of ferric hydroxide. It is most commonly found in macrophages and is especially abundant in situations following haemorrhage, suggesting that its formation may be related to phagocytosis of red blood cells and haemoglobin. Haemosiderin can accumulate in different organs in various diseases.

Low molecular weight **siderophores** are excreted by many aerobic and facultative anaerobic microorganisms growing in environments with low iron content. Bacteria, such as pathogenic bacteria of the genera *Escherichia*, *Aerobacteria* and *Salmonella*, mainly contain catechol siderophores that are important for their acquisition of iron; aerobic and facultative anaerobic microorganisms (some yeasts and fungi) contain siderophores based on hydroxamic acids. A catecholate siderophore **enterobactin** (**6-32**) is primarily found in Gram-negative bacteria, such as *Escherichia coli* and *Salmonella typhimurium*. Examples of the second group of siderophores are **ferrichrome** (**6-33**) and **coprogen** (**6-34**) that are produced by fungi of the genera *Aspergillus*, *Ustilago* and *Penicillium*. Coprogen occurs in some microbially processed cheeses, as *Penicillium roqueforti* and *Penicillium camemberti* are used to ripen the blue and Camembert type cheeses, respectively.

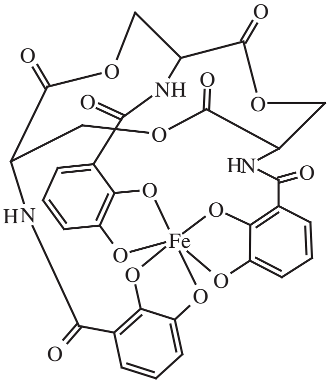
Other types of biologically important compounds are proteins with iron and sulfur. In these compounds, iron is bound to sulfhydryl groups of cysteine residues or even by sulfide ions. This group includes the FeS–proteins **rubredoxins** and Fe_2S_2-proteins and Fe_4S_4-proteins **ferredoxins**. These substances act as electron carriers by reversible change of the iron valency. Proteins with iron and sulfur are found in many organisms, for example in aerobic and anaerobic bacteria, algae, fungi, higher plants and animals.



6-33, ferrichrome



6-34, coprogen



6-32, ferric enterobactin

The main biological function of these proteins is electron transfer. An important non-haem metalloenzyme with bound iron, which occurs in prokaryotic organisms, higher plants and animals, is lipoxygenase, an enzyme catalysing the peroxidation of unsaturated fatty acids.

6.3.6.1.3 Metabolism

Iron resorption occurs predominantly in the duodenum and upper jejunum. The digestive tract resorbs 5–35% of iron present in a typical diet, depending on biological factors (health status, age and sex of the individual) and chemical factors (forms of dietary iron and diet composition). Its bioavailability decreases in the series:

haem > Fe^{2+} > Fe^{3+}. Deficiency of iron in the body can enhance the efficiency of its resorption in exceptional cases to 60%. Haem iron from foods of animal origin (haem pigments in blood and meat and in haemoproteins in the mitochondria) is resorbed more efficiently then haem iron in foods of plant origin (mitochondria). The mechanisms of haem iron resorption are completely different from those of inorganic iron (iron salts); the process is more efficient (10–20% of iron intake) and is independent of duodenal pH. Dietary inorganic iron can be absorbed in the form of divalent ions, which is easier than resorption of trivalent iron.

During the digestion of food, a partial reduction of trivalent iron to divalent iron occurs. The reduction of ferric ions to ferrous ions is partly due to some chemical components of partially digested food, but mainly to the ferric reductase enzyme (duodenal cytochrome *b*) immobilised on the outer membrane of the mucosal cells of the duodenum (enterocytes). The absorption of ferrous ions occurs in the duodenum and jejunum. The transport from the intestinal contents into the cells of the intestinal mucosa through the cell membrane is facilitated by a protein called divalent metal transporter, which transports all types of divalent metals across the enterocyte's cell membrane and into the cell. This transport is compensated by protons moving in the opposite direction. The early phases of haem iron resorption are different. Haem iron is absorbed by the intestinal mucosa as a porphyrin complex in the presence of a specific haem carrier protein 1 (HCP1) carrier. Within the mucosal cells, haem is transformed into biliverdin by haem oxygenase and carbon monoxide and Fe^{2+} ions are released. The cells of the intestinal mucosa (enterocytes) can store the absorbed iron in the form of ferritin, or can move it into the body. Before binding to apoferritin, ferrous ions require oxidation to ferric ions. Inside the enterocyte, the oxidation is ensured by the enzyme hephestin, which is a metalloprotein containing copper. Membrane transfer of divalent iron from enterocytes into the blood circulation is facilitated by a membrane protein called ferroportin. The amount of ferroportin channels in the membrane is controlled by a polypeptide hepcidin, which is synthesised in the liver. The efficiency of the overall process is diminished by the life cycle of the enterocytes and villi (lumenal surface finger-like projections covered predominantly with enterocytes), which last for only a few days (iron stored within the enterocyte then passes back into the intestinal contents).

Ferrous ions transferred into the blood are oxidised to ferric ions and then enter into the molecule of a transport protein under the catalysis of ferro oxidase ceruloplasmin, the main plasma metalloprotein containing copper. Transferrin ensures the transfer of iron to all tissues. Under normal conditions, about 30% of plasma transferrin is saturated with iron, and the remainder is apotransferrin. The target tissue captures transferrin by specific receptors and iron is immediately available for the synthesis of proteins and other haem metalloproteins or temporarily stored in ferritin. A substantial portion of the transported iron from transferrin is taken away in the bone marrow for the production of erythrocytes. New erythrocytes absorb the whole transferrin molecules. The release of iron from transferrin occurs due to a lower pH compared with the pH in the extracellular space. Apotransferrin is then released from the erythrocytes and iron is built into the porphyrin skeleton under the catalysis of ferrochelatase. The cells of the reticuloendothelial system that are located in the liver, spleen and bone marrow capture old and damaged erythrocytes. In these cells, the ferrous ions released from haem are stored in ferritin or haemosiderin, or released into the blood plasma through the ferroportin channel, where it is oxidised by ceruloplasmin to Fe^{3+} and again captured in transferrin.

Effective resorption is dependent not only on the iron valence, but can be enhanced or diminished in the presence of certain food components.

The most important substances that enhance iron resorption from the diet are:

- ascorbic acid, which acts as a reducing and chelating agent;
- organic acids (citric, lactic, malic, succinic and tartaric acids);
- amino acids, especially histidine, lysine and cysteine, which act as triple ligands and peptides and proteins composed of these amino acids;
- carbohydrates, which positively influence the retention of iron (efficiency decreases in the order: lactose, sucrose, glucose and starch).

The mechanism of this effect probably lies in the formation of complexes with iron that prevents the formation of insoluble forms of trivalent iron, especially $Fe(OH)_3$ and $FePO_4$, in the alkaline environment of the small intestine.

Most dietary factors negatively influencing iron resorption probably exert their action within the gastrointestinal lumen by making iron more or less bioavailable for resorption. Substances that reduce iron resorption either form insoluble iron compounds (phytic acid) or stable soluble compounds so that iron cannot be released for binding in proteins (ferritin) formed in cells of the intestinal mucosa. The diminished resorption of iron is mainly caused by tannins and phenolic compounds, phytic acid, fibre, higher doses of calcium and phosphorus and extremely high doses of trace elements (cobalt, zinc, copper and manganese).

Phenolic substances of tea are probably the most powerful factor that reduces iron resorption. Even in the presence of ascorbic acid, the resorption of iron is diminished due to the formation of insoluble complexes with tannins. Non-haem iron resorption is reduced by up to 62 and 35% when food is administered simultaneously with tea or coffee, respectively. In contrast, orange juice increases the resorption of iron by up to 85%.

There is no consistent information on the influence of fibre on the resorption of iron and other minerals. Many studies have focused on the effect of fibre added to food or food with a high proportion of fibre. Cereal fibre contains fairly high amounts of phytic acid, so in these cases it is not possible to distinguish between the effect of fibre and the phytate effect. When the effect of wheat fibre itself on iron resorption was observed in rats (experimental and control diet contained the same concentrations of phytates and various amounts of fibre), there were no differences in iron resorption. Fibre itself does not affect iron resorption, but the combined effect of fibre and

phytic acid is considerable. It illustrates, for example, low utilisation of iron from wheat germ, beans and lentils from foods with high contents of phytic acid. Fruit fibre does not contain phytic acid; therefore, reduced iron retention was found only when the highly esterified pectin fraction was removed from the apple pomace. Iron resorption is also negatively affected by certain proteins, such as soy protein and phosphoprotein phosvitin, which is present in egg yolk.

6.3.6.2 Occurrence in foods

The predominating form of iron in animal tissues is haem (particularly myoglobin and haemoglobin). In egg white, iron is bound in conalbumin, and in the yolk to phosphoprotein phosvitin. Milk contains the iron metalloprotein lactoferrin and part of the iron is bound to casein. Conalbumin and lactoferrin are structurally similar to serum transferrin. In plants, iron is bound in various complexes, especially with phytic acid, aliphatic hydroxycarboxylic acids, aminocarboxylic acids, thiols, phenolic substances, nucleotides, peptides and proteins. The iron content in selected foods is shown in Table 6.8. Foods rich in iron are offal dishes, meat, eggs, pulses, tea and cocoa. Moderate amounts of iron are found in fish, poultry, cereals, spinach, parsley and nuts. Low levels of iron are present in milk, dairy products, fats and oils, potatoes and most fruit.

Iron-deficiency anaemia is one result of the advanced-stage of iron deficiency. For food fortification with iron, many compounds of iron and elemental iron are used. In the evaluation of the biological value of the individual compounds, the increased level of haemoglobin (which cannot be formed in iron deficiency) in experimental animals on an iron dose is used as a criterion. Ferrous sulfate is used as a reference compound. Compared with ferrous sulfate, the usable forms of iron can be divided into three groups:

- good sources of iron with a relatively good biological value (over 70% compared with $FeSO_4$): ammonium ferric citrate, ferric chloride, ferric sulfate, ferric ammonium sulfate, ferrous fumarate, ferrous gluconate, ferrous sulfate, ferrous tartrate;
- sources of iron with a mean biological value (20–70%): ferric phosphate and elemental iron;
- sources with low biological value (<20%) iron oxide, ferric phosphate and ferrous carbonate.

In many countries, fortified milk products for infants contain ferrous fumarate. Other products that are often fortified with iron are cereal products.

6.3.6.3 Nutrition

The recommended daily intake of dietary iron is 6 mg for children under 6 months, 10 mg for children aged 6 months to 10 years, 12 mg for boys aged 11 to 18 years, 15 mg for girls and women from 11 to 50 years, and 10 mg for adult males and women over 50 years. The recommended dose for pregnant women is 30 mg and 15 mg during the lactation period. These values must be assessed with regard to the bioavailability of the iron. They were designed for healthy individuals, provided that the composition of the diet ensures good bioavailability of iron (the resorption efficiency of about 15%). This is only guaranteed by a diet containing a sufficient proportion of meat. The daily diet should provide an adult woman (weight of 60 kg) with about 2.6 mg of resorbed iron, and an adult male (weight of 80 kg) with about 1.4 mg of absorbed iron. Taking into account the very low bioavailability of iron from the diet of vegetarians (usually 5%), which does not contain haem iron and is rich in fibre, phytates and plant phenols, the total daily dose of iron for vegetarians should be about 50 mg for women and 30 mg for men.

Insufficient dietary intake of iron leads to a hypochromic microcytic anaemia and immune deterioration. In this type of anaemia, the amounts of haemoglobin and red blood cells are reduced, which results in reduction of transport of oxygen to the tissues and the decrease of organism performance. Severe anaemia can lead to heart failure. Iron deficiency can be divided into three stages. In the first stage, iron stores are reduced and decreased ferritin levels in plasma occur but functional changes are not noticeable. In the second stage, the proportion of protoporphyrin in erythrocytes increases and the haemoglobin level is slightly reduced (normal level of haemoglobin in plasma of men is 130–160 g/l and in females 120–160 g/l). Simultaneously, however, the total iron content in plasma, the ferritin content in plasma and tissue iron content strongly decrease. In the third stage, the symptoms of iron deficiency anaemia appear, tissue iron stores are depleted, which leads to a significant decrease in haemoglobin levels (hypochromia, also called hypochromasia or hypochromatism) and erythrocytes which are smaller than normal (microcytosis). Anaemia is more often encountered in women than in men and is often subject to inadequate nutrition, especially in developing countries. There are several other types of anaemia, produced by a variety of underlying causes.

Excessive iron intake by diet or dietary supplements (>1000 mg/day) and particularly in the event of a disorder of iron resorption regulation may cause accumulation of haemosiderin in the liver and other unwanted effects. This phenomenon is known as haemosiderosis and can lead to severe liver damage. The disorder of iron resorption known as hereditary haemochromatosis is a genetic disease. Transfusional iron overload can be the result of repeated blood transfusion.

6.3.7 Zinc

6.3.7.1 Biochemistry and physiology

6.3.7.1.1 Occurrence in human body

The adult human body contains from 1.4–3.0 g zinc, which is about a third to half the iron content, approximately 1–15 times the copper content and about 100 times the amont of manganese. Roughly half of the total zinc present is contained in muscles and about a third in the bones. High concentrations of zinc are found mainly in skin, hair, nails, eye, liver, kidney, spleen and male genital organs. In the cells of the liver, kidney and some other internal organs, zinc is bound in metallothionein.

Table 6.8 Iron and zinc contents in some crops and foods.

Food	Content (mg/kg) Fe	Zn	Food	Content (mg/kg) Fe	Zn
Pork meat	10–20	17–40	Beans	59–82	21–38
Beef meat	22–30	30–43	Soybeans	50–110	29–67
Chicken meat	4.3–8.4	8.1–12	Cabbage	3.1–9.0	1.5–2.9
Pork liver	130–370	56–112	Cauliflower	5.0–11	3.2–7.8
Fish	1.3–15	3.3–27	Spinach	10–40	4.3–13
Milk (whole)[a]	0.35–0.8	3.4–4.7	Lettuce	5.8–11	3.3–9.0
Curd	0.91–1.5	13–14	Tomatoes	2.2–5.0	1.2–4.8
Cheese	1.5–4.7	36–44	Carrot	3.4–7.4	2.5–5.9
Yoghurt	0.44–1.2	5.3–5.6	Peas (green)	18–22	11–15
Egg (whole)	21–26	13–15	Onion	3.0–6.1	3.1–5.2
Egg (white)	1.0–2.0	2.0	Potatoes	3.0–8.4	1.7–4.9
Egg (yolk)	61–72	38	Apples	2.3–4.8	0.2–4.9
Wheat	33–66	26–38	Oranges	1.3–5.0	0.9–1.2
Rye	25–28	22–40	Bananas	3.1–5.5	1.8–2.6
Flour (wheat)	12–25	8–36	Strawberries	3.6–9.6	1.1–1.9
Bread (whole wheat)	24–33	13–29	Walnuts	21–24	24
Rice (peeled)	6.0–23	10–15	Tea (black)	110–310	23–38
Peas (mature seeds)	47–68	20–49	Coffee (roasted)	41	6.1–8.0
Lentils	69–130	28–32	Milk chocolate	11–19	18–19

[a]The breast milk concentrations of Fe and Zn are 0.3–0.7 and 1.2 mg/kg, respectively.

The blood contains 6–7 mg/l zinc, with about 75–88% of this amount in erythrocytes, 12–22% in blood plasma (plasma zinc concentration is about 1 mg/l) and the rest is in the leucocytes and platelets. In blood plasma, the majority of zinc is bound to serum albumin and a smaller part to α_2-macroglobulin. The red blood cells contain zinc, mainly in the enzyme carbonate anhydratase.

6.3.7.1.2 Biochemical functions

Zinc is found in the bodies of all organisms. More than 200 metalloenzymes that contain zinc are known. The presence of zinc in molecules of some metalloenzymes is essential for their catalytic function. In other metalloproteins, zinc binding is involved in the fixation of the spatial structure of molecules (e.g. in protein transcription modulators, known as zinc finger proteins, with a specific bond to certain sections of DNA). The mammalian enzymes containing zinc are alcohol dehydrogenase, lactate dehydrogenase, superoxide dismutase, carboxypeptidases A and B and dipeptidase or carbonate anhydratase. Important zinc containing enzymes in the metabolism of yeast are phosphoglucomutase, phosphomannose isomerase, aldolase, alcohol dehydrogenase and pyruvate carboxylase. Bacterial zinc-containing enzymes include alkaline phosphatase, RNA-polymerase, DNA-polymerase and various proteinases. Zinc is therefore involved in the catalysis of reactions in many metabolic pathways. Zinc is also needed for the formation and activity of the pancreatic peptide hormone **insulin**. Human insulin is a peptide composed of 51 amino acids (5808 Da). The active form is a monomer. Six insulin molecules are assembled in a hexamer, and stored in the body by means of zinc ions bound by histidine residues.

6.3.7.1.3 Metabolism

Resorption of zinc in the digestive tract occurs mainly in the duodenum, but also in other parts of the small intestine. Resorption efficiency is normally about 30% and is regulated by intracellular ligands. In the transport of zinc into the intestinal cells (similarly to the iron transport) divalent cations are involved. In enterocytes, zinc is bound in metallothionein (at high doses of zinc in the diet) or in a complex with cysteine-rich intestinal protein (CRIP) (at lower doses of zinc). Resorption of zinc is higher in individuals with lower body weight and in cases of lower body saturation by zinc. In contrast, oral administration of high doses of zinc decreases the absorption efficiency.

The degree of resorption of zinc is dependent *inter alia* on the composition of the diet. A high content of proteins and amino acids increases the efficiency of resorption. Phytic acid and fibre operate in the opposite way. It was found that the molar ratio of phytate to zinc is a measure of the bioavailability of zinc from different foods. For example, bioavailability of zinc is good from a diet low in fibre and phytic acid (ratio phytate : Zn = <5), which is a diet with virtually no whole-grain cereal products. Mean utilisation (15–35%) is achieved in a mixed diet consisting of foods from plant and animal origins, where the ratio of phytate to Zn is approximately 5–10. Long-term intake of foods with a ratio of phytate to Zn greater than 20 leads to a zinc deficiency. Another criterion, which allows estimation of the bioavailability of zinc from food, is calcium content (molar content of calcium multiplied by phytate content and divided by zinc content). Diets with the value of this criterion higher than 3500 mmol/kg lead to slow growth of experimental animals (young rats). In human nutrition, at doses that ensure energy of 4.2 MJ (1000 kcal), the value of this criterion in the diet should not exceed 200 mmol/kg. Higher values mean a risk of serious deficiency. Table 6.9 shows the ratios of phytate/Zn and Ca × phytate/Zn for some cereal products. High calcium content decreases resorption of zinc by competing with zinc and, together with phytate, decreases zinc solubility in the intestinal contents. Zinc is excreted from the body via the faeces. It comprises both the zinc that was not resorbed from the diet and zinc expelled into the small intestine in secreted bile and pancreatic juice.

6.3.7.2 Occurrence in foods

The zinc contents of selected foods are shown in Table 6.8.

6.3.7.3 Nutrition

The recommended daily dietary intake of zinc is 5 mg for children under 1 year, 10 mg for children from 1 year to 10 years, 15 mg for boys and men, 12 mg for girls and women, 10 mg for men and women over 50 years. The recommended dose for pregnant women is 15 mg and 16–19 mg during lactation. In diets containing a high proportion of substances that deteriorate the bioavailability of zinc, the recommended amounts are not sufficient.

Zinc deficiency can occur during long-term acceptance of low-dose zinc diet or dietary components that reduce the bioavailability of zinc. This can be especially dangerous in childhood, where zinc deficiency results in slow growth and poor development of sexual organs in males. These effects were observed in some Arab countries, in cases where the dominant component of the diet is wholewheat bread prepared from unfermented dough. Other symptoms of deficiency can include loss of appetite, and changes in the skin, hair and nails. Many of these changes are reversible and administration of higher doses of zinc may restore the normal state.

Zinc is toxic at higher doses. Oral administration of more than 2 g Zn (as $ZnSO_4$) causes irritation of the mucous membranes of the digestive tract and vomiting. The adoption of such a high dose from food is entirely excluded. Long-term intake of amounts 10–30 times higher than the recommended daily intake (100–300 mg) leads to some changes in the blood count, which are typical for copper deficiency as zinc is an antagonist of copper.

6.3.8 Copper

6.3.8.1 Biochemistry and physiology

6.3.8.1.1 Occurrence in human body

The adult human body contains about 100–180 mg copper, corresponding to an average concentration of about 1.7 mg/kg body weight. The concentration of copper in the bodies of babies is substantially higher, at about 4.7 mg/kg body weight. Average concentrations of copper in different tissues and organs of the human body are as follows: liver 15 mg/kg (newborns up to 230 mg/kg), kidney 2.1 mg/kg, muscles 0.7 mg/kg, brain 5.6 mg/kg and lungs 2.2 mg/kg. In liver cells, most copper is bound in the molecules of the enzyme **superoxide dismutase** (relative molecular mass of 32 kDa). The brain tissue contains the metalloprotein **cerebrocuprein**.

The average concentration of copper in blood is 1.10 mg/l in men and 1.23 mg/l in women. More than 90% of copper in the body is found in the blood plasma. The major copper-binding substance in blood plasma is monomeric glycometalloprotein **ceruloplasmin** from a group of α_2-globulins (132 kDa), which is composed of 1046 amino acids and contains about 7–8% of sugar components. Ceruloplasmin has a blue colour and in the normal state one molecule of ceruloplasmin contains six atoms of copper (at full saturation additional binding sites may be occupied by an additional two copper atoms). Blood plasma contains about 300 mg/l of ceruloplasmin. In erythrocytes, copper occurs in another protein called **erythrocuprein** (31 kDa) and in the enzyme superoxide dismutase.

Table 6.9 Utilisable energy, calcium, zinc and phytic acid contents and values for phytate:Zn and Ca × phytate/Zn in wheat products.

Product	Energy (kJ/100 g)	Ca (mg/kg)	Zn (mg/kg)	Phytate (%)	Phytate:Zn (mol/mol)	Ca × phytate:Zn (mmol/kg)	Ca × phytate/Zn × 4.2 (mmol/MJ)
Wheat flour (white)	1520	170–240	10.2–16	0.21–0.34	14–29	86–138	24–38
Wheat flour (whole)	1418	340	29	0.68–0.92	23–31	194–264	57–78
Wheat germ	1506	390	123	1.64–2.24	13–18	129–185	36–49
Wheat bran	904	730	73	1.98–2.69	27–37	490–670	227–309

6.3.8.1.2 Biochemical functions

Copper is an essential trace element for humans and other animals. Copper ions are included in the active centres of many enzymes, especially cytochrome *c* oxidase, superoxide dismutase, various aminoxidases (such as lysyl oxidase), hydroxylases (e.g. dopamine β-hydroxylase and tyrosinase), galactose oxidase or different phenoloxidases, such as laccase and other oxidoreductases. The so-called blue copper proteins, for example plastocyanin, azurin and plantacyanin, occur in many prokaryotic organisms and plants. These proteins, by a change to the bound copper valency, provide electron transfer in various redox processes.

In some invertebrates, oxygen is transported in the blood by the cupric metalloprotein **haemocyanin** (oxyhaemocyanin). Haemocyanin contains two copper atoms (Cu^{+}) linked by three bonds with histidyl residues. One molecule of oxygen in oxyhaemocyanin forms a bridge between two atoms of Cu^{2+}. Cytochrome *c* oxidase is an enzyme that requires haem and copper. It catalyses the final reaction of the respiratory chain (the electron transport from the cytochrome system to an oxygen molecule):

$$O_2 + 4\ \text{ferrocytochrome}\ c\ (Fe^{2+}) + 4\ H^+ \rightarrow 2\ H_2O + 4\ \text{ferricytochrome}\ c\ (Fe^{3+})$$

The enzyme superoxide dismutase is essential for protecting subcellular structures from damage by oxidative reactions (free radicals), as it catalyses the disproportionation of superoxide anion radicals ($2O_2^{\bullet-}$), which are toxic products of oxygen metabolism (see Section 3.8.1.13):

$$2\ O_2^{\bullet-} + 2\ H^+ \rightarrow H_2O_2 + O_2$$

The resulting hydrogen peroxide is then decomposed in the presence of other enzymes (catalase, peroxidase). There are many different superoxide dismutases (SODs) and all are metalloenzymes. The most common enzymes are superoxide dismutases containing copper and zinc (CuZnSOD). Other superoxide dismutases include enzymes containing bound manganese (MnSOD), iron (FeSOD) or nickel (NiSOD). The change in the copper valence is essential for the catalytic activity of CuZnSOD that proceeds in two steps. Reaction of the oxidised form of the enzyme (Cu^{2+}) with the first molecule of superoxide produces oxygen and reduced enzyme (Cu^{+}), which reacts with the second molecule of superoxide yielding hydrogen peroxide and, simultaneously, the enzyme is reduced:

$$Cu^{2+}ZnSOD + O_2^{\bullet-} \rightarrow Cu^{+}ZnSOD + O_2$$
$$Cu^{+}ZnSOD + O_2^{\bullet-} + 2\ H^+ \rightarrow Cu^{2+}ZnSOD + H_2O_2$$

Some aminoxidases provide oxidative deamination of biogenic amines or amino acids. Lysyl oxidase is an enzyme essential for the integrity of connective tissue as it catalyses the post-translational deamination of lysyl or hydroxylysyl residues in proteins that subsequently form cross-linked **collagen** and **elastin** macromolecules. The lysyl residue reacts with oxygen, loses an ε-amino group and the terminal methylene group is oxidised to an aldehyde group. This allows the condensation of the aldehyde group with amino hydroxylysyl residue in the other chain to produce the corresponding imine. Amadori rearrangement of the imine produces a stable inter-chain bridge. This process leads to cross-linking of tropoelastin and continues to form desmosine and isodesmosine units (**2-98**) containing a pyridine nucleus and connecting the individual chains to form extremely resistant protein elastin.

Tyrosinase is an enzyme found in melanocytes (melanin-producing cells located in the bottom layer of the skin's epidermis) that participates in the pigmentation of skin and hair. This enzyme catalyses the hydroxylation of tyrosine to dopamine and two other reactions in the reactions sequence, leading to the main pigments known as **phaeomelanins** and **eumelanins** (see Section 9.3.1.1).

Another Cu-enzyme, α-amidating monooxygenase, is widespread in most higher animals. It provides oxidation elimination of the glycyl residue from the *C*-terminus of some peptide hormones (such as vasopressin, oxytocin, gastrin or calcitonin). At the same time the *C*-terminal amino acids are amidated. This reaction regulates the activity of the hormone. The original peptidylglycine reacts with ascorbic acid in the presence of oxygen with the formation of an intermediate peptidyl 2-hydroxyglycine. The final products are then deglycylpeptide amide, dehydroascorbic acid and glyoxylic acid.

Copper is also necessary for the efficient utilisation of iron and for the biosynthesis of some physiologically important compounds, such as the enzyme **ceruloplasmin**, which is produced in liver cells and acts in the blood plasma as the main Cu compound, but it is not involved in copper transport to the target organs. Plasma copper is transported primarily bound to albumin and partly in the form of complexes with low molecular weight ligands, such as histidine. Ceruloplasmin also has the catalytic activity of ferro oxidase, which means that it catalyses the oxidation of Fe^{2+} ions absorbed in the blood plasma to Fe^{3+} ions, thus allowing fixation of iron in the transferrin molecule. Copper deficiency, therefore, is similar to iron deficiency and leads to anaemia.

6.3.8.1.3 Metabolism

Copper is resorbed mainly in the duodenal part of the digestive tract of man. The degree of resorption is estimated at between 25 and 70%. Resorption of copper depends on the current saturation of the organism (its deficit leads to a higher degree of resorption). As a binding agent, metallothionein may play a role in the intake of copper by intestinal epithelial cells. The resorption of copper is achieved by two mechanisms: active transport, which prevails in the copper deficit in the body, and simple diffusion. Copper is excreted from the body primarily via the faeces, while the majority of the resorbed copper is excreted in the bile. If the daily dose of copper received in diet is approximately 2.5 mg, the amount resorbed into the blood circulation is about 1.2 mg. At the same time the liver eliminates in one day, via the bile, about 0.8–0.9 mg of copper into the intestine, and the kidney excretes about 0.1 mg of copper in urine. The real total daily intake of copper by the body is then only 0.2–0.3 mg, which is about 10% of the copper that is resorbed.

6.3.8.2 Occurrence in foods

Most foods contain less than 10 mg/kg copper. Milk is especially poor in copper, but the bioavailability of copper from human milk is very high. Higher concentrations of copper are found in the liver (especially in calf's liver), followed by legumes and some fungi. These concentrations are very variable. Copper content in selected foods is shown in Table 6.10. Copper naturally present in food is almost always linked in complex compounds with proteins and low molecular weight ligands. The level in foods can be, in exceptional cases, increased by contamination. This applies to crops (e.g. grapes or hops) treated with some pesticides based on compounds containing copper. Another possibility of contamination by copper may occur when copper containers for food processing of food raw materials are used (e.g. in brewing technology). Copper ions act as a catalyst in the oxidation of labile components of food (L-ascorbic acid and lipids).

6.3.8.3 Nutrition

The recommended daily dietary doses of copper are 0.4–0.7 mg for children under 1 year, 0.7–2.0 mg for children aged 1 to 10 years, 1.5–2.5 mg for adolescents and 1.5–3.0 mg for adults. Resorption of copper and its retention in the body depend on the chemical form in which this element is present in the diet. Experiments on laboratory animals have shown a higher utilisation of copper in the form of neutral and anionic complexes contained in plant material than in the form of copper sulfate. Availability of copper increases the presence of proteins and amino acids in the diet. Also, carboxylic and hydroxycarboxylic acids stimulate resorption of copper. In contrast, higher doses of ascorbic acid, fructose, molybdenum, sulfur compounds and zinc significantly reduce the resorption of copper. Ascorbic acid reduces cupric compounds to slightly soluble cuprous compounds. The effect of phytic acid and dietary fibre on copper resorption is, in comparison with the effect of these components in zinc, less pronounced.

Molybdenum and zinc are known antagonists of copper, so that high dietary doses of these elements can cause symptoms of copper deficiency. In the case of high doses of molybdenum, this is due to reduced resorption and increased copper excretion from the body in urine. Higher doses of dietary zinc lead to increased production of metallothionein in enterocytes, which leads to its retention in these cells, so that copper is released into the bloodstream to a lesser extent.

Copper deficiency in humans is very rare. The prolonged low intake of copper (0.8–1.0 mg daily) results in higher levels of cholesterol in the blood, changes in heart rhythm and reduced glucose tolerance. Experiments on animals have shown that copper deficiency causes serious disorders of iron metabolism and subsequently hypochromic microcytic anaemia. Other symptoms are movement disorders, changes in skin, hair, nails (impaired pigmentation and formation of keratin) and bones (facile fragility and deformation).

Copper toxicity to mammals is relatively low (LD_{50} value for oral administration of cupric sulfate, $CuSO_4{\cdot}5H_2O$, in rats is 300 mg/kg body weight). Copper ions are very toxic to fish.

6.3.9 Manganese

6.3.9.1 Biochemistry and physiology

6.3.9.1.1 Occurrence in human body

The adult human body contains about 10–20 mg manganese. Higher concentrations of manganese are found in the bones (2.6 mg/kg), liver (1.4 mg/kg), pancreas and kidney (1.2 mg/kg); lower concentrations (approximately 0. 2–0.3 mg/kg) are found in brain, spleen, heart and lungs and even lower in skeletal muscle (around 0.06 mg/kg). With regard to the subcellular level distribution, manganese is mostly present in the mitochondria. Biological structures containing keratin (such as bones and skin) are relatively rich in manganese. The manganese content in the blood is about 70 μg/l and according to some data only 8–10 μg/l. Manganese is mostly contained in blood erythrocytes, probably in the form of a porphyrin complex. In blood plasma, the majority of the trivalent manganese is bound to β_1-globulin.

6.3.9.1.2 Biochemical functions

The binding of manganese by most biologically important ligands is relatively weak, but manganese ions (Mn^{2+}) function as cofactors for a large variety of enzymes with many functions. This applies to oxidoreductases and other enzymes (some transferases, hydrolyses and lipases). Oxidoreductases catalyse oxidation and reduction (redox) reactions associated with the change of manganese valence (Mn^{II} versus Mn^{III} or Mn^{III} versus Mn^{IV}). The most important enzymes of the second group include pyruvate carboxylase and arginase. Both enzymes contain four molecules of Mn^{2+} ions. In the presence of biotin as a cofactor, pyruvate carboxylase catalyses the reaction: pyruvic acid + CO_2 + ATP + $H_2O \rightarrow$ oxaloacetic acid + ADP + H_3PO_4. Oxaloacetic acid is an intermediate of the citric acid cycle and carbohydrate biosynthesis (gluconeogenesis).

Arginase is an enzyme that catalyses the hydrolysis of arginine to urea and ornithine. This reaction represents the terminal phase of the urea (ornithine) cycle, which in mammals provides (in the form of urea) excretion of ammonia nitrogen released during decomposition of amino acids. The enzyme is composed of two subunits, each containing two atoms of Mn^{2+}, which are connected by two oxygen bridges. In the active centre, manganese atoms are fixed by coordination with four carboxylic groups of aspartic acid residues and nitrogens of the imidazole nuclei of two histidine residues.

Superoxide dismutases of some microorganisms (such as *Escherichia coli*) and some animals contain Mn^{3+}/Mn^{2+} ions instead of copper and zinc ions as the cofactor (see Section 3.8.1.13.2). Catalases of some microorganisms (e.g. the bacteria *Lactobacillus plantarum*) contain manganese instead of haem iron.

In addition to true metalloenzymes that contain manganese, there are a number of enzymes activated by manganese ions. These enzymes include various hydrolases, kinases, decarboxylases and glycosyltransferases. Manganese may also be bound, instead of magnesium, in enzyme molecules in which the catalytic function requires magnesium, while enzyme activity is maintained. In the enzyme glutamine synthetase, the bound manganese probably has

Table 6.10 Copper, manganese, nickel, cobalt and chromium contents in some crops and foods.

[a]Breast milk concentrations of Cu, Mn, Ni, Co, Mo and Cr are 0.26–0.4, 0.006–0.03, 0.001–0.01, 0.0001, 0.002–0.01 and 0.0003 mg/kg, respectively.

a function of fixing the molecular structure and is not involved in the catalytic function.

Manganese is also important in the light reactions of photosynthesis in plant chloroplasts. The oxygen evolving complex is a part of photosystem II, occurring in the thylakoid membranes of the chloroplasts, which is responsible for the terminal photooxidation of water. Photosystem II is the oxidoreductase complex containing a cluster of four atoms of Mn and one Ca atom. Chlorophyll *P680*, which is present in this photosystem, absorbs light and transfers an electron to a pheophytin molecule from which it is transferred by other electron carriers to plastoquinone. This creates an electron hole that attracts electrons in the chlorophyll *P680* molecule. Chlorophyll *P680* thus acts as a strong oxidant ensuring, through changes in the oxidation state of the manganese cluster $CaMn_4$, oxidation of water (O^{2-}, respectively) to elemental oxygen. The reaction takes place as a cyclic action between five stages of transelectronase, which are referred to as S_0 to S_4. In the stage S_0, all four Mn atoms in the cluster are in the oxidation state III. Through four successive losses of electrons, the stage S_4 is then achieved, in which all four Mn atoms of the cluster are in the oxidation state IV. In the final phase of this cycle, two water molecules yield one molecule of oxygen and regenerated transelectronase is again in the stage S_0.

6.3.9.1.3 Metabolism

Resorption of manganese from food takes place in all parts of the small intestine. The efficiency of manganese resorption in adult humans is about 3–4%. In animal experiments it was found that resorption of manganese from food containing various manganese compounds with different solubilities (such as MnO, $MnCO_3$, $MnSO_4$ and $MnCl_2$) is very different. Although the mechanism of manganese resorption is not precisely known, there are some similarities with the metabolism of iron. Resorbed manganese is transported in blood plasma bound to transferrin. Part of manganese in plasma is also bound to albumin and α_2-macroglobulin. As with iron, binding of manganese to a transferrin molecule requires oxidation of divalent ions to trivalent ions, which is probably provided by ceruloplasmin. The concentration of manganese in the cytoplasm of primary cells is approximately 1×10^{-7} mol/l. Significantly higher amounts of manganese are found in some organelles.

Resorption of manganese is increased in the presence of low molecular weight ligands (such as citric acid or histidine). A high intake of iron in the diet can reduce the efficiency of manganese resorption. Also, high doses of calcium and phosphates reduce the bioavailability of manganese. In contrast, high doses of manganese reduce the resorption of iron and lead to a decrease in the haemoglobin level. There is also a competition in the resorption of manganese and cobalt.

In a diet containing low quantities of manganese and iron (e.g. in milk), the efficiency of manganese resorption is high. The resorption of manganese from breast milk is higher than the resorption of manganese from cows' milk. It probably relates to the different localisation of manganese in these fluids. In human milk, the majority of manganese is in the whey fraction, whereas in cows' milk, manganese is mostly contained in the casein fraction. The efficiency of manganese resorption from meat and fish is higher than from legumes.

The major route of excretion of manganese is through the bile excretion. The amount of manganese excreted in the urine is negligible.

6.3.9.2 Occurrence in foods

Food of animal origin contains low levels of manganese. Good sources are cereals and legumes. Fruits, especially some berries, have high concentrations of manganese. For example raspberries contain 6.7–18 mg/kg and blueberries 23–48 mg/kg manganese. Tealeaves and some spices have particularly high levels of manganese (e.g. cloves have manganese content of about 600 mg/kg, cardamom 320 mg/kg and ginger 160 mg/kg). The manganese content in selected foods is shown in Table 6.10. With regard to the chemical form of manganese in food, the major portion is in ionic form (especially as Mn^{2+}) or in the form of labile complexes.

6.3.9.3 Nutrition

Adequate and safe daily dietary doses of manganese are 0.3–1.0 mg for children under 1 year, 1.0–3.0 mg for children from 1 year to 10 years and from 2.0 to 5.0 mg for adolescents and for adults. Long-term deficiency in the diet can result in slow growth, abnormal bone development and impaired reproductive function. In neonates, deficiency may result in movement disorders. Owing to the influence of manganese on carbohydrate metabolism, deficiency may result in a reduced ability to synthesise and utilise glucose. Manganese deficiency in experimental animals causes a decrease in pancreatic insulin secretion and reduced insulin activity in peripheral tissues, as well as changes in activity of pancreatic amylase.

Toxic effects of manganese (growth retardation and anaemia) occur only at very high doses or long-term inhalation exposure. Poisoning by manganese from food is almost impossible. Chronic manganese poisoning, which was recorded in the miners working with manganese ore in dusty environments, leads to mental disorders and neurological symptoms similar to Parkinson's disease. Decreased blood pressure, elevated levels of calcium, bilirubin, cholesterol and total lipids in blood serum and a decrease of magnesium and protein levels may accompany inhalation exposure. The exposed individuals have a higher incidence of pneumonia.

6.3.10 Nickel

6.3.10.1 Biochemistry and physiology

6.3.10.1.1 Occurrence in human body

The body of an adult contains about 10 mg nickel. Data on concentrations of nickel in various tissues and organs of the human body are not entirely consistent. The nickel content can be influenced by many factors (such as age, gender, environment and smoking). The concentration of nickel in the lungs is 85 ± 65 μg/kg, kidney 10.5 ± 4.1 μg/kg, liver 8.2 ± 2.3 μg/kg, heart

$6.4 \pm 1.6\,\mu g/kg$ and bones $333 \pm 147\,\mu g/kg$. The normal concentration of nickel in the blood is about $5\,\mu g/l$ and in serum of about half of this. The serum nickel is bound to different proteins: albumin, HR-glycoprotein (histidine-rich glycoprotein), nickel plasmin (700 kDa), α_1-glycoprotein and in part also to the low molecular weight substances (mainly histidine).

6.3.10.1.2 Biochemical functions

So far there is no known specific biochemical function for nickel in animal organisms. In plants and microorganisms, some metalloenzymes containing nickel have been found. Such an enzyme is urease, found in soybeans, other legumes (this enzyme was first isolated from the seeds of the Jack bean, *Canavalia ensiformis*), rice and tobacco. Molecule of urease (580 kDa) contains 12 nickel atoms in six subunits. In the active enzyme centre, two nickel atoms are coordinated by four histidyl residues and one residue of ε-*N*-carbamoyl lysine, while the carbamoyl group and one molecule of water form a bridge between the two nickel atoms. Urease catalyses the hydrolysis of urea to ammonia and carbamate (carbamic acid), which is hydrolysed spontaneously to hydrogen carbonate (bicarbonate) and ammonium ions:

$$(H_2N)_2C{=}O + H_2O \rightarrow H_2N{-}COOH + NH_3$$
$$H_2N{-}COOH + H_2O \rightarrow HCO_3^- + NH_4^+$$

Some bacteria of the genera *Acetobacterium*, *Alcaligenes*, *Clostridium*, *Desulfovibrio*, *Methanobacterium* and *Vibrio* produce a variety of Ni-dependent oxidoreductases. Although no known animal enzymes containing nickel are known, the element can act as an activator of some enzymes. For example, calcineurin, which has phosphatase activity against phosphoproteins, is strongly activated by nickel ions. This enzyme contains bound iron and zinc and its activity is regulated by conformational changes that depend on the binding of other metal ions (Ni^{2+}, Mn^{2+} and Ca^{2+}) to some places in the molecule. A possible function of nickel is the participation in the resorption of iron. Nickel, through as yet unknown mechanisms, apparently facilitates resorption of iron by conversion of Fe^{3+} into Fe^{2+}.

Allergies to nickel are a phenomenon that has become increasingly important in recent years, largely because of the introduction of cheap fancy jewellery in which the underlying metal layer consists of nickel.

6.3.10.1.3 Metabolism

Most of the nickel contained in food passes through the gastrointestinal tract without resorption. The effective absorption of nickel is usually less than 10%. Increased resorption of nickel (20%) can occur if the saturation with iron is low. Resorbed nickel is excreted from the body mainly in urine. In the cytosol of renal cells, nickel is bound to a glycoprotein (15 kDa). The protein component of this glycoprotein contains a high proportion of glycine and no cysteine, so it is not identical with metallothionein. This glycoprotein also binds nickel in the urine.

6.3.10.2 Occurrence in foods

Fruits, cereals and foods of animal origin, with the exception of some seafood (oysters), have very low nickel content (hundredths to tenths of mg/kg). Higher concentrations are found in legumes, nuts, tealeaves, cocoa beans and cocoa products, such as chocolate. Refined vegetable oils and animal fats usually contain only trace amounts of nickel (around the thousandths of mg/kg) and of other transitional elements. Somewhat higher concentrations (hundredths to tenths of mg/kg) are found in margarine as solid fats may be manufactured from oils by hydrogenation in the presence of a nickel catalyst (a nickel–aluminium alloy known as Raney nickel), under controlled conditions. The concentration of nickel in food may increase during storage in metal containers, which has been shown in canned fruits. The nickel content in selected foods is shown in Table 6.10.

6.3.10.3 Nutrition

The recommended daily dietary doses of nickel have not been determined. Actual dose depends on dietary habits, and ranges between 150 and $700\,\mu g$/day. Animal experiments suggest that a deficit of nickel in the diet leads to slower growth.

Toxic effects of nickel occur only at levels $\geq$250 mg/kg food. Symptoms of nickel poisoning in animals are changes in fur and diarrhoea. High doses of dietary nickel are accompanied by changes of an increased number of erythrocytes, increased haemoglobin level and increased serum proteins in plasma, increased urea, iron, zinc, copper and nickel in the liver, increased hepatic activity of glutamate dehydrogenase and decreased activity of glucose 6-phosphate dehydrogenase. At the same time, the amount of iodine in the thyroid gland decreases. Nickel compounds are also irritating to the skin. Highly toxic and carcinogenic volatile nickel tetracarbonyl, $Ni(CO)_4$, used as a reagent in organometallic chemistry, is readily absorbed through the lungs.

6.3.11 Cobalt

6.3.11.1 Biochemistry and physiology

6.3.11.1.1 Occurrence in human body

The total amount of cobalt in the human body is <1.5 mg. The liver contains approximately 0.11 mg/kg of cobalt, skeletal muscle 0.2 mg/kg, bones 0.28 mg/kg, hairs 0.31 mg/kg, adipose tissue 0.36 mg/kg and blood about $0.3\,\mu g/l$ (mostly in plasma). The main biologically active compound of cobalt is vitamin B_{12}.

6.3.11.1.2 Biochemical functions

Cobalt is an essential element for bacteria, algae and ruminant mammals. For other organisms, including monogastric animals, cobalt is essential, in the form of the essential compound vitamin B_{12} (cobalamin). Rumen microflora of ruminants synthesises cobalamin from cobalt in the diet. Derivatives of vitamin B_{12} cobamides are cofactors of some enzymes, for example of methylmalonyl coenzyme A mutase, glutamate mutase and methionin synthetase.

6.3.11.1.3 Metabolism

In the gastrointestinal tract of humans, 20–97% of cobalt present in the diet is resorbed. For the resorption of vitamin B_{12}, a glycoprotein known as the gastric factor is essential, which allows the transport of cobalamin into cells in the intestinal mucosa. The effectiveness of cobalt resorption increases with iron deficiency. Cobalt is excreted from the body mainly in the urine.

6.3.11.2 Occurrence in foods

The richest sources of cobalt in the diet are beans and offal. Poor sources of cobalt are milk and dairy products, white flour products and sugar. Rich sources also include tea, coffee and chocolate. Cobalt content in selected foods is shown in Table 6.10.

6.3.11.3 Nutrition

The recommended dose of cobalt has not been established. Actual daily dietary doses are very low, being estimated at 5–10 μg.

6.3.12 Molybdenum

6.3.12.1 Biochemistry and physiology

6.3.12.1.1 Occurrence in human body

The total content of molybdenum in the human body is about 5–10 mg. The molybdenum content in the liver is approximately 0.36–0.9 mg/kg, in kidney 0.4 mg/kg and in brain and muscles 0.03 mg/kg. The molybdenum content in the blood fluctuates over a very wide range of concentrations (0.003–0.41 mg/l). Mean concentrations are 0.01–0.07 mg/l.

6.3.12.1.2 Biochemical functions

Molybdenum is an essential element for microorganisms and plants and even in animals several enzymes containing molybdenum have been found (such as xanthin oxidase, sulfite oxidase and dimethyl sulfoxide oxidase). Other enzymes containing molybdenum include formate dehydrogenase from *Escherichia coli* or arsenite oxidase from *Alcaligenes faecalis*. These enzymes contain molybdenum cofactor molybdopterin (**6-19**), a heterocyclic compound with a pyran ring fused to a pterin ring. The pyran ring is substituted by two thiol groups, which serve as ligands in molybdoenzymes (and tungstoenzymes). The *cis*-dithiolene group of the pyran ring binds the molybdenum, which is coordinated by three more (oxygen) ligands. Xanthin oxidase also contains, besides flavin adenine dinucleotide cofactor (FAD), two clusters of iron and sulfur in each of the two subunits. Xanthin oxidase catalyses the oxidation of hypoxanthine to xanthine and the oxidation of xanthine to uric acid (see Section 11.3.5):

$$\text{hypoxanthine} + H_2O + O_2 \rightarrow \text{xanthine} + H_2O_2$$
$$\text{xanthine} + H_2O + O_2 \rightarrow \text{uric acid} + H_2O_2$$

Xanthine oxidase is a very important enzyme in the catabolism of purines. In the congenital metabolic disorder called xanthinuria, xanthin oxidase is missing. The enzyme sulfite oxidase catalyses the oxidation of sulfites to sulfates using oxygen. It occurs in animals, plants and microorganisms. Dimethyl sulfoxide oxidase is capable of reducing dimethyl sulfoxide to dimethyl sulfide. This enzyme serves as the terminal reductase under anaerobic conditions in some bacteria. Formate dehydrogenases are enzymes that catalyse the oxidation of formate ($H{-}COO^-$) to hydrogen carbonate (HCO_3^-). Bacterial formate dehydrogenase H is known to use a selenium–molybdenum version of molybdopterin. Arsenite oxidase belongs to a sub-class of the dimethyl sulfoxide reductase family of molybdenum-containing enzymes. This enzyme also possesses a [3Fe–4S] iron–sulfur centre in the same sub-unit as the molybdenum centre, as well as an [2Fe–2S] centre in a separate sub-unit.

All organisms use the ammonia to manufacture amino acids, proteins, nucleic acids and other nitrogen-containing components necessary for life. Biological nitrogen fixation is the process that changes inert nitrogen from the atmosphere into biologically useful ammonia. This process is only mediated in nature by bacteria. Some plants benefit from nitrogen-fixing bacteria. In legumes and a few other plants, the bacteria live in small growths on the roots called nodules. Within these nodules, nitrogen fixation is carried out by the bacteria and the ammonia produced is absorbed by the plant. Among others, enzymes containing molybdenum, such as nitrogenases and nitrate reductases are involved nitrogen fixation. Nitrogenases ensure the conversion of elemental nitrogen into ammonia and nitrogen fixation in the soil. These enzymes are produced, for example, by some species of the genera *Rhizobium*, *Azotobacter*, *Clostridium* and *Klebsiella*. The overall reaction catalysed by nitrogenase proceeds according to the following equation:

$$N_2 + 8\,H^+ + 8e^- + 16\,\text{ATP} + 16\,H_2O$$
$$\rightarrow 2\,NH_3 + H_2 + 16\,\text{ADP} + 16\,H_3PO_4$$

Nitrogenases containing molybdenum are an intermolecular complex consisting of two parts called MoFe protein and Fe protein, respectively. The MoFe protein (230 kDa) has a heterotetrameric structure with an Fe–Mo cofactor and [Fe–S] cluster, while the Fe protein (64 kDa) has a homodimeric arrangement of sub-units bound by an [4Fe–4S] cluster. In some nitrogenises, molybdenum can be replaced by vanadium or iron.

Nitrate oxidase reduces nitrates (NO_3^-) to nitrites (NO_2^-). This enzyme occurs in microorganisms, algae, fungi and plants. The enzyme molecule is composed of two types of sub-units and contains, in addition to molybdenum and haem, non-haem iron. The electron transfer ensuring substrate reduction by cyclic changes in molybdenum valence is coupled with the cytochrome system. Reduction of nitrate to nitrite is the first phase of the denitrification process in which some microorganisms use nitrate ions as terminal electron acceptors instead of oxygen. The other phase of denitrification lies in the gradual reduction to nitric oxide, nitrous oxide and elemental nitrogen. Part of the generated nitrous oxide is released into the atmosphere and causes the greenhouse effect. All the enzymes that catalyse the individual reaction stages of denitrification (nitrate reductase, nitrite reductase, nitric oxide reductase and nitrous oxide reductase) are metalloenzymes. The reverse process is nitrification, oxidation of ammonia nitrogen to

nitrate nitrogen. The nitrification bacteria involve bacteria of the genera *Nitrosococcus*, *Nitrosomonas*, *Nitrobacter* and *Nitrococcus*. The intermediates of nitrification are hydroxylamine and nitrite ions, minor byproducts include nitrogen oxides, hydrazine and molecular nitrogen. The processes of nitrification, denitrification and nitrogenation are, together with the consumption of nitrogenous nutrients by eukaryotic organisms and the catabolism of nitrogenous compounds, included in the nitrogen cycle in nature.

6.3.12.1.3 Metabolism

Molybdenum contained in food is resorbed in all parts of the small intestine and in part previously in the stomach. Resorption is quite effective (25–80%). With the exception of MoS_2, molybdenum is resorbed well from the soluble compounds (such as sodium and ammonium molybdates) and less soluble compounds (molybdenum trioxide and calcium molybdate). Resorption of molybdenum is competitively inhibited by sulfate anions. The excess of molybdenum is excreted in the urine.

Resorption, intermediary metabolism, excretion and physiological effects of molybdenum are strongly dependent on the interactions with sulfur compounds and their metabolites occurring in the diet. These interactions govern retention of molybdenum in various tissues and determine the tolerance to potentially toxic doses of molybdenum and molybdenum effects on the utilisation of copper. In the metabolic antagonism of molybdenum and copper, sulfur compounds mitigate the negative effects of higher doses of molybdenum.

6.3.12.2 Occurrence in foods

Relatively high contents of molybdenum are found in pulses (units of mg/kg). Moderate amounts are found in whole grain cereals and offal (tenths to units of mg/kg) and low amounts (<0.1 mg/kg) in most vegetables, fruits, fish, meat, milk, dairy products and fats. The molybdenum content in foods is presented in Table 6.10.

6.3.12.3 Nutrition

An adequate and safe daily dose of dietary molybdenum is 15–40 μg for children under 1 year, 25–75 μg for children from 1 year to 6 years old and 75–250 μg for individuals older than seven years. The actual daily dietary dose of molybdenum is in the range of about 120–240 μg. Symptoms of molybdenum deficiency are seen mainly in farm animals that live in areas with a low molybdenum content in the soils and vegetation.

6.3.13 Chromium

6.3.13.1 Biochemistry and physiology

6.3.13.1.1 Occurrence in human body

The total chromium content in the human body is estimated to be 5 mg, which is fairly evenly distributed. The concentration of chromium in individual tissues and organs, except the lungs, decreases with age. The normal content of chromium in blood plasma is 0.1–0.4 μg/l.

6.3.13.1.2 Biochemical functions

Chromium is a controversial element with important essentiality and toxicity, depending on its different species. Chromium in the oxidation state III is an important essential element. In contrast, hexavalent chromium compounds (chromates and dichromates) are toxic and may be responsible for certain allergenic, mutagenic and carcinogenic effects.

Trivalent chromium is an important metal in carbohydrate metabolism. It probably facilitates the interaction between sulfhydryl groups in cell membranes with the disulfide groups of insulin and thus allows insulin-stimulated utilisation of glucose. A complex compound of Cr^{III} with glycine, cysteine, glutamic acid and nicotinic acid, known as the glucose tolerance factor, was previously considered to be a physiologically active substance containing chromium. This substance, isolated from the yeast biomass, was able to increase glucose tolerance in experimental animals, but later it was shown that it was an artefact produced by acid hydrolysis of the chromium-binding substance chromodulin.

Today there are two known biologically active complexes of Cr^{III} with oligopeptides. The first compound, called **chromodulin**, occurs in the liver and kidney tissue of mammals, the second was isolated from cow colostrum. The oligopeptide **apochromodulin** (1.4 kDa), mainly containing glycine, cysteine, aspartic and glutamic acids, strongly binds four Cr^{III} atoms forming chromodulin. The peptide from colostrum has a similar amino acid composition. Both peptide complexes (but not apopeptides alone) stimulate glucose metabolism in adipocytes of rats. Chromodulin is incorporated into the amplification mechanism of insulin action. In the presence of insulin, chromodulin increases the activity of insulin receptors in adipocyte membranes. Apochromodulin is probably stored in the cells sensitive to insulin. The increase in plasma insulin level and subsequent insulin binding to insulin receptors in cells causes a conformational change that leads to phosphorylation of tyrosine residues on the inner side of the receptor. The Cr^{III} entry into cells and formation of chromodulin, which apparently interacts with insulin receptors, can stabilise the active conformation of receptors and increases their kinase activity.

Chromium compounds, through the potentiating of insulin effects and probably also by other mechanisms, also interfere with the metabolism of lipids and proteins. Increasing doses of dietary chromium partially reduce the levels of cholesterol and triacylglycerol in the blood plasma and simultaneously increase the proportion of high density lipoproteins (HDL). Chromium compounds are also involved in maintaining the structural integrity of nucleic acids as chromium protects RNA against thermal denaturation. It accumulates in the cell nuclei.

6.3.13.1.3 Metabolism

Inorganic chromium compounds are resorbed very little in the gastrointestinal tract of humans and other mammals. Resorption efficiency ranges from 0.4 to 3% and decreases with an increasing

dose of chromium (about 2% is resorbed at a dose of 10 μg/day and about 0.4% at a dose greater than 40 μg). Resorption of chromium is very fast. Even 15 min after administration, an increase in chromium concentration in the blood may be observed, and after 2 h in urine. The resorption efficiency of natural chromium complexes is probably much higher. Oxalic acid significantly increases and phytic acid decreases the resorption of trivalent chromium.

The resorption of hexavalent chromium compounds is 3–5 times higher than resorption of trivalent chromium compounds. In blood, hexavalent chromium enters into blood cells and erythrocytes more easily than trivalent chromium and binds to haemoglobin. Trivalent chromium is resorbed in the blood plasma bound to α-globulin and transferrin. Transferrin provides chromium transportation to the tissues. In some target tissues, chromium from transferrin binds to apochromodulin with the formation of chromodulin. In the cells, about 50% of chromium is contained in the nucleus and about 20% in the cytoplasm. Chromium is excreted from the body mainly in the urine. Excessive intake of chromium by experimental animals or chromium intoxication also leads to excretion of chromodulin in the urine. Biosynthesis of this metallopeptide thus participates in the detoxification of chromium.

6.3.13.2 Occurrence in foods

Data on the content of chromium in biological materials derived from the years 1950–1970 placed the chromium levels quite high, but these are now considered incorrect. Improved analytical techniques have helped to obtain the real chromium contents, which in some materials (including blood plasma and milk) is in the ultra trace region. Despite this progress in analytical methods, the results of different studies are contradictory. A summary of these results suggests a very wide interval of concentrations of chromium in various materials. During manufacture and storage, foods come into contact with metallic materials (such as stainless steel) and the initially very low content of chromium (several μg/kg) can be increased significantly due to contamination. A rich source of biologically utilisable chromium is brewer's yeasts. The chromium content in selected foods is shown in Table 6.10.

Under the assumptions that higher doses of chromium in the diet prevent diabetes and can to some extent increase weight loss, chromium compounds (usually complex of Cr^{3+} with picolinic acid) are often part of some food supplements. However, the effectiveness of such supplementation is still very controversial.

6.3.13.3 Nutrition

An adequate daily dietary dose of chromium is considered to be 50–200 μg. The actual dose of chromium found in several studies is in the range of 25 to 100 μg. In chromium deficiency, the following symptoms have been identified: impaired glucose tolerance, persistently elevated blood glucose level, elevated blood serum cholesterol and triacylglycerol levels and the presence of carbohydrates in urine. There is thus a link between chromium deficiency and the development of diabetes and cardiovascular diseases. Nerve and brain disorders have also been recorded in connection with the lack of chromium.

Toxic effects of Cr^{3+} compounds are manifested only at extremely high doses. Much more toxic are hexavalent chromium compounds, which cause growth failure and liver and kidney damage. Chromate contact with the skin may cause dermatitis. Chronic exposure to dust containing chromates increases the risk of lung cancer development.

6.3.14 Vanadium

6.3.14.1 Biochemistry and physiology

6.3.14.1.1 Occurrence in human body

The known levels of the transition metal vanadium in the human body are unreliable. Natural concentrations of vanadium in various tissues and organs are very low, but may substantially increase on exposure to vanadium compounds. For example, vanadium content in the kidney is in the range of 1–140 μg/kg, in liver 3–110 μg/kg, in muscles 10–110 μg/kg. The vanadium concentration in blood plasma is 0.02–1.3 μg/l.

6.3.14.1.2 Biochemical functions

As yet, the biological functions of vanadium have not been defined clearly. However, vanadium has an effect on the activity of important enzymes, especially the inhibition of (Na,K)-ATPase, other ATPases, phosphatases and phosphotransferases by metavanadate ions (VO^{3-}). Vanadium also stimulates the synthesis of cyclic AMP by adenylate cyclase activation and may therefore interfere with the metabolism of carbohydrates and lipids.

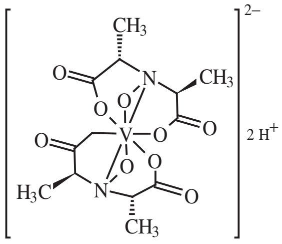
6.3.14.1.3 Metabolism

In the human gastrointestinal tract, only 0.1–1% of vanadium contained in the diet is resorbed. For some laboratory animals, however, fairly high resorption of vanadium from the diet with a predominance of casein and carbohydrates has been observed. Vanadium resorbed in the form of metavanadate ions (VO_3^-) containing V^V is reduced by glutathione in the blood to VO^{2+} ions that contain V^{IV} and form 2 : 1 metal–protein complexes with ferritin and transferrin. Transferrin then obviously provides the distribution of vanadium in the tissues. Vanadium is also present in a metalloprotein (metalloporphyrin) called **haemovanadin**. Excessive intake of vanadium is excreted in the urine.

6.3.14.2 Occurrence in foods

The vanadium content of most foods is extremely low. Milk, fats, vegetables and fruits contain <1–5 μg/kg of vanadium; whole grain cereals, meat, fish and liver contain 5–40 μg/kg. According to some sources, marine crustaceans and molluscs (e.g. oysters) have a higher content of vanadium, above 100 μg/kg. There is a high content of vanadium in some fungi of the genus *Amanita* (Amanitaceae) (36–250 mg/kg dry weight), such as the fly agaric

(*A. muscaria*), which concentrate vanadium to levels of up to 400 times those typically found in plants. These toxic toadstools contain a blue coloured complex (1 : 2) of V^{4+} cations with (2*S*,2′*S*)-*N*-hydroxyimino-2,2′-dipropionic acid, called **amavadin** (**6-35**).



6-35, amavadin

6.3.14.3 Nutrition

The recommended daily intake of vanadium has not been determined. The actual food intake of vanadium is estimated at 10–30 μg.

6.3.15 Selenium

6.3.15.1 Biochemistry and physiology

6.3.15.1.1 Occurrence in human body

The body of an adult contains about 15 mg of selenium. The highest concentrations of selenium are found in the kidney (0.2–1.5 mg/kg), liver (0.24–0.4 mg/kg), hairs (0.6–6 mg/kg) and bones (1–9 mg/kg), while muscles have a lower content (0.07–0.1 mg/kg). Concentrations of selenium in the blood range from 40 to 350 μg/l.

6.3.15.1.2 Biochemical functions

The essential importance of selenium was demonstrated in 1957 when selenium was detected in the so-called factor 3, which prevents liver necrosis in rats. In 1973, the first enzyme containing selenium, glutathione peroxidase, was identified. Selenium, as a part of glutathione peroxidase, enhances the biological effects of vitamin E. Glutathione peroxidase catalyses the reduction of hydrogen peroxide (H_2O_2) and hydroperoxides of fatty acids (R–O–O–H) using a tripeptide glutathione (see Section 2.3.3.1.1) that exists in reduced (G–SH) and oxidised (G–S–S–G) states:

$$2\ \text{G–SH} + H_2O_2 \rightarrow \text{G–S–S–G} + 2\ H_2O$$
$$2\ \text{G–SH} + \text{R–O–OH} \rightarrow \text{G–S–S–G} + \text{R–OH} + H_2O$$

The first step involves oxidation of the selenol of a selenocysteine residue (R–SeH) by hydrogen peroxide, which yields a derivative of selenenic acid (R–Se–OH). Selenenic acid is then converted back into selenol by a two-step process:

$$\text{R–SeH} + H_2O_2 \rightarrow \text{R–Se–OH} + H_2O$$
$$\text{R–Se–OH} + \text{G–SH} \rightarrow \text{G–S–Se–R} + H_2O$$
$$\text{G–S–Se–R} + \text{G–SH} \rightarrow \text{G–S–S–G} + \text{R–SeH}$$

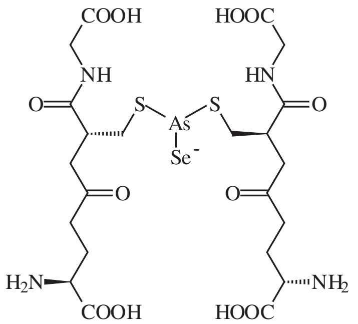
These reactions take place, for example, in erythrocytes and ensure removal of lipid hydroperoxides from damaged biological membranes (lipoproteins). Glutathione peroxidase thus provides protection against oxidative damage of biological structures. After removing the hydroperoxyl group, the hydroxylated lipids may be normally metabolised by β-oxidation. Reduced glutathione is regenerated by NADPH under the catalysis of glutathione reductase:

$$\text{G–S–S–G} + \text{NADPH} + H^+ \rightarrow 2\ \text{G–SH} + 2\ \text{NADP}^+$$

Glutathione peroxidase isolated from erythrocytes has a relative molecular weight of 85–95 kDa and consists of four subunits, each of which contains one selenocysteine molecule in its peptide chain.

Another selenoenzyme is iodothyronine 5′-deiodinase (also known as thyroxine 5′-deiodinase) from a subfamily of deiodinase enzymes important in the activation and deactivation of the thyroid gland hormones. There are two types of deiodinases: type I occurs in the liver, kidney, muscle and thyroid gland, type II is present in the brain, pituitary and adrenal glands. Iodothyronine 5′-deiodinase catalyses the conversion (deiodination) of the thyroid hormone thyroxine into the metabolically active triiodothyronine (see Section 2.2.1.2.5) and significantly enters into the metabolism of iodine and thyroid hormones.

A number of other selenium proteins have been discovered in biological materials, but their function is not yet sufficiently known. For example, a selenium protein (17 kDa) was found in rat sperm. It is interesting that high concentrations of selenium in male sexual organs are maintained in animals with selenium deficiency; therefore, selenium compounds are likely to be important for reproductive function. Some anticarcinogenic effects are also attributed to this element. Selenium also reduces the toxic effects of arsenic, cadmium, mercury, thallium and tellurium. With arsenic, the mechanism of this protective effect is the formation of selenobis(*S*-glutathionyl)arsinium anion, which is formed in erythrocytes and excreted in bile (**6-36**).

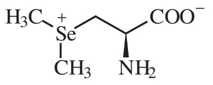


6-36, selenobis(*S*-glutathionyl)arsinium ion

6.3.15.1.3 Metabolism

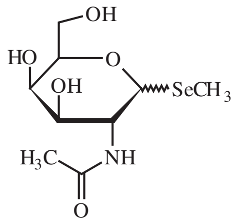
The effectiveness of selenium resorption in the gastrointestinal tract of humans is quite high, but depends on the selenium form. Organic and inorganic dietary selenium are both typically well absorbed through the intestinal membrane (70–95%). Since selenium and

sulfur have very similar properties, certain selenocompounds can be absorbed through the same pathways as their sulfur analogues. This is the case for selenate, which shares an active transport route with sulfate, and of selenomethionine, which passes the intestinal barrier using the same Na^+-dependant process as methionine. In contrast, selenite and selenocystine are taken up by a passive process (only in the direction of the concentration gradient) that is not affected by sulfite; however, selenocysteine does not seem to be influenced by Cys. Selenomethionine absorption is 95–97%, while selenite (SeO_3^{2-}) absorbtion is from 44 to 76%. Following their absorption, selenium species in the blood are partially accepted by blood cells and partially translocated towards different organs and tissues with the help of protein transporters (albumin and selenium-binding protein) in the blood plasma. It is suggested that ingested selenium is initially bound to albumin, which transports the element to the liver, where selenium is released and serves in the synthesis of selenoproteins. The most common selenoprotein is selenoprotein P, which is then released into the bloodstream to itself become a selenium transporter between the liver and various other organs and tissues. In the resorption and metabolism of selenium compounds, reduced glutathione (G–SH) and cysteine play an important role. Inorganic selenium compounds are metabolised in the body with the formation of selenotrisulfides (R–S–Se–S–R). The reaction of G–SH with selenite yields selenotrisulfide, known as selenodiglutathione (G–S–Se–S–G). With an excess of glutathione, unstable selenodisulfide (G–S–Se–H) forms and decomposes to selane (hydrogen selenide, H_2Se) and glutathione. Amino acids containing selenium are metabolised in methylation reactions. For example, methylation of selenocysteine gives *Se*-dimethyl-L-selenocysteine (**6-37**), which decomposes to L-alanine and volatile dimethylselenide $(CH_3)_2Se$. Methylation of dimethylselenide yields the trimethylselenonium ion $(CH_3)_3Se^+$.



6-37, *Se*-dimethyl-L-selenocysteine

Selenium is excreted from the body mainly in the urine (approximately 60%). Major selenium compounds in the urine are trimethylselenonium ions and selenosugars, such as 1,2-dideoxy-1-methylseleno-2-acetamido-D-galactopyranose (**6-38**). Part of the selenium is excreted by the lungs in the form of volatile compounds such as dimethylselenide, dimethyldiselenide and selane.



6-38, 1,2-dideoxy-1-methylseleno-2-acetamido-D-galactopyranose

6.3.15.2 Occurrence in foods

The average natural content of selenium in the earth's crust is 0.09 mg/kg, but it is distributed very unevenly. Selenium accompanies sulfur in nature, so it is a minor component of sulfides of copper, silver, lead and mercury. The highest concentrations of selenium are found in igneous and sedimentary rocks (in sulfide rocks at concentrations of more than 1000 mg/kg). In areas with geological sub-soil such as this, concentrations of selenium in the soil are elevated (30–300 mg/kg). Normal levels of selenium in the soil are 0.1–2.0 mg/kg dry matter. In natural waters only trace amounts of selenium occur. Concentrations of selenium in lake and river waters range from about 0.02 to 10 μg/l. Sea water contains 0.03 to 0.25 μg/l of selenium.

In some territories there are areas with high or low concentrations of selenium in the soil. For example, in China there are areas with both selenium deficiency and with extremely high concentrations of selenium. Mean concentrations of selenium are found in soils in large parts of the United States (in the states on the Atlantic and Pacific coasts). In Canada (excluding the province of Ontario), mean levels of selenium in soils also occur. By contrast, in some European countries (such as Finland, Switzerland and Czech Republic) and New Zealand, concentrations of selenium in the soil are very low. If the land is used for growing crops or grazing, the concentration of selenium in crops and animal bodies are characteristic of the region. Therefore, there are very significant regional differences in concentrations of selenium in agricultural products and foods. An overview of the selenium content in foods is given in Table 6.11.

The foods that are rich in selenium are mainly marine fish, crustaceans and molluscs (such as oysters and prawns), freshwater fish and offal (mainly kidneys). Eggs also have relatively high levels; most selenium is contained in the yolk. The content of selenium in milk, dairy products and meat is lower and is highly dependent on the animal nutrition. Concentrations of selenium in fruits and vegetables, except garlic, are very low (<0.02 mg/kg). Mushrooms contain selenium at the level of 0.03–1.4 mg/kg. The selenium content in foods of plant origin is fundamentally influenced by the selenium content in the soil or fertiliser used and its availability to the plant. The concentration of selenium in foods of animal origin is determined by the selenium content in the animal feed. Some pet foods are deliberately fortified with selenium compounds.

The level of selenium in the soil largely determines its concentration in plants. The ability of plants to absorb selenium depends on pH, moisture, oxygen and iron contents of the soil. The highest availability of selenium for plants usually comes from slightly alkaline aerobic environments. Hexavalent selenium compounds are very soluble in the soil. Tetravalent selenium compounds are less soluble, and their solubility decreases in the presence of ferric oxide. The vegetation in areas with a high content of selenium in the soil can contain up to tens of mg/kg of selenium in dry matter. Such a concentration can poison animals grazing on this vegetation. In addition, some plant species growing on seleniferous soils are selenium tolerant and accumulate very high concentrations of this element (selenium accumulators), but most plants are selenium non-accumulators and are selenium sensitive. Concentrations of

Table 6.11 Selenium content in major food materials and foods from different countries.

[a]Samples are from areas with a medium content of selenium in the soil.

[b]The table shows results from the 1970s, currently the levels of selenium in most Finnish foods are significantly higher due to the use of fertilisers with added selenium.

[c]The breast milk concentration of selenium is 0.006–0.028 mg/kg.

[d]Data from the Slovak Republic.

selenium in some species of the genus *Astragalus* from the Fabaceae family (commonly known as the legume family), for example in the selenium accumulating plant *A. bisulcatus*, commonly called two-grooved milkvetch or silver-leafed milkvetch, native to central and western North America, can reach thousands of mg/kg, and the plant can be toxic to cattle. Moderately selenium-accumulating plants belong to the Asteraceae family (commonly referred to as the aster, daisy or sunflower family). In most plants, the selenium level does not usually exceed 1 mg/kg.

In plants that strongly accumulate selenium, this element is present mainly in the form of free selenium amino acids and peptides. Selenium in foods is mainly in the form of selenium amino acids bound in protein molecules. In most plant foods, the major form of selenium is selenomethionine. For example, total selenium concentrations for Canadian lentils ranged from 0.16 to 0.72 mg/kg and almost all the selenium (86–95%) is present as selenomethionine with a small part (5–14%) as selenate, but the main components of garlic are selenocysteine and organic selenides. In foods of animal origin, the majority of selenium is bound in selenocysteine.

6.3.15.3 Nutrition

The recommended daily dietary doses of selenium are 10–15 μg for children under 1 year, 20 μg for children from 1 year to 6 years, 30 μg for children from 7 to 10 years, 40 μg for boys and 45 μg for girls from 11 to 14 years, 55 μg for adult women and 70 μg for adult men. For pregnant and lactating women, the daily dose should be increased to 65–75 μg.

The actual daily intake of selenium in the diet varies in different countries and depends on many factors. For example, the following amounts were determined: 330 μg in Venezuela, 130–200 μg in Canada, 80–130 μg in the United States, about 60 μg in Great Britain, in Finland 30–40 μg (in the 1970s) and in New Zealand 23–33 μg. For example, the mean selenium intakes in the United Kingdom have declined from >60 μg/day in 1974 to 29–39 μg/day by 1997 and in 2010 was estimated to be 48–58 μg/day. One reason for the decrease in selenium intake was that up until the mid-1970s approximately 50% of the wheat used to produce bread in the United Kingdom was imported from North America, particularly Canada, but by 1995 this import had fallen to <10% of the 1970 figure and in 2007/2008 82% of wheat for human consumption was grown in the United Kingdom, where the selenium content of food is low in areas where the selenium concentration in soil is low or where the selenium exists in chemical forms that are not readily available for the plants.

Owing to low levels of selenium in the blood serum of the population of Finland, at the beginning of the 1980s it was decided to increase the selenium content in food crops by the addition of sodium selenate to the fertilisers used (the doses were 6–16 mg of selenium per kg of fertiliser). In a few years (from 1984–1986), the content of selenium in important crops and livestock products had increased. For example, wheat selenium content increased from 0.01 to 0.23, in potatoes from <0.002 to 0.02, in milk from 0.008 to 0.03 and in eggs from 0.16 to 0.31 mg/kg. The average daily dose of dietary selenium increased to about 90 μg, and the selenium concentration in breast milk increased from 0.007 to 0.015 mg/kg.

The selenium content of foods, for example in the Czech Republic, is very low due to trace concentrations of this element in soil (0.07–0.12 mg/kg). There, the daily dietary intake was estimated at 25–40 μg. According to some sources, one third to half of population was in a state of mild to severe selenium deficiency. Average data from the last decade show some increase in levels of selenium in foods, so the intake (about 60 μg/day) is close to the recommended values. Importation of foods with high selenium contents contributed to the improved situation.

Selenium deficiency in animals is manifested by hepatic necrosis and a set of symptoms called white muscle disease. Very serious selenium deficiency in humans has been reported in China, in the Keshan region, where there is very low selenium content in the

soil. The heart disease known as Keshan's disease can be cured by increased doses of selenium.

Although selenium is an essential trace element, it is toxic if taken in excess. The symptoms of chronic selenium poisoning of animals (cattle, horses and sheep) have been known since the 19th century and are called alkali disease, because it was assumed that it was caused by drinking water with a high salt content. Poisoning in its first stage involves loss of hair, hoof deformities, and hoof and motion disorders. The second stage of poisoning (called Blind Staggers) causes blindness and often ends in the death of cattle.

Symptoms of poisoning in humans (selenosis) can occur even at doses that are 20 times the recommended daily dose (1–2 mg). Chronic human exposure to higher doses of selenium is manifested by inflammation of the respiratory tract, pulmonary oedema, bleeding, skin changes and depression. The characteristic garlic breath and metallic taste in the mouth is caused by the presence of dimethyldiselenide. In severe cases, jaundice, liver cirrhosis, hair and nails falling out, dental caries and kidney failure can appear.

6.3.16 Iodine

6.3.16.1 Biochemistry and physiology

6.3.16.1.1 Occurrence in human body

The body of an adult contains 10–30 mg of iodine. About 70–90% of iodine in the body is contained in the thyroid gland, a vitally important hormonal gland that plays an essential role in metabolism, growth and maturation of the human body.

6.3.16.1.2 Biochemical functions

Iodine is part of the thyroid hormones, iodinated aromatic amino acids derived from tyrosine that are known by their trivial names as 3,5,3′,5′-**tetraiodothyronine** (**thyroxine**, often abbreviated as T4) and 3,5,3′-**triiodothyronine** (also known as T3). Thyroid hormones regulate the rate of cellular oxidative processes that affect the consumption of oxygen in the liver, kidney and heart tissue, breakdown of lipids (lipolysis) and hydrolysis of glycogen to glucose (glycogenolysis), enhance resorption of glucose and galactose and affect thermoregulation. Activity of the thyroid gland is controlled by both the autonomic nervous system and the action of thyrotropin-releasing hormone (also known as thyroliberin or TRH). Thyroliberin is a tripeptide composed of 5-oxopyrrolidin-2-carboxylic acid, histidine and proline amide (362 Da) and produced in the hypothalamus, a small part of the brain. This hormone releases thyrotropin-stimulating hormone (also known as thyrotropin, thyrostimulin or TSH; α- and β-forms have relative molecular weight of 10.8 and 13 kDa, respectively) from the anterior pituitary gland, which in the thyroid gland influences the formation of thyroglobulin (Tg), a dimeric glycoprotein (660 kDa), which contains bound iodine.

6.3.16.1.3 Metabolism

In the form of iodide anions (I^-), which are the main form of iodine contained in foods, iodine is easily and completely absorbed in the gastrointestinal tract of humans. Other forms of iodine (salts of iodic acid iodates, IO_3^-) are first reduced to iodide ions. Iodine is rapidly transported by the blood to the thyroid gland, which captures about 60 μg of iodine in the form of iodide a day. During lactation, part of the iodine passes nto the milk and the rest is eliminated from the body in urine.

Synthesis of thyroid hormones has several stages. In the thyroid gland, iodine ions are oxidised to the active form (cation I^+) by the action of a specific thyroid peroxidase (thyroperoxidase), which reacts with tyrosyl residues of thyroglobulin to form 3-iodotyrosine. Subsequent iodisation of 3-iodotyrosine yields 3,5-diiodotyrosine. The condensation reaction of 3,5-diiodotyrosine with 3-iodotyrosine in the colloid of the thyroid follicle yields 3,5,3′-triiodothyronine. Two molecules of 3,5-diiodotyrosine combine to form thyroxine. These hormones, bound to thyroglobulin, are then released into the blood as a result of thyroglobulin proteolysis regulated by thyrotropin. In the blood, normal concentrations of 3,5,3′-triiodothyronine can vary by as much as 1–1.5 μg/l, and thyroxine concentrations range from 60 to 120 μg/l.

6.3.16.2 Occurrence in foods

The iodine content of most foods is in the tenths and hundredths of mg/kg. An overview of the iodine content in some common foods is given in Table 6.12. The content in foods of plant origin depends on the concentration of iodine in the soil. The highest concentrations of iodine were found in seafood and seaweed. The average concentration of iodine in seawater is about 60 μg/l and in sea salt 82 mg/kg. The level of iodine in animal products depends on the level of this element in feed, feed iodine supplements and the use of veterinary drugs containing iodine. The natural iodine content in milk and dairy products can also be increased through contamination from disinfection preparations containing iodine compounds. These products are used, for example, to disinfect the udders of cows and production equipment in dairies.

Certain food additives contain iodine. For example, potassium iodate and calcium iodate are components of preparations for stabilising dough. The synthetic red food colouring erythrosine contains 58% iodine (four iodine atoms in the molecule). Therefore, foods coloured using this pigment have a higher iodine content, but the bioavailability of erythrosine iodine is low (2–5%). The content of iodine in foods and meals may also increase with the use of table salt fortified with iodine (as sodium iodide or sodium iodate). The iodine concentration in table salt is 20–50 mg/kg.

6.3.16.3 Nutrition

The required daily dose of iodine, needed to prevent deficiency symptoms in adults, is estimated at 50–75 μg. To ensure some reserves, however, higher doses are recommended. The official recommended daily intake of iodine is 40–50 μg for children under 1 year, 70 μg for children 1 to 3 years old, 90–120 μg for children 4 to 10 years old and 150 μg for older children, adolescents and adults. During pregnancy, the recommended daily dose is 175 μg, and during lactation 200 μg. In several European and some other

[a]Unless otherwise specified, data on the iodine content come from the United States.

[b]Data from the Czech Republic.

[c]The breast milk concentration of iodine is 0.06–0.18, of fluorine 0.016–0.04, of boron 0.06–0.08 and of silicon 0.7 mg/kg.

[d]In the United States, typical iodine concentrations in milk are 0.12–0.29 mg/kg, but some extreme values were also found (0.08 and 1.9 mg/kg).

countries, iodine deficiency is a significant public health problem. For example, in the Czech Republic, the average daily intake of iodine is about 100 µg. In a study in the United Kingdom published in 2011, almost 70% of test subjects were found to be iodine deficient.

Decreased thyroid gland function, called **hypothyroidism**, may be due to insufficient iodine intake or insufficient biosynthesis of hormones influenced by antithyroid agents also known as **goitrogens**. Iodine is necessary especially in the first 3 months of pregnancy, so that the nervous system of the baby can develop. Congenital hypothyroidism then manifests by cretinism. Hypothyroidism in young organisms leads to failure of growth, known as nanism or dwarfism (dwarf growth in which intelligence is not violated), and later to excessive enlargement of the thyroid gland. In the past, the thyroid gland enlargement occurred in inhabitants of the inland mountains, where the iodine content in food is low (e.g. in Switzerland). If the occurrence of such a disease is characteristic for certain areas, then we talk about endemic goitre.

Perchlorates (see Section 6.3.2.2) and some degradation products of glucosinolates, such as goitrin, isothiocyanates, nitriles and thiocyanate (rhodanide) ions (SCN^-), have goitrogenic (antithyroid) activities. Thiocyanate ions also arise in the body as detoxification products of cyanides. The other compounds that show antithyroid activity are some congeners of polychlorinated biphenyls (PCBs), some pesticides and a number of veterinary drugs containing thiourea residues (such as thiouracils, aminothiazoles and mercaptoimidazoles) that inhibit the enzyme thyroid peroxidase. These substances may be present in foods as contaminants (see Section 12.8.3.1).

Hyperfunction of the thyroid gland, called **hyperthyroidism**, manifests itself by production of an excessive amount of thyroid hormones. A disease where the thyroid gland is overactive is known as Graves' disease, whose symptoms are increased metabolism, body temperature and weight loss. Over-production of the hormone in childhood leads to giant growth (gigantism), while over-production in the later stages of growth leads to the growth of only the distal parts of the body (acromegaly).

6.3.17 Fluorine

6.3.17.1 Biochemistry and physiology

The human body contains about 0.8 to 2.5 g of fluorine. Fluorides are structural components of bones and teeth, and fluorine has a protective effect against dental caries. For healthy teeth development, adequate doses of fluorine are important, especially in childhood. In some countries, a sufficient amount of fluoride is supplied in drinking water. The optimal concentration of fluoride in water is about 1 mg/l. During teeth development, concentrations of fluorine in water higher than 10 mg/l lead to dental fluorosis in children. Teeth impacted by fluorosis have visible discoloration, ranging from white spots to brown and black stains. Fluorides present in food and drinking water are rapidly and efficiently absorbed in the gastrointestinal tract. Resorption efficiency is 85–98%. Resorption of fluorides, however, is significantly reduced in patients taking antacids (substances neutralising stomach acidity) based on aluminium oxide or aluminium hydroxide. In the body, fluorine is incorporated into hydroxyapatite, an inorganic calcium-containing constituent of the bone matrix and teeth. Under adequate dietary doses of fluorine, 50–70% of the ingested amount is excreted from the body in the urine.

6.3.17.2 Occurrence in foods

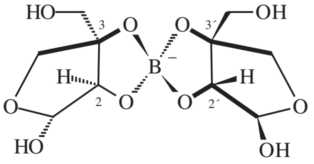
The fluorine content of most foods is in the tenths and hundredths of mg/kg (Table 6.12). Tealeaves have an extremely high fluorine content, so tea is the main source of fluorine in the diet.

6.3.17.3 Nutrition

The recommended daily dose of fluorine for children under 6 months ranges from 0.1 to 0.5 mg, for children from 6 months to 1 year this dose is 0.2–1.0 mg, for children from 1 to 3 years 0.5–1.5 mg, for children 4–10 years old 1.0–2.5 mg and 1.5 to 4.0 mg for adults. Insufficient intake of fluorine in the diet and drinking water increases tooth decay and can lead to osteoporosis. When long-term elevated fluoride doses (20–80 mg per day) are taken, symptoms of poisoning (fluorosis) appear, which leads to damage of the teeth, bones, kidney and nervous system as fluoride ions act as inhibitors of some enzymes.

6.3.18 Boron

Boron is a metalloid that occurs in nature mainly as borate minerals, such as borax, $Na_2B_4O_5(OH)_4{\cdot}8\ H_2O$, and borosilicates. In biological material, compounds of boron (boric acid and borates) form stable complexes with polyhydroxy compounds, such as sugar alcohols, sugars and substances derived from them (nucleotides, riboflavin and ascorbic acid). An example is the binding of boric acid, $B(OH)_3$ or more accurately of borate ions, to the *cis*-hydroxyls (at positions C-2 and C-3) of two β-D-apiose residues (**6-39**) located in different chains of a structural type of pectin called rhamnogalacturonan II, which are cross-linked in this way (see Section 4.5.6.6.1).



6-39, boric acid complex with β-D-apiofuranose in pectin

Boron is an essential element for plants. Whether it is essential for animals has not yet been unequivocally confirmed. Nevertheless, the biological effects of some compounds of boron are known. Boron has an impact on the effect of parathormone (also known as PTH or parathyrin), a hormone secreted by parathyroid glands, which increases blood levels of calcium by its mobilisation from bones (the antagonist of parathormone is calcitonin) and

affects the metabolism of magnesium, calcium, phosphorus and cholecalciferol. Boric acid also affects the activity of many enzymes, such as chymotrypsin, pyridine nucleotide-disulfide oxidoreductase and flavin oxidoreductase.

The recommended daily intake of boron is <20 mg. Actual amounts are dependent on food composition and local conditions. It is estimated that people ingest about 2–10 mg of boron a day, but boron deficiency in humans has not yet been recorded. Boron contained in foods is easily absorbed in the gastrointestinal tract, but 30–92% of boron ingested is excreted in the urine. At higher doses of boric acid, boron accumulates in the nervous system.

An overview of the boron content in some foods is given in Table 6.12. Foods of animal origin are very poor sources of boron. The boron content of meat, fish, eggs and dairy products does not usually exceed 0.3 mg/kg. The highest amounts of boron contain plant products such as legumes, nuts (tens of mg/kg) and fruits (units of mg/kg). The content of boron in vegetables and cereals is usually <2 mg/kg. Wines have a relatively high content of boron (2–11 mg/l). The plant content of boron is dependent on its level in the soil. In addition to the data listed in Table 6.12, significantly higher concentrations of boron in fruits and vegetables have also been found (apples 468, tomatoes 1258 mg/kg dry matter). Boric acid and disodium tetraborate are allowed to be used for the preservation of certain foods (such as caviar) in some countries.

6.3.19 Silicon

Silicon is a metalloid used as a structural material referrd to as biogenic silica (polymerised silica acid) by the major group of algae known as diatoms, by amoeboid protozoa (radiolarian) and also by siliceous sponges. Some plants can deposit silicon within different intracellular and extracellular structures, and silica from decayed plants is re-deposited in the soil in the form of microscopic structures known as phytoliths. Some grasses and horsetails (plants of the genus *Equisetum*, Equisetaceae) contain up to 20% of silicon dioxide (SiO_2). Although silicon was assumed to be an ultra trace element, its exact function in animals is still under discussion. It is assumed that silicon is essential for the synthesis of collagen and connective tissue integrity. The silicon is probably in the form of *ortho*-silicic acid (H_4SiO_4) and disilicic acid ($H_2Si_2O_5$), bound by ester bonds in some mucopolysaccharides. The total silicon content of the human body is about 1.4 g.

The mechanism of silicon resorption in the digestive tract is not known. It is assumed that the available forms of silicon (contained in the diet) are *ortho*-silicic acid and soluble silicates. When given in the form of silicon aluminosilicates, only about 1% of silicon is resorbed. In contrast, some organosilicon compounds used in medicine (such as methylsilantriol salicylate) are resorbed of up to 70%. Resorption efficiency of silicon contained in the diet varies over a wide interval of 5–100%. Beer has a high bioavailability (about 50%) of silicon. The efficiencies of silicon resorption from meat, dairy and soy products usually exceed 50%. From cereals and other foods containing high amounts of silicon, this element is resorbed poorly. Silicon is excreted mainly in the urine.

The silicon content in certain foods is given in Table 6.12. Most foods of animal origin (milk, the meat of mammals and birds) contain only traces of silicon, but higher silicon content has been detected in marine molluscs. In contrast, cereals, mainly barley and oats, have high silicon contents. Wheat contains less silicon than barley. During brewing, most of the grain silicon remains in the husk, but significant quantities of silicon (bioavailable *ortho*-silicic acid) are extracted into the wort and much of this gets into the beer, which is relatively rich in silica (10–30 mg/l). A large share of the silicon is also contained in the surface layers of rice. Brown rice contains 110–570 mg/kg, while in peeled (polished) rice the silicon content is 30–90 mg/kg. Examples of fruits and vegetables with higher silicon contents are bananas and spinach.

The recommended daily dose of silicon has not yet been established. The total daily intake of silicon in the diet is estimated to be 20–50 mg. Silicon intake (e.g. in beer) can reportedly reduce the bioavailability of aluminium, which has been implicated as one of the possible causal factors contributing to Alzheimer's disease. Silicone intake might also help to prevent bone thinning and osteoporosis. High doses of silicon may contribute to the formation of kidney and urinary stones.

6.4 Non-essential elements

6.4.1 Aluminium

Aluminium has long been considered a non-toxic and non-essential element. Today, however, some of its adverse health effects are known. The content of aluminium in the Earth's crust is 8% and aluminium is the third most abundant element (after oxygen and silicon). The content of aluminium in biological materials is low to trace (e.g. 10–50 mg/kg dry matter in grass, 100–300 mg/kg dry matter in leaves of trees and 0.2–0.6 mg/kg in animal tissues), except the lungs that contain aluminium at a level of 20–60 mg/kg.

Aluminium compounds contained in rocks, soil and sediments are very slightly soluble, and in natural waters very low concentrations of aluminium occur (mostly <20 μg/l). Aluminium ions are easily hydrolysed even in neutral media and form insoluble multinuclear complexes of either aluminium ions or aluminium hydroxide $Al(OH)_3$. In addition, in a soil solution at neutral pH, the aluminium concentration is low and its intake by plants is very limited. For example, soil acidification by acid rain increases the solubility of aluminium compounds and aluminium can thus enter the hydrosphere and biosphere in higher amounts. In slightly acidic solutions (pH 5), the predominant cations are $[Al(OH)_2]^+ > [Al(H_2O)_6]^{3+} > [Al(OH)]^{2+}$. Under these conditions, aluminium is actually toxic to certain organisms. A higher intake of aluminium by birds leads to abnormalities of their eggs. Soluble compounds of aluminium in plants cause slower growth, because aluminium is a phytotoxic substance.

6.4.1.1 Occurrence in foods and dietary intake

Older data on the content of aluminium in foods are often overestimated, since the determination of trace amounts of aluminium

(<0.1 mg/kg) in biological materials is very difficult and the published data should be assessed critically.

Aluminium is found in larger amounts in foods of plant origin than in foods of animal origin. Tealeaves have very high concentrations of aluminium (850–1350 mg/kg, and older leaves can even have up to 5000 mg/kg dry matter), because the tea plants (*Camellia sinensis*, Theaceae) accumulate aluminium from the soil. Aluminium present in tea leaves is soluble in hot water (about one-third), so that the brine prepared from 1 g of tea and 100 ml of water has an aluminium concentration 2.7–4.9 mg/l. Aluminium in tea is mainly bound in the form of complexes with catechins, less often with organic acids (such as chlorogenic, gallic, citric, malic and oxalic acids) and fluorine. Complexes with fluorine have the general composition $AlF_n^{(3-n)+}$. The plant obtains them from the soil mainly as AlF^{2+} and AlF_2^{+} cations. Higher aluminium contents are also found in particular spices, such as basil (310 mg/kg), bay leaf (440 mg/kg), oregano (600 mg/kg), pepper (140 mg/kg), cinnamon (80 mg/kg) and thyme (750 mg/kg).

Cereals have moderate amounts of aluminium (e.g. the aluminium content is 4–14 mg/kg in wheat flour, 3–6 mg/kg in wheat bread, 5–6 mg/kg in peeled rice, 5–64 mg/kg in unpeeled rice and 2 mg/kg in maize) and legumes (lentils 15–22 mg/kg, peas 14–27 mg/kg), a lower aluminium content is found in some root crops, vegetables (potatoes 1–6 mg/kg, carrots 1–6 mg/kg, spinach 5–25 mg/kg, cauliflower 0.2–12 mg/kg), meat (pork 2–5 mg/kg, beef 0.2–5 mg/kg) and fish (0.4–9 mg/kg). As already mentioned, recent results have quoted lower concentrations of aluminium in vegetables (0.1 mg/kg in cabbage, 0.05 mg/kg in carrots and 0.2 mg/kg in potatoes). Offal sometimes contains medium to high amounts of aluminium (e.g. beef liver 4–46 mg/kg, pork kidney 2–18 mg/kg and pork brains 7–130 mg/kg). The concentrations of aluminium in milk, dairy products and eggs are very low (0.011–0.035 mg/kg in milk, 0.15–0.34 mg/kg in Edam cheese, <0.2 mg/kg in eggs). The aluminium concentration in breast milk generally ranges from 0.004 to 0.03 mg/kg, but can also reach values of from 0.2 to 2.4 mg/kg.

Some aluminium compounds, such as sodium aluminium phosphate, $Na_8Al_2(OH)_2(PO_4)_4$, are used in the United States and other countries as additives (e.g. as a baking powder components). The aluminium content in foods can also be increased during their contact with metal aluminium. Some foods and beverages are commonly packed in aluminium foils, tubes or cans. Until recently, aluminium barrels were used for beer and soft drinks. Also, during the cooking of foods in aluminium cookware, the aluminium can be partially dissolved. This applies especially to acidic foods and drinks, such as fruits, fruit puree and juices, and vegetables in vinegar brine.

The average daily dietary dose of aluminium for adults, found in Western countries, ranges from 4 mg (Switzerland 1985) to 27 mg (United States 1985). Sources other than foods, such as some medicinal drugs, may sometimes be more important. For example, oral antacids neutralising gastric juices contain aluminium oxide or aluminium hydroxide. Daily dietary doses of aluminium compounds can then reach 2 g. Aluminium is also contained in various toothpastes and cosmetic preparations.

6.4.1.2 Metabolism and toxic effects

The effectiveness of aluminium resorption in the gastrointestinal tract of humans under normal conditions is about 0.1–0.3%. Lactic, citric and ascorbic acids facilitate gastrointestinal resorption. Approximately 95% of orally administrated aluminium binds to transferrin and albumin and then is excreted in the urine. The normal concentration of aluminium in blood serum is 2–40 μg/l, and the concentration of aluminium in various organs, except the lungs, is very low and does not increase with age. The total aluminium content in the human body is about 35 mg.

Aluminium has the potential to accumulate, especially when the gastrointestinal barrier is bypassed. If a significant load exceeds the excretory capacity of the body, the excess is deposited in various tissues, including bones, brain, liver, heart, spleen and muscles. It is now commonly acknowledged that aluminium toxicity can be induced by oral exposure (as a result of aluminium-containing pharmaceutical products such as aluminium-based phosphate binders or antacid intake) and by infusion of aluminium-contaminated dialysis fluids. In the early 1970s, aluminium toxicity was first implicated in patients with chronic renal failure involving bone (renal osteomalacia) or brain tissue (dialysis encephalopathy) who were undergoing dialysis. For example, with intravenously infused aluminium, 40% is retained in adults and up to 75% is retained in neonates. The exact mechanism of aluminium toxicity is not completely understood. It is known that aluminium combines with many proteins and cofactors that are required in intermediary steps of metabolism. There is probably a link between aluminium intake and increased incidence of Alzheimer's disease.

6.4.2 Tin

The average tin content of the Earth's crust is 3 mg/kg. In nature, tin occurs mainly as the mineral cassiterite (stannic oxide, SnO_2) and as an accompanying metal in some sulfides. Metallic tin is an important component of conventional alloys (bronze) and of cans made of tinplate (tin-coated steel) and is used in the food industry. A large amount of tin is used for the production of organometallic compounds (annual production of about 30 000 tons). Dibutyltin dilaurate and analogous octyltin compounds are used as stabilisers of plastics, i.e. poly(vinylchloride), PVC. Tributyltin compounds are used for wood preservation and as ingredients in special paints for ships and other bodies exposed to the long-term effects of seawater. Triphenyltin acetate and triphenyltin hydroxide are used in agriculture as fungicides.

Natural fresh waters contain only trace amounts of tin (0.01–1 μg/l), with concentrations of about 3 μg/l in sea water. Aquatic organisms can accumulate tin (bioconcentration factor is 10^2–10^3). Some microorganisms may methylate inorganic compounds and dealkylate synthetic organometallic compounds. Tin concentrations in soils are in the range of 2–200 mg/kg dry matter.

The natural content of tin in foods is very low and mean concentrations are <1 mg/kg in most foods (meat 0.007, meat products 0.18, offal 0.014, poultry 0.006, fish 0.032, milk 0.003, dairy products 0.297, eggs 0.003, fresh fruit 0.019, green vegetables 0.003,

other vegetables 0.05, potatoes 0.004 and nuts 0.029 mg/kg fresh weight). High levels of tin are often a result of migration from cans. Although tin is corrosion-resistant, acidic foods such as fruits and vegetables can still cause corrosion of the tin layer. Hence, fruit juices and canned vegetables can contain a significantly higher level of tin (e.g. 30–260 and 41 mg/kg, respectively). A 2002 study showed that 99.5% of 1200 tested cans contained less than the UK regulatory limit of 200 mg/kg of tin. In recent years, the use of tinplated cans for fruit juices, canned fruit and other acidic foods has been restricted. In some foods, traces of tin organometallic compounds may be found, for example wines transported in PVC containers contain dibutyl tin at concentrations of up to 160 μg/l.

The daily dietary intake of tin is estimated at 3 mg. The tolerable daily intake for an adult man (weighing 70 kg) is 140 mg. The effectiveness of resorption of tin in the gastrointestinal tract depends on the metal valence (stannous compounds 3–8%, stannic compounds about 1%). The normal concentration of tin in blood plasma is 30–40 μg/l. The tin that is absorbed is excreted in the urine and partly in the bile. Nausea, vomiting and diarrhoea have been reported after ingesting canned food containing 200 mg/kg of tin. Toxic effects of tin appear in cases of long-term consumption of foods with a high content of tin (1400 mg/kg). Organometallic compounds of tin are highly toxic.

6.5 Toxic elements

The most important toxic elements include lead (Pb), cadmium (Cd), mercury (Hg) and arsenic (As). We may also include many trace elements (and the radioactive metals) when considering high toxic doses. Examples of such metals are iron, zinc, copper, manganese, molybdenum, cobalt and chromium, which are required by living organisms. The term **heavy metals** is often incorrectly used as a synonym of toxic elements to describe the group of toxic metals, but lighter metals such as beryllium (Be) also show toxicity, arsenic is a metalloid, and not all heavy metals are particularly toxic. Strictly speaking, the term heavy metals should only be used for those elements with an atomic weight of 200 and above, such as mercury (200), thallium (204) and bismuth (209).

Excessive levels of toxic elements can be damaging to the organism as they tend to bioaccumulate. Bioaccumulation means an increase in the concentration of a chemical in an organism over time, compared with its concentration in the environment. The presence of toxic chemical elements in foods is mainly connected with environmental pollution. A number of anthropogenic and natural sources contribute to the toxic elements entering into the food chain. The main anthropogenic causes of contamination by toxic elements are burning fossil fuels, transport, industrial production of metals, use of various elements in industry and technology and their related waste, excessive use of mineral fertilisers and other agrochemicals (such as pesticides) or the application of sewage sludge on to the soil. Natural sources of toxic elements in the environment include the weathering of rocks, forest fires and volcanic activity.

There are some sources that contribute substantially to the contamination of one particular element (e.g. lead contamination of the atmosphere from the exhaust of motor vehicles that use leaded gasoline), but most causes cannot be characterised in this way. For example, the environmental contamination in the vicinity of metallurgical plants is manifested by significantly elevated levels of many elements (Cd, Pb, Tl, In, As, Ga, Hg, Ni, Cr, Cu, Zn and Ge), simultaneously in different sections of the environment. This is due to the polymetallic character of the processed ore, generated intermediate products and waste. Emissions from thermal power plants and other energy sources, including incinerators, contain many metals simultaneously. It is therefore quite difficult to identify specific sources of contamination of individual elements. In addition, air and water flows act as transmission media of toxic elements in the environment. In particular, there can be metals that occur in solid particles and aerosols or in the gas phase (mercury and organometallic compounds; arsine, H_3As; various methylarsins) transmitted in the atmosphere over large distances. The fallout of solid particles and wet deposition are the main routes of surface contamination of soil and plants. Wet deposition occurs when rain or snow removes metals from the atmosphere and delivers them to the ground, plants or other surfaces.

The level of toxic elements in foods is among the main indicators of pollution, ecological risk and food safety assessment. For lead, cadmium, mercury and arsenic (as well as for tin, aluminium, chromium, copper, nickel, zinc and iron), the tolerable daily intake levels of individual minerals that are unlikely to pose a risk of adverse health effects have been established for raw and finished food products, and specifically for individual groups of foods in many countries. The levels of aluminium and iron are limited only for selected commodities. Examples of maximum levels for mineral elements in foods are summarised in Table 6.13. At the European level, the maximum levels are given only for lead, cadmium, mercury and tin. The maximum levels for lead and cadmium are given for various types of food of plant and animal origin. Mercury is limited only in the flesh of fish, such as tuna, shark and other seafood. Generally, this limit is set at 0.5 mg/kg (wet weight) and for listed species at a level of 1.0 mg/kg. Recently, it was shown that food supplements (especially if they contain seaweed, which naturally accumulates cadmium) can contribute significantly to human exposure to lead, cadmium and mercury. Therefore, limits for these products have been included. Tin is limited in all canned foods other than beverages (200 mg/kg) and canned beverages, including fruit juices and vegetable juices (100 mg/kg). The maximum levels for canned infant formulae, baby foods and foods for young children are only 50 mg/kg. For some foods, which are not subject to limits for lead, cadmium, mercury and tin in European legislation (Table 6.13), there are national limits for these and some other elements (such as As, Cu, Fe and Zn) that are still valid.

Heavy metal poisoning is treated by substances with a complexing effect, which immobilise the metal ions prior to excretion. Examples of these chelating agents are 2,3-dimercaptopropan-1-ol (known as Dimercaprol or British Anti-Lewisite, abbreviated BAL), 2,3-dimercaptosuccinic acid, 2,3-dimercaptopropane-1-sulfonic acid

Table 6.13 Examples of maximum levels for mineral elements in foods.[a]

Food	Maximum levels (mg/kg fresh weight)

[a]Official Journal of the European Union, 20.12.2006, L 364/5: Commission Regulation (EC) No. 1881/2006 of 19 December 2006 setting maximum levels for certain contaminants in foodstuffs. Official Journal of the European Union, 3.7.2008, L 173/6: Commission Regulation (EC) No. 629/2008 of 2 July 2008 amending Regulation (EC) No. 1881/2006 setting maximum levels for certain contaminants in foodstuffs.

(abbreviated DMSA; the meso isomer and its sodium salt, known as Unithiol), glutathione, ethylenediaminetetraacetic acid (abbreviated as EDTA) and its salts. Dimercaprol is used in the treatment of arsenic, lead, mercury and other toxic metal poisoning, DMSA for treating lead and mercury poisoning, EDTA for treating lead and mercury poisoning and to remove excess iron from the body. For treatment of arsenic poisoning, similar or identical substances, such as those for mercury poisoning (2,3-dimercaptopropan-1-ol, 2,3-dimercaptosuccinic acid, glutathione, selenium preparations) are used.

6.5.1 Lead and cadmium

The average lead content in the Earth's crust is 13 mg/kg and cadmium content is 0.1 mg/kg. In nature, these metals are found mainly in sulfide and carbonate ores. Lead sulfide is known as galena (PbS), cadmium sulfide occurs in the rare ore greenockit (CdS), and both metals are present as admixtures in sphalerite (ZnS) and smithonite ($ZnCO_3$).

Metallic lead is used to make batteries, sheets and pipes (including water pipes). Inorganic lead compounds are found in various pigments (such as orange lead tetroxide, also called minium, Pb_3O_4, and yellow lead chromate, $PbCrO_4$, or are used in the production of lead glass (lead oxide, PbO). Organometallic compounds of lead, tetraethyl and tetramethyl lead, were used in gasoline as antiknock additives. Every year, the world production of lead amounts to about 5 million tons.

Cadmium is used in anticorrosive metal protection coatings and in battery production. Cadmium sulfide is used as a yellow pigment, and cadmium salts of fatty acids as stabilisers in PVC production. The annual world production of cadmium is about 20 000 tons.

6.5.1.1 Occurrence in environment, transport and distribution

The levels of lead and cadmium in the air vary locally. In a few areas, polluted air contains 0.005–0.3 μg/m^3 of lead and 0.0001–0.002 μg/m^3 of cadmium. In contrast, the air in large cities has been found to contain 0.2–5 μg/m^3 of lead and 0.007–0.05 μg/m^3 of cadmium. Natural waters contain only traces of lead and cadmium. Lead concentrations in uncontaminated river and lake waters range from 0.1 to 5 μg/l and the cadmium content is even lower (0.07 to 0.8 μg/l). Significantly higher concentrations of these metals are found in sediments of uncontaminated rivers and reservoirs (10–30 mg/kg of lead, 0.04–0.8 mg/kg of cadmium). The contents in sediments from contaminated localities can be up to several orders of magnitude higher. Numerous aquatic organisms (algae and other aquatic plants, zooplankton, crustaceans and molluscs) accumulate cadmium and other elements (mercury, arsenic and selenium) in their bodies to a significant exent. Even if they live, such as oysters, mussels or shrimp, in only slightly contaminated water (concentration of cadmium in water is in units of μg/l), the level of cadmium in their bodies can reach up to 100 mg/kg. The content of lead in uncontaminated soil can range from 5 to 40 mg/kg dry matter, and cadmium in the range of 0.2–1 mg/kg dry matter (the concentrations in polluted localities may be much higher).

In addition to the level of toxic elements in the soil, their availability to plants is another important factor. Plants take toxic elements either from the soil through their root system or from the atmosphere through deposits mainly on the surface of their leaves (foliar deposits). The intake of toxic elements through the root system depends not only on the type of plant and the content of relevant elements in the soil, but also on the distribution

of metals in the soil horizon depths, the metal mobility in the soil, organic matter content and other factors. The bioavailability of heavy metals for the plant strongly depends on the pH and redox potential of the soil solution. The relative mobility of lead and cadmium (and mercury) increases in acidic and oxidising environments. Transition coefficients of elements for soil–plant transfer reach values ranging from 0.01 to 0.1 for lead, and from 0.1 to 10 for cadmium. Intake of individual elements by plants is quite different between plant species and even between different cultivars. Some plants accumulate only certain elements. In these cases, the element does not possess strong phytotoxic effects. Plants that accumulate cadmium and lead from the soil include spinach, lettuce and some oilseeds. Cereals accumulate only small amounts of these elements.

Distribution of metals in different parts of the plants is not uniform. If foliar versus root intake is negligible (less polluted localities), the concentrations of these elements generally decrease in the order: roots > leaves > stems > fruits > seeds. These factors should be taken into account when assessing the levels of toxic elements in plants, because only certain parts of the same plant are consumed by herbivores, and only certain parts of cultivated plants are processed for food or feed use. It is in this way that the toxic elements present in the plants enter the food chain.

Contamination of the environment by the toxic elements increases their content in the organs and tissues of animals. Toxic elements enter the bodies of animals in particular by the oral route via consumed food. In human nutrition, the concentration of these elements in muscle and viscera of animals (farm as well as wild animals) is the most important factor. The content of lead and cadmium in the liver and kidneys of wild animals indicates the load of the contaminated animal food and habitat pollution level in which an animal lives. Under normal conditions, the content of lead and cadmium in meat is very low (thousandths of mg/kg), in contrast to the concentration in the kidney and liver, which are sometimes up to 2–3 orders of magnitude higher. In these organs, lead and cadmium accumulate significantly.

6.5.1.2 Occurrence in foods and dietary intake

The content of lead and cadmium in foods is low and very variable. A survey of toxic element levels in major foods and food raw materials is given in Table 6.14. For plant foods, the concentrations of lead and cadmium depend mainly on the content of these elements in the soil. Relatively high concentrations (in hundredths to tenths of mg/kg) are characteristic of some vegetables (spinach, lettuce and carrots), edible mushrooms and oil seeds (e.g. poppy seeds contain 0.04–1.96 mg/kg of cadmium). Although grains have fairly high maximum values, in most cases cadmium concentrations do not exceed 0.1 mg/kg and lead concentrations 0.3 mg/kg. Relatively high concentrations of lead were found in wines (0.016–0.17 mg/l). The highest content of lead and cadmium from foods of animal origin is in offal, the internal organs and entrails of butchered animals. The level of cadmium in the kidney is especially high, and can reach up to units of mg/kg. The toxic metal content in the liver and kidneys of animals is related to diet and age of the animals. In older animals, concentrations are higher. Meat, eggs, milk and dairy products contain only traces of lead and cadmium. Higher levels of lead are often found in foods packed in cans. This is due to contamination with lead contained in the alloy of tin, which is found in the seam of sealed cans. Packing of foods in glass rather than cans is recommended for foods that require more stringent standards (such as baby food).

The tolerable daily intake of lead is 250 μg and of cadmium 70 μg (at 70 kg body weight). The actual daily dietary dose of lead found in several studies in European countries formerly ranged from 27 (Sweden 1983) to 180 μg (Belgium 1983). Increased doses of lead and consequently higher levels of lead in blood were observed in wine drinkers. The long-term monitoring of the actual average daily dietary doses from the 1970s to late 1990s recorded a significant drop in the lead intake (e.g. in Great Britain the values dropped from about 110 to about 25 μg). Actual daily dietary intake of cadmium in the 1980s ranged from 10 (Sweden 1983) to 33 μg (United States 1985). Long-term studies also found some decrease in daily dietary intake, but this was less pronounced in comparison with lead.

6.5.1.3 Metabolism and toxic effects

Lead and cadmium enter the body not only in food through the digestive tract, but also through the lungs. For smokers, the proportion of inhalation exposure to cadmium intake is comparable to the intake of this element from food. The level of cadmium in tobacco is about 1–2 mg/kg. Resorption of lead depends on age, composition of the diet and health. The effectiveness of resorption in adults is estimated at 10%. A child's body resorbs around 40–50% of lead from food. Lead resorption is higher in foods containing higher amounts of protein, and lower in the presence of large amounts of fibre, phytic acid, iron and calcium. The normal levels of lead in blood are in the range of 50–120 μg/l. The proportion of resorbed cadmium amounts to an average of 6% or more (e.g. the amount from oatmeal is 4–37%). Blood levels of cadmium in non-smokers are 0.2–3 μg/l, and in smokers 0.2–5 μg/l.

Resorbed lead and cadmium are transported by blood to the liver and kidneys, where these elements accumulate. Part of the lead in the liver is excreted via the bile into the intestine. A small percentage of lead is excreted in the urine. Long-term exposure leads to lead accumulation in bones. During intoxication, lead or cadmium can damage the kidneys and liver. Lead also damages the blood, as well as the nervous and cardiovascular systems. Cadmium has teratogenic and carcinogenic effects, damages reproductive organs and affects blood pressure. Children are particularly susceptible to lead poisoning (due to the possibility of ingestion of soil or dust, higher resorbed amounts and higher sensitivity of the organism). Even at a level of 150 μg/l in blood, a number of adverse effects may appear (such as slower mental and physical development, lower learning ability, lower intelligence and decreased immunity).

Lead inhibits the synthesis of porphyrins, so that in chronic poisoning the amount of haemoglobin in erythrocytes decreases and anaemia develops. Lead is an inhibitor of two enzymes essential for the synthesis of haem, δ-aminolevulinic acid dehydratase and ferrochelatase. Aminolevulinic acid dehydratase catalyses condensation of two molecules of δ-aminolevulinic acid to form

[a] Table summarises the data from Sweden, Finland, Holland, Germany, Canada and the United States.

[b] The breast milk concentrations are: Pb 0.0004–0.002, Cd 0.0001–0.0006, Hg 0.0003–0.001 and As <0.001 mg/kg.

porphobilinogen. Ferrochelatase catalyses the incorporation of iron into protoporphyrin IX to form haem. Bodily exposure to lead can also damage the central and peripheral nervous system. In some cases, lead poisoning leads to motor skills disorders and slowing of movement reactions, and to similar symptoms. Neurotoxic effects of lead are particularly dangerous for children. Brain damage (encephalopathy) occurs during heavy exposure to lead (blood levels of 800–1000 μg/l).

Cadmium poisoning can cause acute kidney failure. The kidneys are the organ that accumulates the most cadmium (in adults the kidney contains 4–10 mg of Cd). The normal concentration in the renal cortex of humans is 10–30 mg/kg. Formation of metallothionein prevents acute renal damage, if the concentration of cadmium in the renal cortex does not exceed about 100 mg/kg. Intoxication with cadmium is manifested by the occurrence of proteins and sugars in the urine, but only very small amounts of cadmium are excreted in the urine. Cadmium also accumulates significantly in the liver (normally in the amount of 2–4 mg). At concentrations not exceeding 30 mg/kg of tissue, the binding of cadmium to liver metallothionein prevents liver damage. Cadmium poisoning also results in decalcification and softening of bones. Itai-itai disease was the first well-documented case of mass cadmium poisoning by rice (containing 1–3 mg/kg of cadmium) that was irrigated with contaminated river water in Toyama Prefecture, Japan, officially recognised in 1968.

6.5.2 Mercury

The average mercury content in the Earth's crust is about 0.05 mg/kg. In nature, mercury occurs in deposits mostly as mercuric sulfide, cinnabar (HgS). Roasting of the sulfide ore produces carbon dioxide and elemental mercury vapour, which condenses to give liquid mercury. The annual global production of mercury is about 7000 tons. Owing to its high toxicity, limits on the use of mercury have been introduced. Mercury is used mainly:

- in electrical engineering for the production of batteries, switches, electrodes and measuring instruments;
- for the electrochemical production of chlorine and caustic soda by electrolysis of NaCl solution (mercury is the cathode);
- for the manufacture of paints (a red pigment, vermilion, is mainly obtained by reduction from cinnabar), catalysts and fungicides (phenylmercuric chloride for seed treatment);
- for preparation of dental amalgam used as a filling material in dentistry.

6.5.2.1 Occurrence in environment, transport and distribution

The input of mercury into the environment is mainly caused by volcanic activities, burning coal, using mercury in industry and agriculture and through handling of waste. The total amount of mercury entering the atmosphere is estimated at 150 000 tons per year. About two-thirds of this amount comes from natural resources.

Migration of mercury in the environment depends on some of the important properties of mercury and mercury compounds. Organometallic compounds of mercury and elemental mercury are volatile and fat soluble (solubility of metallic mercury in fat is approximately 5–50 mg/l). At a temperature of 24 °C, an atmosphere saturated with mercury contains 18 mg Hg per m^3. Mercuric salts are mostly water soluble. Mercurous chloride (Hg_2Cl_2) has a very low solubility (2 mg/l), mercuric chloride is more soluble (74 g/l at 20 °C) and mercuric sulfide (HgS) is practically insoluble.

The level of mercury in the air of large cities is in the tens to units of ng/m^3. Natural waters contain only trace amounts of mercury. The concentration of mercury in rivers is in the region of 0.01–0.2 μg/l (while the permissible limit for drinking water

is 1 μg/l). The concentration of mercury in seawater is even lower (0.0004–0.002 μg/l). Despite their very low concentrations, the oceans and seas represent a large reservoir of mercury. For example, the Mediterranean Sea contains about 3700 tons of mercury, and each year through fallout and tributaries some 240 tons enter it, with about 80 tons per year going into the marine sediment and 150 tons of mercury evaporating into the atmosphere.

In the aquatic environment important chemical transformations of mercury species also take place, in particular the methylation reaction of bacteria and microscopic fungi, oxidation–reduction reactions and precipitation reactions. The products of mercury biomethylation are the organometallic compounds methylmercury and dimethylmercury. In anaerobic conditions (as in the depths of the seas), mercuric salts can be reduced to elemental mercury or mercuric ions, and little soluble Hg_2Cl_2 is formed. Mercury compounds are susceptible to disproportionation. In the formation of slightly soluble compounds (mainly HgS), mercury is transferred from water to the sediment. The concentration of mercury in non-polluted sediments of rivers and lakes ranges from the tenths to units of mg/kg dry matter. About 1% of mercury in sediments is present in the form of methylated compounds. Aquatic organisms accumulate mercury from the water. The highest bioconcentration factors (see Section 12.1) were found in invertebrates (1×10^5), with lower factors in freshwater fish (6×10^4) and marine fish (1×10^4). The concentration of mercury in their bodies is several orders of magnitude higher than in the surrounding environment. About 90% of mercury in fish is methylated.

The concentration of mercury in uncontaminated soils ranges from 0.02 to 0.2 mg/kg. The main forms of mercury in neutral and alkaline soils are the slightly soluble oxide (HgO) and carbonate ($HgCO_3$). Sulfur bacteria produce almost insoluble sulfide (HgS). Most of the remaining forms of mercury are adsorbed on organic matter, hydrated iron and manganese oxides and clay minerals. Owing to the low mobility of mercury in the soil, only small amounts of mercury pass from the soil to plants.

The mercury content of plants is in the tenths to tens of μg/kg. Some mushrooms contain higher concentrations of mercury (tenths to units of mg/kg). The level in the bodies of animals is dependent on the composition of their food. High concentrations of mercury were found, for example, in the liver and kidneys of aquatic birds. Environmental pollution with mercury and other metals is often monitored using bioaccumulative indicators (biomonitors) such as the fur of mammals or the feathers of birds.

6.5.2.2 Occurrence in foods and dietary intake

The concentration of mercury in most foods ranges from ten thousandth to hundredths of mg/kg (Table 6.14). High concentrations of mercury (tenths to units of mg/kg) are found in some edible mushrooms, fish, shellfish and crustaceans. For example, mercury concentrations in fish in the Czech Republic were as follows: carp 0.01 mg/kg, roach 0.08–0.23 mg/kg, tench 0.14–0.64 mg/kg, perch 0.14–2.43 mg/kg, pike 0.16–2.87 mg/kg, zander (pike-perch) 0.34–1.90 mg/kg, eel 0.13–2.40 mg/kg.

The tolerable daily intake of total mercury for an adult is 50 μg, and the tolerable daily intake of methylmercury is 16 μg (at 70 kg body weight). The actual daily dietary dose of mercury found in several studies in Western European countries varied (depending on the composition of the diet) over a very wide range, from 0.7 (Holland 1989) to 14 μg (Belgium 1983). The dietary intake of mercury is critically related to the eating of fish. Owing to the presence of methylmercury, the prevailing form in fish and other sea foods, the tolerable daily intake can very often be achieved almost entirely by consuming these products.

6.5.2.3 Metabolism and toxic effects

About 7% of mercury from food is resorbed in the small intestine. The resorbed mercury is taken up by the liver, kidneys and brain. Part of the mercury is eliminated from the liver via the bile into the intestine. Mercury also accumulates in hair and nails. The toxic effects of mercury and its compounds are related to the high affinity of mercury for thiol groups in peptides and proteins. Binding of mercury to these functional groups occurs in enzymes and leads to their inhibition. The toxicity of various forms of mercury decreases as follows: alkylmercury compounds (mainly CH_3Hg^+) > elemental mercury vapours > mercuric salts (Hg^{II}) > arylmercury (diphenylmercury) and alkoxymercury compounds (RHgOR) > mercurous salts (Hg^I). In terms of food toxicology, methylmercury is the most important compound due to its presence in fish. Water in the Minamata Bay in Japan was heavily polluted in the 1950s and 1960s by wastewater containing methylmercury (units of μg/l) from the Chisso Corporation's factory in Minamata. Methylmercury bioaccumulated in fish and shellfish in the bay, which gave rise to the so called Minamata disease when the fish were eaten, with more than 10 000 people affected. In 1970, Cargill Incorporated (a multinational corporation based in Minnesota, USA) sold seed grain treated with methylmercury to Basra, Iraq. Although this seed was not intended for human or animal consumption, but only for use in agriculture, a number of recipients consumed the surplus seed, which led to the deaths of 93 people.

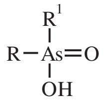
Poisoning by inorganic mercury compounds and by elemental mercury occurs mainly through occupational exposure (workers in chemical plants and laboratories). The main organs that are damaged during intoxication are the kidneys and the brain. Effects of the individual forms of mercury are somewhat different. In methylmercury poisoning, neurotoxic effects prevail, manifesting themselves by disturbances of sensory functions (vision, hearing and balance), speech, swallowing disorders, morphological changes in the brain and mental malfunction. Methylmercury also has teratogenic effects. There is a risk of foetal damage in expectant mothers where the concentration of mercury in the hair reaches about 15–20 mg/kg. The symptoms of poisoning in adults appear when mercury concentrations in hair are above 30 mg/kg. Therefore, it is recommended that pregnant women significantly reduce their consumption of fish.

Poisoning by inorganic mercury compounds can lead to reduced production of urine and even to kidney failure. Poisoning by elemental mercury can occur either by inhalation of mercury vapours or ingestion of mercury. The ingestion of mercury manifests by increased salivation, a metallic taste in the mouth, swollen

gums, loss of appetite, loss of teeth, insomnia, muscle tremors, vomiting, diarrhoea, fatigue, loss of self-control and muscle weakness. The renal function deteriorates and sometimes the thyroid gland is enlarged. Inhalation of mercury vapours leads to some further symptoms (bronchitis, chest pain, coughing and difficult breathing).

6.5.3 Arsenic

The average content of the metalloid arsenic in the Earth's crust is 1.8 mg/kg. In nature, arsenic occurs in the form of sulfide minerals (e.g. arsenopyrite, FeAsS; realgar, As_4S_4; and cobaltite CoAsS) and is included as a minor component in sulfide ores of copper, lead and other metals. The main industrially produced compound of arsenic is arsenic trioxide (As_2O_3). Annual world production of this oxide is about 60 000 tons. Elemental arsenic is used as an ingredient in alloys of lead and other metals. Some inorganic arsenic compounds, such as cupric hydrogen arsenite, $CuHAsO_3$, a green pigment used in the past in some paints (Scheele's Green), copper (II) acetoarsenite, $Cu(CH_3COO)_2{\cdot}3Cu(AsO_2)_2$, known as Paris green, have been used as a rodenticides and insecticides for fruit trees and vines, and also as pigments. Other substances, such as $Pb_3(AsO_4)_2$, $Ca_3(AsO_4)_2$ and Na_3AsO_3, were used for the treatment of tobacco and cotton. Synthetic organic arsenic compounds in the United States and some other countries are used as growth stimulators in pigs and poultry, and as veterinary medicines. These compounds are mainly derivatives of phenylarsonic acid (**6-40**), for example 4-aminophenylarsonic acid (known as arsanilic acid) and 4-hydroxy-3-nitrobenzenearsonic acid (known as roxarsone). Arsanilic acid is used in the prevention and the treatment of swine dysentery in veterinary medicine. Roxarsone was widely used agriculturally as a chicken feed additive to promote growth.



6-40, phenylarsonic acid, R = C_6H_5, R^1 = OH
methylarsonic acid, R = CH_3, R^1 = OH
dimethylarsinic (cacodylic) acid, R = R^1 = CH_3

6.5.3.1 *Occurrence in environment, transport and distribution*

Arsenic enters the environment mainly as a result of smelting activities, the combustion of coal (e.g. fly ashes from thermal power plants in the Czech Republic contain arsenic at levels of 40–110 mg/kg) and from wood preserved by arsenic compounds. In countries where pesticides based on arsenic compounds are permitted, these agrochemicals may be the dominant source. Volcanic activity and weathering of rocks contribute to the entry of arsenic into the environment to a lesser extent. Annual world emissions of arsenic have been estimated at 120 000 tons.

For example, the annual mean concentrations of arsenic in the UK rural environment are typically in the range of 0.001–0.004 $\mu g/m^3$, whilst annual mean urban concentrations are higher, in the range of 0.005–0.007 $\mu g/m^3$. Typically, the highest concentrations are found at sites located in the immediate vicinity of industrial processes such as smelters, incinerators and cement works. The highest reported concentration of arsenic, found in the vicinity of a smelter in Walsall, West Midlands, UK, was 573 $\mu g/m^3$. For the monitoring period covering 1975–1990, the highest annual mean concentration of arsenic reported in Walsall was 0.223 $\mu g/m^3$, whilst for other urban sites, during the same period, annual mean values were found to vary from 0.001 to 0.018 $\mu g/m^3$. The concentrations of arsenic (methylated forms such as methylarsonic and dimethylarsinic acids prevail; **6-40**) in the air are locally variable and are higher in winter (e.g. in Prague, concentrations of 0.56 $\mu g/m^3$ in the winter and only 0.07 $\mu g/m^3$ in summer were found, and the annual average was 0.3 $\mu g/m^3$). In the vicinity of thermal power plants, the concentrations of arsenic are higher (tens of $\mu g/m^3$).

Natural waters, with the exception of some mineral and thermal waters, contain only traces of arsenic. Concentrations in unpolluted river and lake waters are in the range of from 0.15 to 0.45 $\mu g/l$, where the arsenic is found in inorganic compounds. Seawater contains 0.1–2 $\mu g/l$ of arsenic in the form of arsenite (*ortho*-arsenite, AsO_3^{3-}), arsenate (AsO_4^{3-}), methylarsonic and dimethylarsinic acids (**6-40**). Aquatic organisms, particularly marine organisms contain arsenic at concentrations ranging from 1 to 100 mg/kg as a result of bioaccumulation and biotransformation processes. Marine organisms accumulate arsenic compounds from the water and transform them in particular into arsenobetaine (**6-21**), arsenocholine (**6-22**) and other organic compounds. For instance, a marine bivalve mollusc variegated scallop (*Chlamys varia*) with a total arsenic content of 3.36 mg/kg contained 0.10 mg/kg arsenite (As^{III}), 0.11 mg/kg arsenate (As^{V}), 0.35 mg/kg dimethylarsonic acid, 2.73 mg/kg arsenobetaine and 0.14 mg/kg arsenocholine. Atlantic cod (*Gadus morhua*) with a total arsenic content of 34.9 mg/kg contained 0.05 mg/kg arsenite (As^{III}), 0.09 mg/kg arsenate (As^{V}), 0.13 mg/kg dimethylarsonic acid, 33.2 mg/kg arsenobetaine and <0.03 mg/kg arsenocholine.

The level of arsenic in soil is dependent on the geological bedrock and the distance from sources of contamination. The concentration of arsenic in uncontaminated soils ranges from 2–10 mg/kg dry matter. Land used for agricultural purposes should not contain more than 20 mg/kg dry matter of arsenic. Arsenic in soil, unlike lead, cadmium and mercury, is quite mobile under neutral or slightly alkaline and reducing conditions. This relates to better solubility of trivalent arsenic compounds in comparison with pentavalent compounds. The mobility of arsenic in the soil determines its availability to plants. The transition coefficient of arsenic for soil–plant transfer is about 0.02–0.1. In areas with high rates of deposition and in areas where arsenic containing pesticides are applied, the predominant intake of arsenic by plants is foliar intake. Some crops (tobacco, cotton and oats) have a high tolerance to arsenic and concentrate it more than other plants.

6.5.3.2 *Occurrence in foods and dietary intake*

The total content of arsenic in selected foods is shown in Table 6.14. The toxic forms of arsenic include inorganic ions of

As(III) and As(V), methylarsonic and dimethylarsinic acids. High concentrations of arsenic are characteristic of seafood, especially of crustaceans and molluscs (oysters 3.7 mg/kg, squids 7.2 mg/kg, prawns 3.2–26 mg/kg, lobsters 1.5–122 mg/kg). In these foods, however, most of the arsenic occurs in almost non-toxic organic compounds, such as arsenobetaine (**6-21**) and arsenocholine (**6-22**). Higher amount of arsenic in foods of vegetable origin (tenth mg/kg) occur in oats and rice, and some wines can also contain higher amounts of arsenic. The normal levels of arsenic in wines range from 0.002 to 0.1 mg/l.

The tolerable daily intake of arsenic for an adult is 150 μg (at 70 kg body weight). According to earlier sources, the actual daily dietary dose of arsenic ranges from 17 μg (Canada 1987) to 130 μg (United Kingdom 1985). The major food contributors to arsenic exposure are fish and shellfish. For example, according to Belgian research (2009), the average total As concentrations in fish and shellfish species from the North Sea were 12.8 and 21.6 mg/kg, respectively. An average As concentration of 0.132 mg/kg was found in fish and 0.198 mg/kg in shellfish (approximately 10% of total As exposure from foods are the toxic As forms). Vegetables, fruit juices and fruits, rice, beer and wine and flour (wheat and maize) may also contribute to As dietary intake. Higher amounts may be found in wine if arsenic pesticides are used in the vineyard. In the last decade, the average daily dietary dose of arsenic in Western Europe countries has typically been in the tens of μg. In countries with increased consumption of fish and shellfish, a person eating seafood easily exceeds this value, as the average daily dietary dose can be about 300 μg.

6.5.3.3 Metabolism and toxic effects

The effectiveness of resorption of inorganic arsenic compounds in the gastrointestinal tract is about 5–25%. Organic arsenic compounds are apparently completely resorbed. Inhalation is also a route of exposure and a significant source is tobacco smoking, particularly when the tobacco was treated with arsenic-based pesticides. Owing to the high affinity for keratin, arsenic accumulates in hair and nails. The normal level of arsenic in hair is about 0.5 mg/kg. Inorganic arsenic compounds are metabolised in the body to methyl dimethylarsinic and methylarsonic acids (**6-40**) and are then excreted in the urine. The half-life of arsenic in the human body is 10–30 days. The toxicity of arsenic compounds decreases in the order: AsH_3 (arsine) > AsO_3^{3-} (*ortho*-arsenite), respectively, As_2O_3 (arsenic trioxide) > AsO_4^{3-} (arsenate) > methylarsonic acid > dimethylarsinic acid > arsenobetaine ≈ arsenocholine. The toxic effects of arsenic are related to its influence on the activity of important enzymes by binding to their thiol groups. Arsenic inhibits glutathione peroxidase, alanine aminotransferase, aspartate aminotransferase, glucose 6-phosphate dehydrogenase, cholinesterase, various phosphotransferases and enzymes with lipoic acid as the cofactor. In the glycolysis process, arsenate can replace inorganic phosphate, yielding 1-arseno-3-phosphoglyceric acid from glyceraldehyde 3-phosphate. Glyceraldehyde 3-phosphate is decomposed into 3-phosphoglyceric acid but 1,3-bisphosphoglyceric acid is not formed. Glycolysis proceeds, but one molecule of ATP produced from 1,3-bisphosphoglyceric acid is lost. Arsenate and other arsenic compounds also inhibit the citric acid cycle by blocking the conversion of pyruvate into acetyl-CoA, which results in further loss of ATP.

Chronic arsenic poisoning can occur even at a constant intake of 10 mg of arsenic per day. Large-scale accidental arsenic poisonings have occurred in the past. In the early 1900s, more than 6000 British beer drinkers were apparently poisoned with arsenic in the well-known Staffordshire beer epidemic in the United Kingdom. In 1955, more than 12 000 Japanese infants were poisoned, causing 130 deaths, when the sodium phosphate used as a stabiliser in infant formula preparations was contaminated with arsenic. More recently (in 1973), 11 cases of arsenic poisoning in western Minnesota, USA, were attributed to the consumption of water contaminated by an arsenic-based insecticide. Chronic poisoning involves loss of body weight, increased ptyalism and deterioration of vision. Typical skin changes include swelling, eczema and keratosis. Haematological and neurological changes can also occur (motor paralysis of the fingers, sleepiness, memory loss, confusion and impaired hearing). Arsenic also has carcinogenic, mutagenic and teratogenic effects.

The symptoms of acute poisoning with arsenic trioxide (As_2O_3) are abdominal pain, vomiting and diarrhoea. The skin is moist, and the pulse and breathing are weak and intermittent. A fatal dose for an adult is 70–180 mg, depending on their weight. Death occurs in 1–4 days. In the past, there have been some rare cases of acute poisoning in children by fruit treated with pesticides containing arsenic.

6.6 Toxic inorganic anions

In food, drinking water and drinks there are numerous inorganic anions. Some anions are forms of organogenic elements (such as carbonates and hydrogen carbonates), of essential elements (chlorides, phosphates, sulfates, iodides, fluorides, borates) and of non-essential elements (bromides). These and many other anions are mostly beneficial or harmless, and toxic effects exhibit only if present in food, drinking water and drinks in large quantities. Toxic effects can also result from an excessive accidental intake of these anions (fluorides, iodides and bromides).

Bromides have sedative and anticonvulsant properties. At high levels they replace chlorides in nerve transport mechanisms, stabilising the membrane and impairing nerve transmission. Bromide salt is an effective antiepileptic and sedative in small doses and was once a common ingredient of many medicines. Intoxication by bromides (bromism) is reported at serum levels as low as 400 mg/l, with 1500 mg/l considered to be toxic. The most common manifestations of bromism are psychiatric and dermatologic (bromoderma). Patients present with weakness, slurred speech, emotional instability, agitation, hallucinations, seizures and coma. Bromoderma occurs in approximately 35% of cases and is characterised by acneiform eruptions or, less commonly, granulomatous plaques, ulcers or bullae, usually on the face and trunk.

In addition to toxic mineral elements, some anions exhibit toxic effects on the human organism even if ingested in low concentrations. Legislation only specifies the maximum levels for nitrates and nitrites. Other anions, however, may also have toxic effects, such as

arsenates and arsenites (see Section 6.5.3.3), chromates and dichromates (see Section 6.3.13.1.2), perchlorates (see Section 6.3.2.2) and cyanides (see Section 10.3.2.3.1). Antinutritional effects are found in thiocyanates (rhodanides), which are metabolic products of cyanides or form by degradation of some glucosinolates occurring in certain vegetables in the mustard family (Brassicaceae), known as brassica or cruciferous vegetables (see Section 10.3.2.4.2).

Organic anions (such as citrate, malate and lactate) are absorbed mainly in the digestive tract and metabolised in various tissues, especially in the intestine and liver, and finally yield CO_2 and energy. The renal organic anion transport system is also an elimination route for many toxic organic anions (xenobiotics) as well as for endogenous organic anions (e.g. non-steroidal anti-inflammatory drugs, β-lactam antibiotics, cyclic nucleotidesand nucleoside analogues).

6.6.1 Nitrates and nitrites

Nitrates and nitrites are natural components of the environment and participate in the nitrogen cycle, a process of converting nitrogen into its various chemical forms. Important processes in the nitrogen cycle include fixation, mineralisation, nitrification and denitrification. The conversion of gaseous nitrogen from the atmosphere into a form available to plants (and hence to animals and humans) is associated with leguminous plants through their symbiotic association with *Rhizobium* bacteria and other bacteria (e.g. of the genus *Azotobacter*) that produce ammonia (NH_3) or ammonium ions (NH_4^+) using the enzymes known as nitrogenases. The soil nitrogen also comes from decaying plant and animal residues (crop residues, green manures and animal manure) containing proteins, nucleic acids and other nitrogenous substances, which are decomposed to ammonia by various microorganisms, such as bacteria and fungi. Ammonium salts and nitrates are used as commercial fertilisers. Nitrification is the process by which ammonium ions or ammonia are oxidised into nitrites (NO_2^-) by ammonia-oxidising bacteria (e.g. of the genus *Nitrosomonas*) and the nitrites are further oxidised into nitrates (NO_3^-) by nitrite-oxidising bacteria (of the genus *Nitrobacter*). The two processes of nitrification are called nitritation and nitratation. Denitrifying bacteria release nitrogen from nitrates, and nitrogen returns to the atmosphere.

The soil nitrogen occurs mainly in the form of ammonium ions and nitrates available to plants. Ammonium ions are retained in the soil since the cation is attracted to and held by the negatively charged soil clay and not leached to any great extent. The majority of the nitrogen used by plants is absorbed in the nitrate form. Heavy fertilisation leads to increased content of nitrates in the soil. However, nitrate is highly leachable and readily moves with water through the soil profile. If there is excessive rainfall or over-irrigation, nitrate will be leached below the plant's root zone and can eventually contaminate groundwater.

6.6.1.1 Occurrence

Nitrites and nitrates are an integral part of the nitrogen cycle in nature. Plants use nitrates from the soil to satisfy nutrient requirements and may accumulate them in their leaves and stems, and from there they can get into animal feed and human food. Nitrates and nitrites are likewise used as food additives. Nitrites act as nitrosation agents in reactions leading to the formation of toxic nitrosamines and other nitroso compounds in foods (see Section 12.2.7). Very high concentrations of nitrates and nitrites have been implicated in the appearance of methaemoglobinaemia and possibly in gastric cancer.

6.6.1.1.1 Foods of plant origin

The nitrate content in plants is strongly influenced by genetic and environmental factors. A large variability of nitrate content is observed between plant species and even between cultivars of the same species. Nitrate distribution is unequal between plant parts. Leaf blades have a lower content than stems and petioles, and young leaves show a lower nitrate concentration than older leaves. Accumulation of nitrates occurs in situations where the plant does not reduce nitrates to more easily assimilable ammonium salts. These situations specially include adverse humidity, temperature and insufficient light intensities that cause a lack of carbon compounds necessary for conversion of accumulated nitrates into amino acids and proteins. High irradiance reduces nitrate accumulation in plants. A decrease of nitrate accumulation in edible parts of plants during the day period and an increase during the night and under controlled irradiance in glasshouses, and also a correlation between plant water and nitrate concentration have been shown. Reducing the nitrate concentration in the nutrient solution or partly replacing nitrate with reduced compounds (such as ammonium salts or urea) lowers the plant nitrate content.

Vegetables (especially leafy vegetables, such as fresh lettuce and fresh spinach) and potatoes occupy a very important place in the human diet, but unfortunately constitute a group of foods that contributes maximally to nitrate consumption. Under excessive application of nitrogen fertiliser, these vegetables can accumulate high levels of nitrate and, upon being consumed, pose serious health hazards. Individual vegetables accumulate nitrates in varying quantities. According to their ability to accumulate nitrates, vegetables and root crops can be divided into three groups:

- vegetables with high concentrations of nitrates (>1000 mg/kg) such as lettuce, spinach, endive, chard (also known as mangold), Pekinensis and Chinese cabbages, radishes, small radishes, celery, rhubarb and sweet maize;
- vegetables with a medium content of nitrates (250–1000 mg/kg), which include cabbage, kale, cauliflower, eggplant, parsley, carrots, broccoli, garlic and potatoes;
- vegetables with low nitrate content (<250 mg/kg), which include Brussels sprouts, onions, tomatoes, peas, artichokes, asparagus and cucumbers.

The common nitrate content of some vegetables is listed in Table 6.15. In some crops, however, the nitrate content varies over a wide range (up to hundreds of per cent), due to genetic, climatic and soil conditions during the vegetation (such as light intensity,

Table 6.15 Levels of nitrates in important vegetables and potatoes.

Vegetable	NO_3^- content (mg/kg)		Vegetable	NO_3^- content (mg/kg)	
	Minimum	Maximum		Minimum	Maximum
Celery	0	3640	Bell pepper	4	330
Onion	0	1435	Parsley	0	5400
Garlic	44	2400	Leek	30	2159
Beans	14	717	Tomatoes	0	136
Pea	10	58	Rhubarb	300	2525
Savoy cabbage	0	3192	Radish (daikon, mooli)	300	3770
Brussels sprouts	0	2500	Radish	390	5200
Kohlrabi	80	4380	Red beet	45	4700
Cauliflower	0	2685	Lettuce	60	6600
Aubergine (eggplant)	71	960	Spinach	20	4500
Carrots	0	3337	Cabbage	0	3230
Cucumbers	0	490	Potatoes	0	2795

rainfall intensity and fertilisation). In fruits, nitrates are present in much smaller concentrations in comparison with vegetables. Only bananas and melons can have somewhat higher levels, of around 600–800 mg/kg.

6.6.1.1.2 Foods of animal origin

The natural content of nitrates in animal tissues is very low compared with plant tissues. The only exceptions are some meat products (such as ham and some sausages) and cheeses where nitrates or nitrites were used as additives in their manufacture.

Nitrates and nitrites are also used as food additives to produce a pink colour and a specific flavour in meat. This is the effect we see in cured meats. The nitrite used in meat curing is produced commercially as sodium nitrite. Sodium nitrite possesses antimicrobial properties that make it a good preservative. One special property of sodium nitrite is that it prevents the growth of the bacteria *Clostridium botulinum*, which produce several toxins that cause a paralytic illness that can lead to respiratory failure, which is seen in food born botulism (see Section 12.3.2.1). In some particular meat products, such as certain types of ham, sodium nitrate is used instead of sodium nitrite, because of the long aging period. Sodium nitrate is also used in the manufacture of some aged, semi-hard and hard cheeses (such as Emmental, Gouda and Edam) to prevent the late-blowing defect (characterised by eyes, slits and cracks caused by the production of gas bubbles), along with an aberrant and unwanted aroma, due to the growth of *Clostridium tyrobutyricum* bacteria that produce hydrogen, butyric acid and acetic acid as the major metabolites. The added sodium nitrate is reduced to nitrite, which inhibits the germination of bacterial spores.

6.6.1.1.3 Water

Nitrates and nitrites are present in all tap and bottled waters. They are produced by erosion of natural deposits and during the natural decay of vegetable material in soil. Rainfall washes these salts from the sub-soil into groundwater. Nitrogenous fertilisers used on arable farmland and leaks from septic tanks can be significant sources of nitrates in groundwater and surface water.

Many developed countries specify drinking water quality standards to be applied in their own country (such as the Drinking Water Directive in EU and Safe Drinking Water in the United States). For countries without a legislative or administrative framework for such standards, the World Health Organisation (WHO) publishes guidelines on the standards that should be achieved (see Section 7.2.3.1). The following standards are included in the Drinking Water directive: 50 mg/l nitrate (as NO_3^-) and 0.5 mg/l nitrite (as NO_2^-) to ensure that drinking water will not cause methaemoglobinaemia. Maximum Contaminant Levels (MCLs) set for nitrates and nitrites by the US Environmental Protection Agency (EPA) for drinking water quality are: nitrates 10 mg/l (as nitrogen), nitrite 1 mg/l (as nitrogen).

6.6.1.2 Health and toxicological evaluation

The content of nitrates in food is regulated in the EU and also in many other countries. Limits for their content in foods in the EU are shown in Table 6.16. At typical concentrations, nitrates are relatively non-toxic for adults because they are relatively rapidly excreted in the urine. The ADI (Acceptable Daily Intake) value, which quantifies the daily amount of nitrates in food that a person can ingest over a lifetime without a health risk, is 3.7 mg/kg body

Table 6.16 Maximum levels for nitrates in foods.[a]

Product	Maximum levels in mg/kg	
Fresh spinach[b]	Harvested 1 October to 31 March	3000
	Harvested 1 April to 30 September	2500
Preserved, deep-frozen or frozen spinach		2000
Fresh lettuce (protected and open-grown) excluding iceberg-type lettuce	Harvested 1 October to 31 March	
	lettuce grown under cover	4500
	lettuce grown in the open air	4000
	Harvested 1 April to 30 September	
	lettuce grown under cover	3500
	lettuce grown in the open air	2500
Iceberg-type lettuce	Lettuce grown under cover	2500
	Lettuce grown in the open air	2000
Processed cereal-based foods and baby foods for infants and young children[c]		200

[a] Official Journal of the European Union, 20 December 2006, L 364/5. Commission Regulation (EC) No. 1881/2006 of 19 December 2006 setting maximum levels for certain contaminants in foodstuffs.

[b] The maximum levels do not apply for fresh spinach to be subjected to processing and which is directly transported in bulk from the field to processing plant.

[c] The maximum level refers to the products ready to use (marketed as such or after reconstitution as instructed by the manufacturer).

weight. However, their potential toxicity results from the possibility of their reduction to nitrites (ADI = 0.07 mg/kg body weight).

Nitrates are partially reduced by the nitrate reductase of microorganisms present in raw materials during transport, storage and processing of vegetable raw materials. Nitrites also form endogenously in the digestive tract by the action of microorganisms. The ingested nitrates are excreted in the urine (about 80%, or about 50% in older people) in 4–12 h, and the rest remains in the body. It is expected that the nitrates remaining in the digestive tract are mainly transformed into ammonium salts. The toxic effect of nitrites, after their absorption into the blood, depends upon their possibility of inducing methaemoglobinaemia. Acquired methaemoglobinaemia is a blood disorder in which an abnormal amount of methaemoglobin (containing Fe^{3+}) is produced by the oxidation of haemoglobin (containing Fe^{2+}) and methaemoglobin is unable to transport oxygen effectively to body tissues (see Section 9.2.1.5.1). Under normal physiological conditions, the amount of methaemoglobin is about 2%. Methaemoglobin reductase in red blood cells of an adult converts the methaemoglobin created back into haemoglobin, but this enzyme may be produced in insufficient amounts or be absent in certain people that have an inherited mutation.

Nitrites are especially dangerous in infants during the first 2–4 months (or even up to 6 months) of life and may cause methylhaemoglobinemia, known as blue baby syndrome. During this period, their corresponding enzyme system is not sufficiently developed. The amount of foetal haemoglobin (haemoglobin F) in infants is about 85% of the total haemoglobin amount and foetal haemoglobin is more easily oxidised than haemoglobin of adults (haemoglobin A). In infants, the stomach also has a lower concentration of acids (higher pH), so there non-pathogenic microorganisms may occur and reduce nitrates to nitrites before nitrates resorb. Nitrates can also partly move to the salivary glands, where they concentrate and re-enter the oral cavity. Endogenous reduction to nitrites already takes place in the mouth, both in children and even adults. This will make up to 65% of the total content of nitrites. The external manifestation of methaemoglobinaemia is the gray–blue to blue–violet colour of mucous membranes, skin and peripheral parts of the body, especially around the eyes and mouth. The first symptoms appear when the methaemoglobin concentration in the blood reaches 6–7%. After the age of 6 months, methaemoglobinaemia is not a threat since the nitrate converting bacteria are no longer present in the baby's stomach. For these reasons, the level of nitrates and nitrites in water and foods for infants and young children is regulated.

6.7 Radionuclides

6.7.1 Radionuclides and radioactivity

Radionuclides are **nuclides** with an unstable nucleus, which are subject to radioactive decay. According to the type of radionuclide, this radioactive nuclei decay creates three main types of radiation (radioactive decay):

- α-decay, a stream of particles composed of two protons and two electrons (identical with the nucleus of helium ^{4}He);

- β-decay, a stream of electrons ($_{-}\beta$) or positrons ($_{+}\beta$) of high speed (about 1×10^8 m/s);
- γ-radiation (γ-rays), an electromagnetic radiation of high frequency ($>1\times10^{19}$ Hz) and short wavelength (<1 nm) that accompanies emissions of α- and β-particles.

Radionuclides can be roughly divided into α-emitters and β-emitters. The emission of α-particles is associated with a decrease in mass number by four units and in the atomic number by two units. The loss of two protons results in an excess of two electrons, so the α-decay is accompanied by the emission of electrons (radiation $_{-}\beta$). In the radioactive β-type conversion, the nucleon in the atom nucleus transforms, a neutron turns into a proton or vice versa, which is associated with the change of particle charge and emitting an electron or positron. The capture of an electron (usually from the sphere K of the electron cloud) by the atom nucleus is also possible, while changing a proton into a neutron. In the electron cloud, the electron from the higher level then jumps to fill the vacant place, which is accompanied by the emission of a photon.[4]

6.7.2 Sources of radioactivity

All the heavy elements, starting from the element with atomic number 84 (polonium, Po), have at least one radioactive nuclide (isotope). However, a number of light elements also form radioactive isotopes (such as tritium ^{3}H, carbon ^{14}C and potassium ^{40}K). In nature there are three types of radionuclides:

- heavy nuclides
- their daughter products (daughter nuclides)
- light nuclides.

The first group includes very heavy elements such as uranium (U) or thorium (Th). Radionuclides of these elements have an extremely long half-life (e.g. ^{232}Th 1.41×10^{10} years, ^{238}U 4.51×10^{9} years, ^{235}U 7.1×10^{8} years). The second group includes daughter nuclides formed by the radioactive decay of the first group of nuclides. For example, radium ^{226}Ra (half-life of 1600 years) arises by decay of uranium ^{238}U. The decay of radium yields the radionuclides radon ^{222}Rn, polonium ^{210}Po and lead ^{210}Pb. Natural heavy nuclides represent three decay chains. A parent isotope is one that undergoes α- or β-decay to form a daughter isotope. The daughter nuclide may be stable or it may decay to form a daughter nuclide of its own. Each decay chain thus has its initial mother nuclide and a final stable nuclide. By tracking the interrelationships of these nuclides, the radioactive nuclides are arranged into the following series:

- thorium series: begins with thorium ^{232}Th and ends with lead ^{208}Pb;
- uranium series: begins with uranium ^{238}U and ends with lead ^{206}Pb;
- actinium series: with so called actinouranium ^{235}U and ends with lead ^{207}Pb.

Another group of radionuclides is generated by cosmic rays in the light elements in the atmosphere. For example, nitrogen forms radioactive carbon ^{14}C. The natural radioactivity in nature is mainly due to radionuclides of light elements. Approximately 90% of the radioactivity is attributable to ^{40}K (it represents 0.012% of natural potassium and has a half-life of 1.3×10^{9} years) and almost all the rest to carbon ^{14}C (half life of 5730 years). Increased radioactivity in certain areas can be caused by abnormally high incidence of radioactive elements (especially uranium) in rocks.

The anthropogenic sources of radioactivity in the environment include the testing of nuclear weapons and radioactive material handling, especially in nuclear power plants. In the explosion of atomic bombs or in nuclear reactors, a complex mixture of different radionuclides is produced, namely uranium ^{235}U, plutonium ^{239}Pu, caesium ^{137}Cs (half-life of 30 years), strontium ^{90}Sr (half-life of 28 years), cobalt ^{60}Co (half-life of 5.3 years), caesium ^{134}Cs (half-life of 2 years), ruthenium ^{106}Ru (half-life of 1 year) and iodine ^{131}I (half-life of 8 days). A number of other radionuclides result from an atomic explosion by collision of neutrons with the atoms of elements that are contained in the casing of the non-explosive parts of the atomic bomb. For example, these activation products include zinc ^{65}Zn (half-life of 245 days).

6.7.3 Content of radionuclides and radiation dose

The content of radioactive nuclides in environmental materials and in foods is usually expressed as the specific activity given most often in Bq/kg and for liquid materials in Bq/l. The dose of radiation absorbed is expressed as the mean energy absorbed per unit of weight or per unit of volume of material. The basic unit of the

[4]Radioactive decay of nuclei is a first-order reaction; decay rate (activity A) is therefore dependent on the concentration (content) of the radionuclide and is the product of this concentration (more precisely, the number of atoms of radionuclide N) and the decay constant λ (in s^{-1}): $A = -(dN/dt) = \lambda.N$. The basic unit of activity, according to the System International (SI system) is the Bq (becquerel). One Bq (in s^{-1}) is defined as the activity of a quantity of radioactive material in which one nucleus decays per second. Previously, the frequently used unit was the Ci (curie) defined as 3.7×10^{10} decays per second. For conversion, the following relationship can be used: 1 Ci $= 3.7\times10^{10}$ Bq. Number of radionuclide atoms transformed in time t is: $N = N_0.e^{-\lambda t}$, where N_0 is the initial number of atoms of the radionuclide at the time $t = 0$. During conversion, the number of radioactive atoms of the radioactive nuclide is continuously decreasing. Combining both equations we get the relation expressing the dependence of activity on time: $A = -(dN/dt) = \lambda.N_0.e^{-\lambda t}$. The period of time it takes for the amount of a radionuclide undergoing decay to decrease by half is called the half-life, abbreviated to T (or $t_{1/2}$), which is inversely proportional to the decay constant: $T = \ln2/\lambda = 0.69315/\lambda$. After the time equal to ten times the half-life, 99.9% of the radionuclide is transformed.

radioactive dose[5] is the gray (Gy); one Gy (in J/kg) is defined as the absorption of one joule of ionising radiation by one kilogram of material.

The individual types of ionising radiation resulting from nuclear processes have different biological effects. Therefore, in addition to the exposure dose (given in Gy), the so-called equivalent dose, absorbed by a given mass of biological tissue, was introduced. The equivalent dose (H) for tissue T and radiation type R is calculated by the formula: $H_{T,R} = Q.D_{T,R}$, where Q is a radiation (radiobiological) quality factor that depends on the type and energy of that radiation, $D_{T,R}$ is the total energy of radiation absorbed in a unit mass of any material. The quality factor Q is also known as the relative biological effectiveness of the radiation. For example, β- and γ-radiation has a value of $Q = 1$, α-radiation has a value of $Q = 10$, radiation quality factor of the neutron flux varies, depending on the neutron energy, from 2.5 to 10. While the unit gray (Gy) measures the absorbed dose of radiation (D) by any material, the sievert (Sv, in J/kg), unit of dose equivalent radiation, measures the equivalent dose of radiation (H) and evaluates the biological effects of the ionising radiation. It means that the dose of α-radiation of 1 Gy corresponds to the dose equivalent radiation of 10 Sv. The same dose equivalent radiation has a dose of γ-radiation of 10 Gy. The load of the organism due to natural radioactivity is around 2 Sv per year, of which about 0.4 mSv is due to radionuclides occurring in food.

To assess the radiation hazard to humans, it is necessary to take into account several factors:

- radionuclide species, including the possibility of its conversion into other radionuclide and the related type of radiation;
- specific activity of the environment (food);
- type and length of exposure (external irradiation, internal irradiation by ingestion of radioactive food or inhalation of radioactive aerosols);
- chemical properties of radionuclides (in the case of internal exposure) that affect their behaviour in the body; their chemical analogy with essential elements and similar reactivity results in the transportation to certain target organs, where they accumulate (e.g. accumulation of radioactive iodine ^{131}I in the thyroid gland, analogy of radioactive caesium ^{134}Cs with ^{137}Cs as well as of strontium ^{90}Sr with potassium and calcium).

According to the potential hazard, radionuclides are classified into four groups with:

- very high radiotoxicity (^{90}Sr, ^{210}Pb, ^{211}At, ^{226}Ra, ^{227}Ac, ^{239}Pu, ^{241}Am, ^{242}Cm; deposited mainly in the bones)
- high radiotoxicity (^{45}Ca, ^{59}Fe, ^{89}Sr, ^{131}I, ^{140}Ba, ^{234}Th, ^{238}U)
- medium radiotoxicity (^{22}Na, ^{24}Na, ^{32}P, ^{35}S, ^{36}Cl, ^{42}K, ^{60}Co, ^{132}I, ^{137}Cs)
- low radiotoxicity (^{3}H, ^{7}Be, ^{14}C, ^{18}F).

6.7.4 Occurrence in environment and in foods

A substantial part of the natural radioactivity is produced by nuclides of light elements ^{40}K and ^{14}C that are dispersed in the nature along with the major isotopes of potassium and carbon. Heavy radionuclides are not uniformly distributed in nature. For example, around 99.284% of natural uranium is ^{238}U that is strongly bound in some rocks (granite). Given the very long half-life (4.468×10^9 years), the effect of ^{238}U in the environment is permanent. The decay of this isotope creates a number of other radionuclides that are generated via ^{234}Th (half-life 24 days) and ^{234}Pa (half-life 1.2 min) and have long half-lives: ^{234}U (245 thousand years), ^{230}Th (75 000 years) and radium ^{226}Ra (1600 years). Radium gives, by α-decay, the radioactive noble gas radon ^{222}Rn with a half-life of 90 hours. The radon activity contributes significantly to the exposure of people in an indoor environment of some buildings, such as those that are thermally insulated from its surroundings using materials containing granite. Because it can be inhaled, a prolonged exposure to radon is quite dangerous. Other members of the decay series are mostly nuclides with short or very short half-lives. The only exceptions are lead ^{210}Pb (22 years) and polonium ^{210}Po (138 days). The stable end product of a decay of uranium ^{238}U is lead ^{206}Pb.

Mining and processing of minerals, ores and fossil fuels are activities that bring, in addition to other toxic substances, radioactive elements into the environment. Handling of nuclear materials, nuclear accidents and nuclear weapons tests also contribute to the total radioactivity in the environment. The most famous incident was the atomic power plant disaster in Chernobyl, Ukraine, which occurred on 26 April 1986. From 1986 to 2000, over 350 000 people were evacuated and resettled from the most severely contaminated areas. Leakage of the radioactive material (with a predominance of ^{131}I, ^{137}Cs and ^{132}Te) into the environment was to such an extent that there was significant contamination not only of the area of the atomic power plant, but due to atmospheric transfer, the radioactivity was spread throughout Europe and parts of Asia. The total radioactivity released as a result of this nuclear disaster is estimated at 3×10^{18} Bq. In order to minimise public exposure to radioactive elements (mainly ^{131}I), Poland and some Western European countries banned the distribution of milk originating from cows grazing freely, and children preventively received non-radioactive potassium iodide. This event significantly increased the interest in studying the behaviour of radionuclides in the environment. In the 1980s and 1990s, as a consequence of this nuclear disaster, radioactivity was monitored in different compartments of the environment virtually worldwide. Significant attention has been paid to long-range transport of radioactive aerosols, to radioactive

[5] Conversion of immediate activity, specific for the given nuclide, to the nuclide mass (m, in grams) is given by the equation: $m = A.M/\lambda.N_A$, where A = nuclide activity (in Bq), M = molar nuclide mass (in g/mol), N_A = Avogadro's number, $N_A = 6.022\ 141\ 527 \times 10^{23}$ per mole. Another unit for the radioactive dose is eV/g or eV/cm^3. The electronvolt (eV) is by definition equal to the amount of kinetic energy gained by a single unbound electron when it accelerates through an electric potential difference of 1 volt (V), $1\ \text{eV} = 1.6021 \times 10^{-19}$ J.

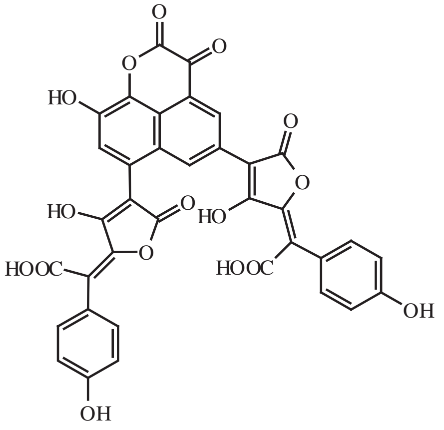
fallout, to contamination of soil and to the possibility of transport of radionuclides from soil to plants.

The mobilities of radionuclides in environmental compartments are determined by the chemical properties of the element, and these mobilities are higher, for example, for halogens (e.g. ^{129}I, ^{131}I and ^{36}Cl), alkali metals (^{40}K, ^{134}Cs, ^{137}Cs), non-metals (^{89}Se) and alkaline earth metals (^{90}Sr) than for transitional metals and especially for transuranium elements. Plants are partially contaminated by direct deposition on the leaves and partly by intake of radionuclides from the soil, which depends on the binding of the radionuclide in the soil components, depth of the root system and developmental stage of plants at the time of deposition. Experience with the transfer of caesium radionuclides from soil to plants and fungi after the Chernobyl disaster can be summarised as follows:

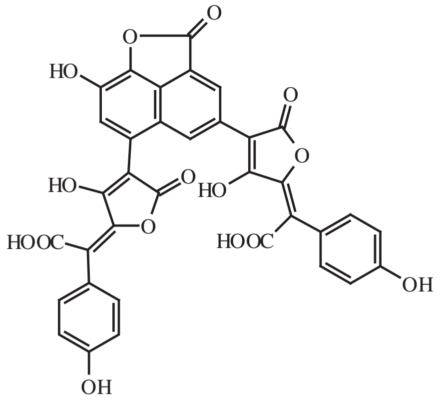
- alfalfa, which has deep roots, was not even in the second generation contaminated by fallout, unlike grasses and wild herbs, which are rooted largely in the surface soil layer;
- compared with the spring cereals, winter cereals had contamination that was roughly twice as high;
- summer fruits (such as currants) were contaminated more than late fruits (apples);
- needles of conifers (often used as bioindicators of pollution) showed the specific activity of caesium ranging from 1×10^2 to 1×10^3 Bq/kg, the fungi and lichens showed values up to one order of magnitude higher (1×10^2 to 1×10^4 Bq/kg).

The Chernobyl disaster in 1986 resulted in substantial radioactive fallout in parts of Norway. The deposition of radioactive dust caused contamination by caesium ranging from 5 to 200 kBq/m^2. In some areas of Czechoslovakia, the contamination with radioactive caesium was higher than 10 kBq/m^2; in other areas it reached only 2–3 kBq/m^2. In different areas of Finland, the transfer of ^{137}Cs and ^{90}Sr from soil to some crops was studied for several years. Radioactive caesium follows the path of potassium and tends to accumulate in plant tissues, including fruits and vegetables. The ratio of specific activities of radionuclides in plants and soil ranged from 0.01 to 2.29 for ^{137}Cs and from 0.02 to 2.44 for ^{90}Sr (values in subsequent years gradually decreased). This value for ^{137}Cs decreased in the individual crops as follows: lettuce, cabbage > carrots, potatoes and onions > cereals. The smallest transition of ^{137}Cs to plants was recorded in the crops grown on clay soils. The order for ^{90}Sr was: lettuce, cabbage > carrots, onions > cereals > potatoes.

Small amounts of ^{134}Cs and ^{137}Cs are released into the environment during nearly all nuclear weapon tests and some nuclear accidents, most notably the Chernobyl disaster. It is well documented that mushrooms, including edible species from contaminated forests, accumulate radionuclides (mainly ^{137}Cs) in their fungal sporocarps. For example, the edible mushroom commonly known as penny bun, porcino or cep (*Boletus edulis*) from Poland (1987) showed about seven times higher activity of ^{137}Cs in comparison with the radioactive background and about double the activity of mushrooms from the United States. This activity (1100 Bq/kg) corresponded to the concentration of ^{137}Cs of around 0.0003 ng/kg, which is negligible in comparison with the content of stable caesium (^{133}Cs). To achieve radiotoxic doses, it would be necessary to consume 3000 kg of dry mushrooms. In addition it was found that radioactive caesium can be effectively removed from the mushroom by washing with water or salt solution. High concentrations of radionuclides found in the fruiting bodies of the bay bolete *Boletus badius* (Boletaceae) after the nuclear reactor accident at Chernobyl have been attributed to the complexation of ^{137}Cs by the so-called naphthalenoid pulvinic acids that occur as their dipotassium salts in the cap skin of this toadstool. The main compounds are badione A (**6-41**) and norbadione A (**6-42**), which are responsible for the chocolate brown and golden yellow colours of the cap skin of this bolete and related bolete species. For example, complexation of ^{137}Cs with norbadione A involves a mixture of *Z*/*E* isomers and conformers of norbadione A with a broad diversity of binding modes. In the mycelia ^{137}Cs is mostly trapped by polyphosphates in vacuoles and other organelles.



6-41, badione A



6-42, norbadione A

The content of radioactive caesium in milk and meat of livestock depends mainly on the contamination of the feed. For example, cows resorb about 30% of radioactive caesium in the feed. In 1986,

Czechoslovakia restricted the pasture of cows and their nutrition was partly ensured using preserved feed from the previous year. Specific activity of ^{137}Cs in beef in 1986 ranged from 14 to 129 Bq/kg. The maximum value observed in 1986 was 240 Bq/kg in milk, and most samples did not exceed a level of 40 Bq/kg. In subsequent years, there was a significant decline (in 1988 only 0.7% of milk samples exceeded the level of 20 Bq/kg).

Significantly higher specific activity of caesium was detected in the meat of game (in 1986, depending on surface contamination of the territory, the observed values for roe deer meat were 120–600 Bq/kg and 170–660 Bq/kg for deer meat). Contamination of wild life by radionuclides decreases in the order: deers > roe deers and fallow deers > mouflons > wild boars (wild pigs) > hares.

As regards the dietary intake of radionuclides, the average exposure of an adult amounting to approximately 1.7 mGy/year was found in Germany in the 1970s. The amount of 0.2 mGy was accounted for by natural radionuclides (mainly ^{40}K and ^{14}C). The total intake of radionuclides ^{90}Sr and ^{137}Cs was in units of Bq per person per day. As a result of the Chernobyl disaster in 1986, the following year-long dietary intake of radionuclides were: 4600 Bq ^{131}I, 1760 Bq ^{134}Cs, 3400 Bq ^{137}Cs and the total dose equivalent increased by 0.04–0.26 mSv.

6.7.5 Fate in organism

After the radionuclides have entered into the body of an animal or human by ingestion or inhalation, distribution to individual tissues and organs and their partial incorporation into these tissues takes place. For example, radioactive caesium as an analogue of potassium, after entering into the body quickly appears in the kidney, liver and spleen and accumulates in muscle tissue. As with other alkali metals, the excess of radioactive caesium washes out of the body relatively quickly in sweat and urine. Radioactive iodine concentrates in the thyroid gland. Heavy radioactive metals accumulate in internal organs and bones. Subsequently, these metals are excreted and their concentration also decreases due to radioactive decay. The time required for the radioactivity of material taken in by a living organism to be reduced to half its initial value by a combination of biological elimination processes and radioactive decay is called the effective half-life $T_{ef} = T_f T_b/(T_f + T_b)$; T_f is the physical half-life of a radionuclide and T_b is the biological (elimination) half-life of the element in the given form.

6.7.6 Legislation and regulation

Radiocaesium is one of the most important artificial radionuclides produced by nuclear fission. Consumption of agricultural products contaminated with radiocaesium represents the principal route of human exposure to this radionuclide. Within the EU, the limits of activity of ^{134}Cs and ^{137}Cs (that is a strong emitter of γ-radiation) of 370 Bq/kg have been established for milk and foods for children. For other food imported into the European Union, a limit of 600 Bq/kg has been set.

7
Water

7.1 Introduction

Water is one of the most widespread substances in the biosphere. In food chemistry, water is one of a group of nutrients (together with proteins, lipids, carbohydrates, vitamins and minerals) that are necessary for the normal functioning of living organisms. Owing to its physico-chemical properties, water is particularly important:

- in temperature regulation of living organisms
- as a transport medium of nutrients, metabolic products and respiratory gases
- as a solvent or dispersion medium
- as a reactant involved in biochemical and chemical reactions.

People's lives and livelihoods depend on water. The normal functioning of the human body inevitably leads to a continuous loss of water that must be compensated by the water produced via the oxidation of primary nutrients: proteins, carbohydrates and lipids. This water is sometimes referred to as **endogenous** or **metabolic water**. The amount of endogenous water is not sufficient to cover the water lost, and the organism has to compensate with **exogenous water** contained in foods and especially in drinks. It is reported that the daily output of water by an adult is approximately 2500 g, of which about 1500 g (minimum of 600 g) are excreted in the urine, with typically about 550 g of water excreted through the skin (sweating), 350 g of water are exhaled into the air and 100 g in faeces. Replacement of the same amount of water is met by exogenous water in the form of various beverages (about 1300 g) and foods (about 900 g), and approximately 300 g of water are obtained by oxidation of the primary nutrients, proteins, lipids and carbohydrates (endogenous water). Oxidation of 1 g of proteins, for example, gives 0.37 g, oxidation of 1 g of fat gives 0.4 g and oxidation of 1 g of carbohydrates (glucose) yields 0.6 g of water. Foods are very important sources of water, a fact that is often overlooked – we tend to concentrate only on the importance of drinking water and on water present in beverages.

This chapter deals, in the first part, with the production of drinking water and its quality requirements. Other parts of the chapter present the water content of foods, and the major changes to the water content that occur during culinary and technological operations. A substantial portion of the chapter is devoted to interactions of water with food components (inorganic compounds, proteins, carbohydrates and lipids) and various phenomena that occur on the phase interfaces (surface tension, adsorption and capillary phenomena). Various food dispersal systems are described (sols, gels, emulsions and foams), where the presence of water significantly affects the texture of the foods. The last part of the chapter deals with water activity in foods and its influence on microorganisms, biochemical and chemical reactions and the organoleptic properties of foods.

7.2 Drinking water

Water is renewable; it exists in an endless cycle, moving between its gaseous, liquid and solid forms. This **hydrological cycle** constitutes nature's way of replenishing, redistributing and purifying the world's natural water resources. In absolute terms, the total renewable freshwater resource in Europe is around 3500 km^3 per year. However, the balance between water demand and availability has reached a critical level in many areas of Europe as the result of over-abstraction and prolonged periods of low rainfall or drought. The Mediterranean islands of Malta and Cyprus and the densely populated European countries (Germany, Poland, Spain, England and Wales) have the least available water per capita.

Drinking (potable) water comes from **surface water** and **ground water** resources. Surface water resources, including rivers, lakes and reservoirs, are the largest and most reliable of all freshwater resources in Europe. For example, the surface water abstraction was

The Chemistry of Food, First Edition. Jan Velíšek.

91% in the Netherlands (in 2008), 82% in Germany and France (in 2007) and Spain (in 2008), 81% in the Czech Republic (in 2009), 78% in Poland and 74% in England and Wales (in 2008). In many areas most drinking water is groundwater, up to 100% in Malta, 98% in Denmark and 79% in Cyprus (in 2009), about 80% in Russia and even more in North Africa and the Middle East.

Natural water is never chemically pure. According to the origin, various substances are dissolved and sometimes suspended in the water. The quality of surface waters, as opposed to ground water, depends on many factors. In comparison with ground waters, surface waters usually have much higher concentrations of organic substances of various origins, contain higher amounts of dissolved oxygen, lower levels of carbon dioxide and have low concentrations of iron and manganese ions. The level of microorganisms in surface waters is significantly higher than in ground waters.

7.2.1 Classification

Surface waters are categorised into five classes according to quality. Classification is based on the evaluation of mandatory water quality indicators that are guides to the oxygen regime (the amount of dissolved oxygen), basic chemical and physical parameters (pH, dissolved substances, conductivity, suspended solids, ammonia nitrogen, nitrate nitrogen and total phosphorus), additional parameters (calcium, magnesium, chlorides, sulfates, anionic surfactants, hydrocarbons and organically bound chlorine), heavy and toxic elements content (lead, cadmium, mercury and arsenic), biological and microbiological parameters (especially coliform bacteria) and indicators of radioactivity. The five classes of surface water are:

- Class 1 is an extra-clean fresh surface water resource, not necessarily required to pass through a water treatment process and needing only basic treatment for the destruction of pathogens.
- Class 2 is a very clean fresh surface water resource used for consumption, which requires basic water treatment processing before use.
- Class 3 is a medium-clean fresh surface water resource used for consumption, which requires passing through a basic treatment process before use in agriculture.
- Class 4 is a fairly clean fresh surface water resource used for consumption, but requires a special water treatment process before being used by industry.
- Class 5 is surface water, which is not classified in classes 1–4.

Extra-clean water (class 1) is suitable for all uses, mainly for consumption (drinking water) and use in the food industry. Very clean water (class 2) is usually adequate for most applications (e.g. for water supply purposes). Classes 3–5 waters are usually only suitable for supplying industrial plants.

Ground waters are divided according to the quality of water suitable for consumption (good status) and water inappropriate for consumption (poor status). Ground waters suitable for consumption can be clearly distinguished from natural mineral waters by their nature, which are characterised by the mineral content, trace elements or other constituents and, sometimes, by certain physiological effects. Local standards differ by country; nevertheless ground waters are often divided into two categories:

- spring waters (with a minimum of 1000 mg of total solids or a minimum of 250 mg of free carbon dioxide);
- mineral waters (where the dissolved solids content is higher than 1000 mg/l).
